It appears that not all children with JIA have the propensity to develop an erosive arthritis that is similar to that frequently seen in adults with RA. Children who develop erosions visualized on plain radiographs are considered to have a worse prognosis, and the current recommendation is to increase the intensity of their treatment accordingly.[24]

Treatment of Systemic Features of Systemic Arthritis

For decades, the mainstay of therapy for sJIA has been systemic glucocorticoids and NSAIDs. Nearly all children with sJIA will respond favorably to systemic glucocorticoids, if given in sufficient doses. However, often children become “steroid dependent,” and efforts to decrease the glucocorticoid burden to minimize adverse effects have been unsuccessful. Presumably because of its different pathogenesis, sJIA has not been shown to respond to TNF inhibitors as favorably as the other categories of JIA. Instead, IL-1 and IL-6 appear to be key cytokines in the disease process. Accordingly, IL-1 (anakinra, canakinumab) and IL-6 (tocilizumab) inhibitors are recommended as the first-line nonglucocorticoid treatments for sJIA.[25]

The appearance of clinically significant MAS generally requires directed therapy. The typical treatment approach involves increased systemic glucocorticoids. The calcineurin inhibitor cyclosporine is frequently added,[1,7] and some authors advocate IL-1 and IL-6 inhibitors for treatment of MAS.[1,7] In severe refractory cases, cytotoxic chemotherapeutic agents, such as cyclophosphamide or etoposide, may be warranted.

Treatment of Arthritis of Systemic Arthritis

Some children with sJIA will develop a chronic course of polyarthritis with a relative absence of concurrent systemic features. In general, it is recommended that these children be treated as those with polyarthritis who did not have systemic features at onset.[24] Based on clinical trial results, the IL-6 inhibitor tocilizumab may be the most effective treatment for these patients.

Treatment of Uveitis

JIA-associated anterior uveitis frequently requires directed therapy. Topical glucocorticoid eye drops, such as prednisolone acetate 1%, are frequently initiated at the time of diagnosis by the treating ophthalmologist.[14] Although effective in decreasing the inflammation of uveitis, glucocorticoid eye drops cannot be tolerated in high doses for extended periods because of the risk of cataracts and glaucoma.[14] For this reason, systemic medications are frequently employed in the treatment of JIA-associated uveitis. Methotrexate has been shown to be effective for uveitis and is the most commonly used systemic medication.[1,14] The mAb TNF inhibitors (infliximab, adalimumab, and others) have been shown highly effective in the treatment of anterior uveitis in uncontrolled studies, and they are a frequent choice for children in whom methotrexate proves inadequate to control the disease.[1,14] Other biological agents (*e.g.*, rituximab, abatacept, tocilizumab) appear to be effective in some children with refractory uveitis, but their overall role remains unclear.

Duration of Therapy

As stated, the current goal of therapy is the attainment of clinically inactive disease. However, once this goal is attained, the appropriate next steps in management are less clear. Although none of the currently available therapies is believed to be curative, many children are able to successfully decrease or discontinue therapies after attaining inactive disease status without immediate recurrence of active disease. Many pediatric rheumatologists will consider decreasing the level of therapy if inactive disease status is maintained for a prolonged period, such as 12 months, although this approach is arbitrary. Further study of the appropriate management of children who attain prolonged inactive disease status will be an important future focus.[32]

TRANSLATIONAL RESEARCH

ON THE HORIZON

- Novel criteria for identifying macrophage activation syndrome (MAS) among children with systemic juvenile idiopathic arthritis (sJIA) have been generated using real patient data that are diagnostically highly sensitive and specific.
- Genetic screening for mutations in cytolytic pathway genes will help identify those individuals at risk for developing MAS.
- Murine models are paving the way for a better understanding of MAS immunopathology and potential pathways for clinical intervention.
- Clinical trials involving treatment of MAS with inhibitors of proinflammatory cytokines are just underway.

The explosion in advances in immunology and genetics are leading to major breakthroughs in therapy for rheumatic diseases, including JIA. Challenges remain, however, in diagnosing and treating MAS complicating sJIA. To distinguish a sJIA disease flare-up from MAS, expert opinion and Delphi techniques are currently being used to explore novel criteria for diagnosing MAS in children with sJIA. Data collection regarding clinical, laboratory, and pathological features of children with sJIA, with and without MAS, have been used to develop new classification criteria.[33] Furthermore, genetic mutations and polymorphisms in genes linked to the defective cytolytic pathway in lymphocytes from patients with MAS are being explored to identify patients with sJIA with a propensity to develop MAS.[18] Mouse models of MAS are helping to better understand MAS immunopathology and the role of pro-inflammatory cytokines in the process.[34] Early recognition of MAS and a better understanding of the role of various cytokines in the pathogenesis of MAS will allow for improved targeted therapy for this often fatal condition.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following is NOT associated with increased risk of uveitis in children with juvenile idiopathic arthritis (JIA)?
   A. Female gender
   B. Antinuclear antibody (ANA) positivity
   C. Rheumatoid factor (RF) positivity
   D. Oligoarticular disease
   E. Young age at disease onset

2. Which of the following is NOT consistent with the diagnosis of macrophage activation syndrome in a child with systemic JIA?
   A. Thrombocytopenia
   B. Coagulopathy
   C. Hyperferritinemia
   D. Rising cross-reactive protein (CRP) level
   E. Rising erythrocyte sedimentation rate (ESR)

3. What is the most reliable finding denoting onset of temporomandibular joint (TMJ) arthritis in a child with JIA?
   A. TMJ pain
   B. Maximal incisal opening <5 cm
   C. Elevated ESR
   D. Synovial thickening on magnetic resonance imaging (MRI)
   E. TMJ popping

54

Sjögren Syndrome

Sarfaraz A. Hasni, Leyla Y. Teos, Ilias Alevizos

Sjögren syndrome (SS) is a chronic systemic autoimmune disease characterized by lachrymal and salivary gland dysfunction. It was named after the Swedish ophthalmologist Henrik Sjögren after he published a report of 19 cases of keratoconjunctivitis in 1933.[1] The hallmark feature of SS is deficient tear and saliva production as a result of lymphocytic infiltration of the salivary and lachrymal glands leading to *xerostomia* (dry mouth) and *xerophthalmia* (dry eyes). In addition, SS can involve any organ system and present with a wide spectrum of clinical features. The autoimmune process seems to primarily affect the lining epithelium of various organs; in fact, some experts have proposed the term "autoimmune epithelitis" to be used instead of SS.[2]

KEY CONCEPTS

- Sjögren syndrome (SS) is one of the most common autoimmune diseases, mainly affecting females. It targets the salivary and lachrymal glands, causing xerostomia and xerophthalmia.
- The diagnosis of SS is complex and requires a multidisciplinary team for the assessment of oral, ocular, and systemic manifestations.
- Anti-Ro/SSA and Anti-La/SSB autoantibodies are encountered in approximately 70% of patients with SS. Significantly increased incidence of congenital heart block is present in the offspring of Anti-Ro/Anti-La positive mothers.
- The risk of lymphoma is significantly higher in patients with SS, and this risk increases over time.
- Currently, there is only palliative treatment for alleviation of the symptoms of SS.

EPIDEMIOLOGY

SS predominantly affects females (female-to-male ratio 9 : 1) in their fourth and fifth decades of life. However, symptoms can be present for a much longer time, and there is usually a 5- to 10-year delay in the diagnosis of SS. The reported prevalence of SS varies widely from 0.1% to 4.8%.[3] This variation may result from the use of different classification criteria, geographical and environmental influences, and varying study sizes and target populations. When a more strict definition is applied to the available data, the true prevalence of SS is estimated to be around 1%,[1] making it the second most common systemic rheumatic disease after rheumatoid arthritis (RA).

IMMUNOPATHOGENESIS

The pathogenesis of SS is largely unknown. In a genetically predisposed individual, various environmental factors, such as viral infections, may lead to epithelial cell activation that triggers a protracted inflammatory response with features of autoimmunity. Autoreactive lymphocytes and autoantibodies are considered important in this process, although the pathogenic role of any particular autoantibody is still undefined.[4]

Immunogenetic Factors

SS is associated with certain human leukocyte antigen (HLA) class II haplotypes. Initial reports of HLA class II associations described enrichment of DR3 and DR2 in European populations of patients with primary SS. This genetic association predominantly involves antibody-positive but not antibody-negative patients with SS. Several genetic polymorphisms previously linked to other autoimmune diseases are also associated with SS. Among these, two transcription factors, STAT4 (signal transducer and activator of transcription 4) and IRF5 (interferon [IFN] regulatory factor 5), which were both independently associated with SS, showed an additive effect, increasing the risk of SS from around 1.6–1.9 for one risk allele to 6.7 when both risk alleles were present.[5]

Although the individual gene approach has successfully identified genes associated with SS, two large-scale genome-wide association studies have increased the number of genetic loci that function as potential risk factors.[6] A study by Lessard et al.[7] genotyped more than 10 000 patients with SS and control subjects of European descent and found seven genetic loci to be significantly associated with SS. These loci included the following genes: *MHC-II, IRF5, STAT4, IL-12A, BLK, CXCR5,* and *TNIP1.* A second large-scale study examined DNA variations from approximately 1700 patients with SS and controls subjects from Han, China, and identified a new gene associated with SS, the transcription factor GTF2I located in 7q21. However, the odds ratio for GTF2I was a moderate 2.2.[8]

Environmental Factors

The inciting etiopathogenic event in SS is not known, and it may not be a single event. The strong predominance of females suggests gender-specific predisposing factors. Although sex hormones are of obvious interest, there is no conclusive proof that the difference in the pathogenesis between males and females can be attributed to sex hormones alone. Overall, estrogens are considered contributors to autoimmunity, whereas androgens are thought to be protective.

Viral infections have also been proposed as inciting events. This theory is supported by the observation that chronic inflammation of the salivary glands occurs with chronic hepatitis C, human T-lymphotropic virus 1 (HTLV-1), and human immunodeficiency virus (HIV) infections, and such infections cause a disease with a

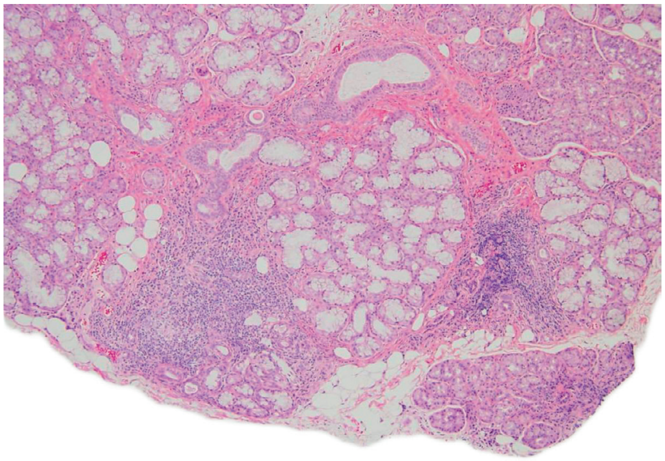

FIG 54.1 Minor salivary gland biopsy with characteristic periductal inflammation.

clinical spectrum similar to that of SS. The fact that some viruses, such as Epstein-Barr virus (EBV), replicate in oropharyngeal and lachrymal glands has led to the hypothesis that these viruses might contribute to the pathogenesis of SS. Other viruses, such as coxsackievirus or endogenous retroviruses, have also been proposed as agents of interest. However, to date, there is no proof that any of these viruses plays a pathogenic role in SS.

Epithelial Cell Activation and Chronic Inflammation

The histological hallmark of SS is a periductal mononuclear infiltrate in salivary and lachrymal glands (Fig. 54.1). The majority of the infiltrating cells are CD4 T lymphocytes, whereas CD8 cytotoxic T cells are found in smaller numbers. Activated B lymphocytes are also present, including autoantibody-secreting plasma cells.

Epithelial cell activation, signified by the expression of HLA class II molecules, is key to initiating recruitment of the inflammatory infiltrate. The expression of these molecules, along with upregulation of adhesion molecules and chemokines, contributes to the recruitment of inflammatory cells, such as T and B lymphocytes, macrophages, and dendritic cells (DCs), and suggests that epithelial cells may act as antigen-presenting cells (APCs), actively participating in lymphocyte activation.[9] The ensuing chronic inflammatory process is characterized by a complex interaction between activated epithelial cells and the innate and adaptive immune systems. In the most severe forms of inflammation, the characteristic periductal infiltrates can progress to the formation of germinal centers, which is associated with a higher risk of lymphoma development. Extraglandular manifestations occur as a result of similar lymphocytic infiltrations in other organs. This is described by some as *autoimmune epithelitis* to better reflect the systemic nature of the disease.[9] In most patients, only partial destruction of the glands is noted. Local production of cytokines, autoantibodies, metalloproteinases, and other inflammatory mediators may contribute to the dysfunction of the remaining epithelial cells. It is increasingly recognized that the innate immune system plays a crucial rule in the immunopathogenesis of SS.

Autoantibodies

Autoantibodies are the hallmark of systemic autoimmune diseases, including SS. The best-defined autoantibodies in SS are anti-Ro/SSA and anti-La/SSB antibodies.[10] Both autoantibodies are targeted against ribonucleoprotein antigens. Anti-Ro/SSA recognizes two RNA binding proteins (the 52-kilodalton [kDa] or the 60-kDa protein), whereas anti-La/SSB antibodies recognize RNA polymerase III. Anti-Ro/SSA antibodies are found in over 70% of patients with SS but are also frequently encountered in systemic lupus erythematosus (SLE) and other autoimmune diseases, even in the absence of oral or ocular dryness. Anti-La/SSB is more specific; it is present in 50% of patients with primary SS or SS/SLE but is rarely seen in other diseases. The pathogenic role of these antibodies has not yet been defined, except in infants born to women with anti-Ro/SSA and/or anti-La/SSB antibodies. These antibodies can cross the placenta and bind to Ro and La antigens located on the cell surface of fetal myocardial tissue, leading to fetal heart block. Other autoantibodies, such as antinuclear antibodies (ANAs) and rheumatoid factor, are frequently present in patients with both primary and secondary SS. Although these antibodies lack specificity, they are markers of a systemic autoimmune response and thus can help distinguish SS from other causes of salivary or lachrymal gland dysfunction.

AUTONOMIC NERVOUS SYSTEM ABNORMALITIES

Autonomic nervous system (ANS) abnormalities are common in SS and may play a critical role in its pathogenesis. Xerostomia and xerophthalmia, the cardinal manifestations of SS, are features of cholinergic parasympathetic ANS dysfunction, whereas sympathetic cholinergic failure results in xerosis and decreased sweating, which are frequently reported by patients with SS.

The complexity of the ANS, along with differences in methodology and studied populations, has resulted in variable results, but abnormalities in SS have been reported in both sympathetic and parasympathetic ANS domains.

CLINICAL MANIFESTATIONS

Clinical manifestations resulting from dysfunction of salivary and lachrymal glands are the dominant features of SS. Symptoms secondary to other exocrine gland dysfunction, such as skin and vaginal dryness, and chronic cough caused by tracheal dryness are frequently reported. Multiple extraglandular manifestations can also be present, reflecting the systemic nature of the autoimmune process.[4]

Constitutional Symptoms

One of the most common extraglandular manifestations of SS is excessive fatigue. Approximately 70% of patients with SS complain about disabling fatigue leading to reduced quality of life.[11] Attempts to identify a biological basis for fatigue have failed to reveal any correlations with levels of inflammatory markers, cytokines, or autoantibodies. This fatigue is commonly associated with arthralgia, malaise, and mental cloudiness (brain fog), resulting in a diagnosis of fibromyalgia or chronic fatigue syndrome. Less commonly, patients also experience low-grade fever and weight loss.

Ocular Involvement

Lachrymal gland dysfunction leads to dry, sandy eyes and sensation of foreign body in the eyes. Frequently, there is a history of intolerance to contact lenses. Patients often complain of sticky eyes and accumulation of thickened mucus as a result of loss of aqueous tear components.

CLINICAL PEARLS

- Chronic fatigue is a prominent presenting feature of Sjögren syndrome (SS).
- Autonomic nervous system involvement and peripheral nervous system involvement are often underrecognized.
- Mimics of SS include immunoglobulin G4 (IgG4)–related disease (Mikulicz disease), hepatitis C infection, sarcoidosis, and human T-lymphotropic virus (HTLV) infection.
- Presence of joint erosions and complement control protein (CCP) antibody is indicative of secondary SS caused by rheumatoid arthritis.
- Prolonged use of topical ophthalmic nonsteroidal antiinflammatory drugs (NSAIDs) and steroid preparations should be avoided to reduce the risk for local complications.
- Sudden normalization of previously elevated rheumatoid factor should prompt evaluation for development of lymphoma.
- Oral candidiasis should be identified and treated. Patients with SS are at a high risk for oral candidiasis, which can present as oral erythema and/or pain.
- Pediatric primary SS is rare and presents with variable, atypical features, most commonly recurrent tender parotid gland swelling.

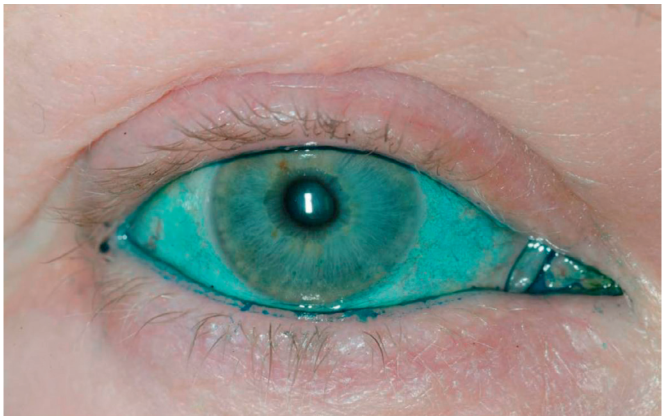

FIG 54.2 Punctate keratitis. Lissamine green stains dead or degenerated corneal epithelial cells green. (Courtesy of Manuel Datiles, MD.)

Enlarged lachrymal glands can be noted at the onset of disease. In the initial stages, injected conjunctivae with strands of thickened mucus at the inner canthus can be found. In more advanced stages, conjunctivae may lose their normal luster and become edematous. Corneal involvement results in punctuate keratitis as a result of epithelial cell death (Fig. 54.2). During early stages, the keratitis may be limited to the lower quadrants of the cornea to eventually involve the entire cornea. If left untreated, corneal ulcers can develop and result in rapid corneal thinning. In addition to reduced tear production, there is also evidence of inflammation of the ocular surface epithelium, as indicated by the presence of inflammatory cell infiltrate and elevated levels of inflammatory cytokines.

Oral Involvement

Saliva plays a critical role in maintaining oral health and comfort. It has antibacterial, lubricating, remineralizing, digestive, buffering, and cleansing properties. Therefore decreased salivary production or altered salivary composition can result in numerous conditions affecting oral health, comfort, and quality of life. Composed of 99% water, electrolytes, and proteins, the initial saliva is secreted by acinar cell clusters, which are innervated by both sympathetic and parasympathetic nerves. The sympathetic nerve activates alpha- and beta-adrenergic receptors at the plasma membrane, initializing a process that eventually catalyzes exocytosis of

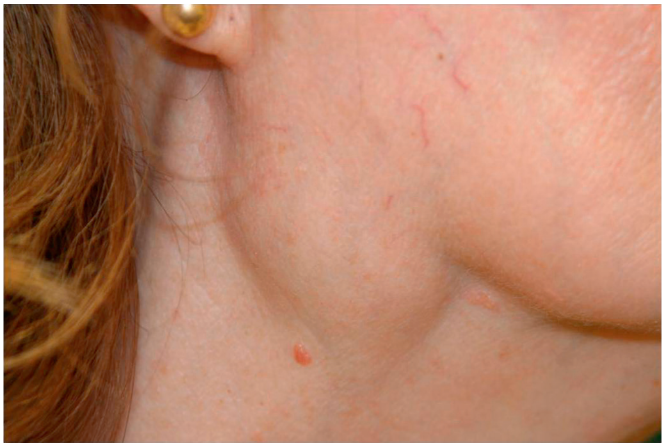

FIG 54.3 Enlargement of the parotid gland.

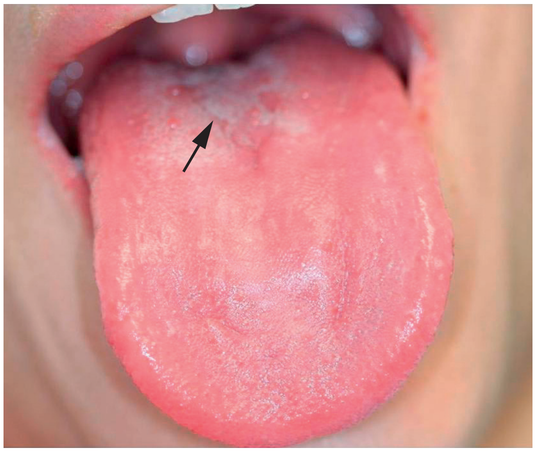

FIG 54.4 Papillary atrophy and candidiasis of the tongue. The loss of filiform papillae results in a smooth surface of the tongue. Oral candidiasis is common in Sjögren syndrome (SS) and can present as erythema only with minimal or no exudate (arrow).

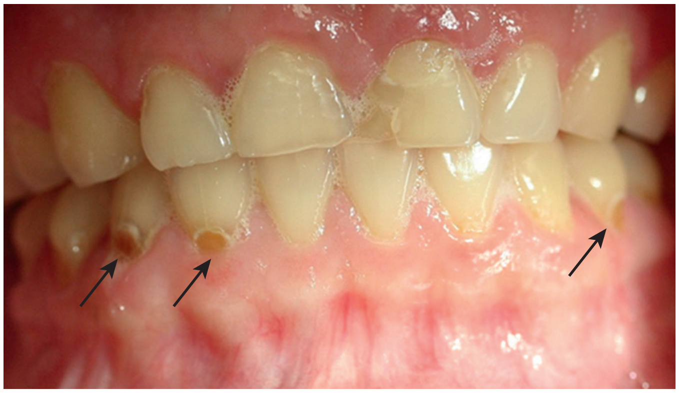

FIG 54.5 Root caries on anterior teeth caused by loss of the protective functions of saliva is a common finding. The cusp tips of the posterior teeth are also commonly affected.

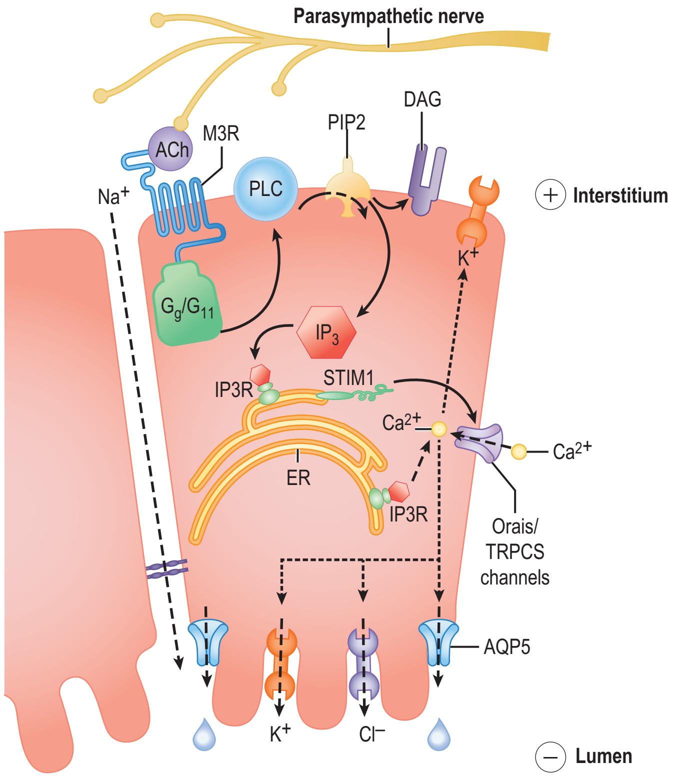

FIG 54.6 Acinar cells fluid and electrolyte regulation signaling pathway. M3 receptors coupled to G proteins activate phospholipase C (PLC); this results in hydrolysis of phosphatidylinositol 1,4 bisphosphate (PIP2) to yield diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP3). IP3 diffuses in the cytosol and binds and activates the IP3 receptors positioned on the plasma membrane of the endoplasmic reticulum (ER).[19] This causes opening of the IP3 receptors releasing calcium from the stores. The decrease in calcium within the ER is sensed by the calcium sensing protein, stromal interaction molecule 1(STIM1). STIM1 translocates to the plasma membrane and activates the Calcium Release-Activated Calcium Modulator (ORAI) and Tansient Receptor Potential, Canonical (TRPCs) calcium channels. These channels are called *store-operated channels* (SOCs), which upon activation cause calcium influx. The calcium (Cl^-) entering the cells originating at the apical pole as a result of polarity activate potassium (K^+) and Cl^- channels releasing K^+ and Cl^- into the lumen. Subsequently, calcium propagates to the basolateral side of the cell where it activates K^+ channels releasing K^+ into the interstitium. This creates an electrochemical gradient that drives sodium (Na^+) across the paracellular pathway.[20] The ion accumulation in the lumen drives water out through the aquaporin 5 (AQP5) channels, causing cell shrinkage.

proteins. Meanwhile, the parasympathetic nerve activates muscarinic receptors (M3) by releasing acetylcholine, which induces a calcium-dependent cascade of acinar cell volume change (majority of salivary fluid) and secretion of electrolytes.[12-14]

Symptoms and signs of salivary gland dysfunction include oral dryness (xerostomia); oral pain and sensitivity; difficulty chewing, swallowing, and speaking; diminished taste; inflamed, morphologically altered, or infected mucosal tissues; and increased tooth decay.

Chronic xerostomia necessitates the use of fluids throughout the day and night. It is not uncommon for patients with SS to wake up at night to drink fluids to relieve dryness and also to require the use of fluids to be able to speak, chew, and swallow. A burning sensation along with taste alterations and decreased tolerance to spicy foods is described by a significant percentage of patients.

Head and neck examination often reveals dry and chapped lips, angular cheilitis, and swollen major salivary glands (Fig. 54.3), which may be recurrent or chronic. Intraoral findings include decreased salivary pooling under the tongue and a depapillated tongue surface often associated with erythematous candidiasis (Fig. 54.4). Vasculitis can also manifest in the oral cavity and lead to tissue breakdown. Teeth often exhibit an increased rate of caries with characteristic decay affecting the roots and cusp tips (Fig. 54.5).

A description of the water secretion molecular mechanism in salivary epithelial cells in shown in Fig. 54.6.

Musculoskeletal Involvement

Musculoskeletal complaints are present in the majority of patients with SS. The rate of incidence of arthralgias has been reported as 50–75% in various studies and precedes sicca symptoms in up to 30% of patients. Arthralgias are symmetrical and usually without evidence of synovitis or erosions. Large-joint and small-joint involvement is equally reported, and 10–20 % of patients have recurrent monoarthritis or oligoarthritis. From a clinical perspective, it is often difficult to differentiate between patients with primary SS and symmetrical joint involvement and those with RA presenting with sicca symptoms.

Neuropsychiatric Manifestations

Primary SS can result in multiple neurological manifestations involving both the central nervous system (CNS) and the peripheral nervous system (PNS). PNS manifestations are more common and are present in 5–20% of patients with SS. PNS involvement can present as sensory neuropathy, small-fiber neuropathy, cranial neuropathy, inflammatory myopathy, and autonomic neuropathy. Small-fiber neuropathy is increasingly being recognized as the most common PNS manifestation of SS. It presents as a subacute to chronic development of excruciating burning pain. There is selective impairment of pinprick and temperature sensation, with preserved vibratory sense and proprioception. Diagnosis is made with skin biopsy. Symptoms suggestive of autonomic dysfunction, such as orthostatic hypotension, temperature intolerance, constipation, urinary frequency or hesitancy, and delayed gastric emptying, are present in up to half the patients with SS.[15] CNS involvement is rare and can present as white matter lesions, difficult to distinguish from multiple sclerosis, myelopathy, and optic neuritis, as well as cognitive dysfunction, seizures, and encephalopathy.[15] Neuromyelitis optica spectrum disorders (NMOSDs), with the hallmark features of acute optic neuritis or transverse myelitis with a relapsing course, have been linked to the presence of antiaquaporin-4(AQP4) serum autoantibody. In 213 patients diagnosed with NMOSD, 78 (37%) were found to fulfill criteria for SS.[16-18] Anxiety and depression are commonly seen in patients with SS, perhaps because of the severe impact of the manifestations of disease on the patients' quality of life.

Dermatological Involvement

Skin is involved in about 50% of SS patients[19]; lesions can be vasculitic or nonvasculitic. The most common nonvasculitic involvement is dry, itchy skin (xerosis) and angular cheilitis. Other less common nonvasculitic lesions include alopecia, vitiligo, eyelid dermatitis, and erythema nodosum–like lesions. Annular erythema, a rash similar to subacute cutaneous lupus, has been reported in about 10% of patients with SS and is closely associated with the presence of anti-SSA and/or anti-SSB autoantibodies. However, the rash is less photosensitive and histologically has deeper perivascular and periappendageal lymphocytic infiltrates.

Vasculitic lesions include nonpalpable purpura caused by hypergammaglobulinemia, palpable purpura, and urticarial vasculitis.[19] Patients with vasculitis have higher prevalence of positive ANA, anti-Ro/SSA antibodies, and rheumatoid factor compared with those with nonvasculitic skin involvement. Palpable purpura is histologically characterized by leukocytoclastic vasculitis and may indicate presence of underlying cryoglobulinemia. Raynaud phenomenon (RP) is seen in 30–50% of SS patients and frequently precedes the development of sicca symptoms.

Gastrointestinal Involvement

Dysphagia is common as a result of dryness of the pharynx and esophageal dysmotility. Nausea, epigastric pain, and constipation are frequently encountered. Gastrointestinal (GI) tract dysmotility can be seen as a result of ANS involvement. Pancreatic dysfunction, with reduced production of amylase and lipase, is present in 25% of patients with SS.

Pulmonary Involvement

Cough is a common complaint in patients with SS and results from tracheobronchitis sicca (tracheal and bronchial dryness). Clinically significant pulmonary involvement is reported in 9–12% of SS patients.[20] Pulmonary manifestations include large airway disease and small airway disease, bronchial hyperresponsiveness, recurrent respiratory infections, interstitial lung disease, pulmonary hypertension, pleuritis, and pulmonary amyloidosis. Interstitial lung disease is increasingly recognized as an extraglandular manifestation of SS and can precede the diagnosis of SS.

Patients with primary SS presenting with unexplained dyspnea should be evaluated for pulmonary arterial hypertension (PAH); an unexpectedly high prevalence (14%) of pulmonary hypertension was found in a cohort of 1158 patients. The majority of patients with SS and PAH manifest symptoms early in the disease course.[21,22]

Cardiac Involvement

Clinically significant cardiac involvement is uncommon in primary SS. Patients may develop pericarditis, thickened pericardium, or left ventricle diastolic dysfunction. Rhythm abnormalities resulting from autonomic dysfunction may be encountered. Placental transfer of anti-SSA/Ro and anti-SSB/La antibodies from pregnant patients with SS can cause lesions in the cardiac conducting system of the fetus. Pregnant women with positive anti-SSA/Ro and anti-SSB/La antibodies have a 2.5% risk of delivering a baby with congenital heart block.

Like patients with other chronic inflammatory conditions, patients with SS are at an increased risk of premature atherosclerosis and cardiovascular events. Some traditional cardiovascular risk factors, such as hypertension and hypercholesterolemia, are more prevalent in patients with SS. However, disease-specific factors also contribute to the pathogenesis of premature atherosclerosis.[23-25]

Genitourinary and Renal Involvement

Renal involvement is frequently caused by tubulointerstitial nephritis often presenting as distal (type1) renal tubular acidosis, renal calculi, and hypokalemia. Glomerular disease has been rarely reported and, in most cases, is linked to cryoglobulinemic vasculitis. Inflammation of the urinary bladder epithelium can cause interstitial cystitis. Vaginal dryness leading to dyspareunia has been reported in 40% of women.

Clinical Manifestations in Children

Primary SS is rarely diagnosed in children, but many adult patients with SS recall the presence of symptoms since childhood. Clinical presentation in children is more insidious with predominant recurrent parotitis and, less commonly, sicca symptoms.[26]

Associated Autoimmune Conditions

Autoimmune thyroiditis is seen in more than one-third of patients with SS. Celiac disease is also increasingly recognized in these patients, with a prevalence 10 times higher than in the general population.

Lymphoma Associated With SS

SS is associated with increased risk of lymphoma, with about 5% of patients developing lymphoma. In a meta-analysis of 20 studies the standardized incidence rate of lymphoma was 18.9% (confidence interval [CI] 9.4–37.9).[27] Most of these are low-grade marginal zone lymphomas of the mucosa-associated lymphoreticular tissue (MALT) type. Only 10% of lymphomas in patients with SS evolve into a less differentiated cell (more aggressive) variety. Risk factors for development of lymphoma include persistent enlargement of the parotid glands, palpable purpura, leg ulcers secondary to vasculitis, mixed cryoglobulinemia, and low C4 levels.

DIAGNOSIS AND CLASSIFICATION CRITERIA

Patients with SS can present with heterogeneous combinations of sicca symptoms and extraglandular manifestations. Moreover, various clinical syndromes and medications can lead to similar symptoms and mimic SS. The diagnosis of SS is based on the combination of subjective symptoms of dryness (sicca symptoms), objective evidence of lachrymal or salivary gland hypofunction, and evidence of autoimmunity or salivary gland inflammation. Classification criteria were proposed by an American–European consensus group (AECG) in 2002,[28] primarily for classification of patients in clinical studies. These criteria are widely accepted and are frequently used as a guide for clinical diagnosis. Application of these criteria to classify patients with primary SS has a sensitivity of 89.5% and specificity of 95.2%, whereas for secondary SS, it has a sensitivity of 97.2% and specificity of 90.2%.[28] The AECG classification scheme is based on a set of two subjective criteria and four objective criteria.

Patients are classified as having primary SS in the absence of any other systemic autoimmune disease, whereas in secondary SS, sicca manifestations are present in conjunction with other underlying autoimmune diseases, such as SLE, RA, polymyositis/dermatomyositis, or systemic sclerosis. SS is excluded if patients use anticholinergic medications or have other conditions that can mimic SS, such as chronic viral infections, graft-versus-host disease (GvHD), or status post irradiation of the head and neck region.

Patients presenting with sicca symptoms suggestive of SS should undergo specialized testing to confirm the diagnosis. Lachrymal function can be assessed by using the Schirmer test to quantify the amount of tear production, whereas corneal and conjunctival damage caused by dryness can be measured by fluorescein and lissamine green staining. Salivary gland evaluation is done by collection of unstimulated saliva or by performing salivary scintigraphy. Laboratory workup should include testing for autoantibodies to SSA/Ro and SSB/La antigens, which are detected in sera of 45–70% and 20–50%, respectively, in patients with SS. However, the AECG criteria have been criticized for including subjective symptoms and physiological tests lacking specificity and for using alternative tests that are diagnostically nonequivalent. In addition, with the potential use of biological agents to treat SS, more standardized, clear, and highly specific criteria are needed.

To address these concerns, in 2012 the American College of Rheumatology (ACR) proposed new classification criteria for SS, which required the presence of two out of three objective criteria in individuals suspected of having SS based on their signs and symptoms (Table 54.1). These new criteria include no subjective ocular and oral symptoms and no functional tests for the salivary glands.

In subsequent studies comparing the AECG and ACR criteria, the degree of concordance ranged from modest ($\kappa = 0.53$) to high ($\kappa = 0.81$), but neither set of criteria has been shown to be clearly superior to the other. At present, it appears that the stricter ACR criteria are more suitable for high-risk clinical trials, such as those using biologicals, and the AECG criteria may have broader applicability in clinical research.[29-31]

Novel Biomarkers for Diagnosis and Management of Sjögren Syndrome

MicroRNAs (miRNAs) are small regulatory noncoding RNAs of 18–25 nucleotides in length. Over the last few years, interest in miRNAs as clinical biomarkers has been increasing steadily. The reasons for this increased interest mainly stems from recognition of the master regulatory roles they play in normal and altered physiological states and also their stability compared with mRNAs, a characteristic that allows them to be readily isolated from archived samples, such as formalin-fixed paraffin-embedded (FFPE) tissues or frozen saliva.[32-34]

TABLE 54.1 **Proposed American College of Rheumatology (ACR) Classification Criteria for Sjögren Syndrome**

The classification of Sjögren syndrome (SS), which applies to individuals with signs/symptoms that may be suggestive of SS, will be met in patients who have at least two of the following three objective features:

1. Positive serum anti-SSA (Ro) and/or anti-SSB (La) or (positive rheumatoid factor and antinuclear antibody [ANA] $\geq$ 1 : 320)
2. Labial salivary gland biopsy exhibiting focal lymphocytic sialadenitis with a focus score ≥ 1 focus/4 mm^2
3. Keratoconjunctivitis sicca with ocular staining score ≥ 3 (assuming that the patient is not currently using daily eye drops for glaucoma, and has not had corneal surgery or cosmetic eyelid surgery in the last 5 years)[3]

Prior diagnosis of any of the following conditions would exclude participation in SS studies or therapeutic trials because of overlapping clinical features or interference with criteria tests:

History of head and neck radiation treatment
Hepatitis C infection
Acquired immunodeficiency syndrome
Sarcoidosis
Amyloidosis
Graft-versus-host disease
Immunoglobulin G4 (IgG4)–related disease

The role of miRNAs in primary SS is being investigated by several groups worldwide not only for their effects on immune cells but also on the target organs, such as the salivary glands.[35-37]

Rheumatoid factor is commonly positive in patients with SS and is part of the new ACR criteria for the diagnosis of SS. Recently, anticentromere antibodies were found to be present in up to 13% of patients with SS.

TREATMENT

THERAPEUTIC PRINCIPLES

Management of Sjögren Syndrome (SS)

Ocular Manifestations

- Symptomatic relief with artificial tear drops and lubricating ointments
- Topical cyclosporine eye drops
- Blockage of nasolacrimal duct by punctual plug placement or surgical cautery

Oral Manifestations

- Symptomatic relief with water and artificial saliva preparations
- Physical measures to increase saliva production: sugar-free candies and gum
- Maintaining meticulous oral hygiene; use of fluoride toothpaste
- Sialogogues: pilocarpine or cevimeline

Systemic Manifestations

- Hydroxychloroquine most commonly used to alleviate fatigue and arthralgias
- Other immunosuppressive medications may be considered in more severe internal organ involvement
- Anti–tumor necrosis factor (TNF) blocking agents are not recommended
- Role of rituximab needs clarification

Patient Education

- Patients should receive the following instructions:
  - Avoid extreme dry environments, such as proximity to open fire places.
  - Wear protective eye glasses or goggles.
  - Use sugar-free sour candies or gum.
  - Maintain good ocular and oral hygiene.
  - Avoid use of medications and substances causing sicca symptoms.
- Women of child-bearing age with positive anti-SSA or anti-SSB antibodies should be counseled about the risk of congenital heart block.
- Educate patients about increased risk of lymphoma associated with SS.
- Safety precautions should be taken with regard to smoke and gas leakage in the environment of patients with loss of smell.
- Information regarding focus groups, such as Sjögren's Syndrome Foundation (http://www.sjogrens.com/) and the British Sjögren's Syndrome Association, should be provided to patients.

Symptomatic Treatment of Sicca Symptoms

The mainstay of treatment in SS is providing symptomatic relief. Use of artificial tears is often helpful. In patients with sticky mucus or strands over the eyes, use of mucolytic agents is indicated. Blockage of lachrymal ducts with punctual plugs or surgically can be beneficial.

Artificial saliva available as spray or lozenges provides only limited relief. Local activation of salivary glands (in patients with preserved function) with sugar-free sour candies or gums provides some relief of symptoms.

Cholinergic agonists, such as pilocarpine and cevimeline, provide effective symptom relief in selected patients. Cevimeline is a more selective muscarinic agonist predominantly affecting M1 and M3 receptors and hence is associated with fewer side effects compared with pilocarpine.[4]

The Sjögren's Syndrome Foundation's Clinical Practice Guidelines Committee recently recommended the use of topical fluoride to reduce dental caries in patients with SS who suffer from dry mouth.[38]

Immune-Modulating Medications

Cyclosporine eye drops are frequently prescribed to reduce the local immune response involving the conjunctiva and the cornea. Use of topical nonsteroidal antiinflammatory and steroid-based eye drops provide short-term benefits and should be used cautiously.

Hydroxychloroquine is commonly prescribed for patients with SS, even though some trials have shown significant laboratory improvement but no beneficial effects on symptoms.

Other immune-modulating agents, such as azathioprine, cyclosporine, methotrexate, and mycophenolate mofetil, have shown only limited benefits in treating sicca symptoms and are used primarily for extraglandular manifestations.[39]

Trials using biological agents, such as infliximab and etanercept, failed to show any significant improvement in the primary outcomes of treatment for oral and ocular dryness.[39]

Data on the use of rituximab are controversial, with some studies showing only modest benefit.[39]

An open-label trial using the anti–B cell–activating factor (BAFF) monoclonal antibody (mAb) belimumab revealed no major safety concerns. There were minor improvements in parotid gland swelling and lymphadenopathy but no significant improvement in salivary and lacrimal gland function or patient-reported outcomes. Despite the central role of autoantibodies in the pathogenesis of SS, targeting of B-cell function has been surprisingly unsuccessful in managing SS.

Treatment for Lymphoma Associated With SS

As discussed above, lymphoma associated with SS is usually low grade with 5-year survival rates of 86–100%. In a study of patients with SS, overall survival rates of patients with MALT lymphoma was similar in both the treated and the untreated groups.[24] However, patients with disseminated and more aggressive lymphoma have reduced overall survival. Recently, high levels of BAFF and Flt3 were shown to be highly predictive of lymphoma development in patients with SS.[40]

PATIENT EDUCATION

Because of its significant impact on quality of life, educating patients and their families is of utmost importance. Excellent resources for patient education are available through focus groups, such as the Sjögren's Syndrome Foundation (http://www.sjogrens.com/) and the British Sjögren's Syndrome Association.

In general, patients are advised to avoid dry environments, protect the eyes from bright sunlight, maintain good dental hygiene, and be aware of symptoms suggestive of lymphoma. They should avoid medications and substances that may worsen their sicca symptoms. Women of child-bearing age with positive anti-SSA/Ro and anti-SSB/La antibodies should be counseled regarding the risk of congenital heart block in the fetus. Patients with loss of smell associated with SS are at an increased risk of injury in the event of gas leakage. Alternative methods should be employed to detect gas leakage in the patient's environment.

LYMPHOMA IN SJÖGREN SYNDROME

Risk Factors

- Increase in risk with time: cumulative risk 3.4% at 5 years and 9.8% at 15 years after diagnosis of Sjögren syndrome (SS)
- Persistent enlargement of parotid glands
- Splenomegaly and lymphadenopathy
- Palpable purpura
- Leg ulcers secondary to vasculitis
- Mixed cryoglobulinemia
- Low complement levels
- CD4 lymphocytopenia

Staging and Management (in Collaboration With an Oncologist)

- Computed tomography (CT) of neck, thorax, and abdomen
- Laboratory tests: Lactate dehydrogenase (LDH), serum and urine electrophoresis and immunofixation, human immunodeficiency virus (HIV), and hepatitis C serology
- Bone marrow biopsy
- Localized low-grade mucosa-associated lymphoreticular tissue (MALT) lymphoma (most common): careful monitoring required
- Multiple extranodal site involvement: single agent chemotherapy
- High-grade transformation or aggressive lymphoma at presentation: rituximab and CHOP (cyclophosphamide, hydroxy doxorubicin, Oncovin, and prednisone)

TRANSLATIONAL RESEARCH AND FUTURE DIRECTIONS

ON THE HORIZON

- Whole transcriptome and exome studies will lead to better understanding of genetic risk factors.
- Further studies are needed to better understand the interaction between immune and nonimmune abnormalities leading to Sjögren syndrome.
- Pilot clinical studies are needed to identify potential therapeutic candidates for larger efficacy trials.
- There is a pressing need to identify and to validate clinically relevant biomarkers.

SS is the clinical manifestation of a complex interplay between genetic factors and environmental and stochastic events that involve innate and adaptive immunity, hormonal mechanisms, and the ANS. A better understanding of these elements is necessary to develop more effective treatments. Two large genome-wide association studies are currently underway to better delineate the genetic risk factors of SS. Pilot treatment trials targeting key cells (B and T lymphocytes) and mediators (Blyss, lymphotoxin, IFN) of autoimmune/inflammatory pathways are expected to identify the most promising molecule(s) that can be tested in larger efficacy studies. There is a clear and present need to identify and validate biomarkers that can be used in clinical trials as well as everyday clinical practice to improve the management of patients with SS.

As no effective treatment is currently available to treat patients with SS, several medications and other non–drug-based modalities are being studied. Currently, several clinical trials using agents targeting IFN, interleukin-6 (IL-6), Toll-like receptors (TLRs), and inhibition of T-cell stimulation are underway. Use of steroids locally in the salivary glands showed some promising initial results, which should be confirmed in independent studies.

MULTIPLE-CHOICE QUESTIONS

1. What is the typical salivary gland histological feature in Sjögren syndrome (SS)?
   A. Diffuse inflammation throughout the salivary gland parenchyma
   B. Clusters of tightly packed lymphocytes surrounding ducts
   C. Increased proliferation of acinar cells
   D. Increased proliferation of ductal cells

2. Which of the following is NOT an exclusion criterion for the classification/diagnosis of SS?
   A. History of head and neck radiation treatment
   B. Hepatitis C infection
   C. Acquired immunodeficiency syndrome (AIDS)
   D. Mucosa-associated lymphoreticular tissue (MALT) lymphoma

3. Which of the following is NOT a risk factor for the development of lymphoma in SS?
   A. Increased CD4 counts
   B. Persistent enlargement of parotid glands
   C. Mixed cryoglobulinemia
   D. Low complement levels

Scleroderma–Systemic Sclerosis

John Varga, Fredrick M. Wigley

Systemic sclerosis (SSc) is a chronic multisystem connective tissue disease characterized by autoimmunity and inflammation, widespread functional and structural abnormalities in small blood vessels, and progressive fibrosis of the skin and visceral organs. Multiple cell types and their products interact to mediate the pathogenetic processes that underlie the diverse clinical manifestations of SSc.

PREVALENCE AND EPIDEMIOLOGY

SSc is a sporadic disease with worldwide distribution. Incidence estimates in the United States range from 9 to 19 cases per million per year, and prevalence rates range from 28 to 253 cases per million. According to the revised American College of Rheumatology classification criteria, which are more sensitive for identifying early stage of disease, the prevalence estimates are expected to be considerably higher.[1] Age, gender, and ethnicity are important factors that determine disease susceptibility.[2] Like other connective tissue diseases, SSc is more prevalent in women, with the most common age of onset in the range of 40–60 years. Disease onset tends to occur at an earlier age among patients of African descent than among whites. Furthermore, black patients are more likely to have diffuse skin involvement, digital ulcers, pulmonary hypertension (PH), and pulmonary fibrosis, and have a worse prognosis.

ETIOLOGY AND PATHOGENESIS

The pathogenesis of SSc involves dynamic interplay among inherited genetic risk factors, environmentally induced stable epigenetic modifications, and acute or subacute environmental exposures.

Genetic Factors

Systemic sclerosis is not inherited in a mendelian fashion, and disease concordance rates among both monozygotic and dizygotic twins are relatively low (<5%). Nonetheless, 1.6% of patients with SSc have a first-degree relative with the disease (relative risk of 13), indicating an important role for genetic background in SSc disease susceptibility. Specific human leukocyte antigen (HLA) haplotypes show strong association with distinct SSc-specific autoantibody responses. Genetic investigations in SSc have focused on candidate genes and genome-wide association studies (GWAS). Candidate genes shown to be associated with SSc include those implicated in interferon (IFN) signaling, T- and B-cell activation, DNA clearance, and innate immunity (Table 55.1). It is remarkable that a majority of these genes are shared with other autoimmune diseases, particularly systemic lupus erythematosus (SLE), and are involved in immune regulation and innate immune responses, highlighting the potential importance of immune dysregulation in the pathogenesis of SSc.[3]

Environmental Factors

Although the etiology if SSc is unknown, microbial exposures and exposure to environmental and occupational agents, dietary factors, and drugs have been implicated as potential triggering factors. Patients with SSc have increased serum levels of antibodies directed against the human cytomegalovirus (hCMV). Evidence for a potentially pathogenic role for CMV, Epstein-Barr virus (EBV), and parvovirus B19 infection or reactivation, as well as *Helicobacter pylori* infection, has also been presented. These studies need confirmation, and the etiological role of microbial pathogens in SSc remains a conjecture. Although reports of apparent geographical clustering of SSc cases suggest shared environmental exposures, careful investigations have generally not been able to substantiate these clusters. Epidemic outbreaks of apparently novel multisystemic illnesses with SSc-like features have been linked to environmental exposures, such as contaminated rapeseed cooking oils in Spain (the toxic oil syndrome) and L-tryptophan dietary supplements (eosinophilia–myalgia syndrome) in the United States.[4] The incidence of SSc is increased among miners and others with occupational exposure to silica. Additional occupational exposures linked to increased risk of SSc include polyvinyl chloride, trichloroethylene, and organic solvents. Drugs potentially implicated in SSc-like illnesses include bleomycin, taxane, pentazocine, cocaine, and anorexigens associated with pulmonary artery hypertension. The apparent association of SSc with silicone breast implants originally raised concern, but epidemiological investigations have not substantiated the hypothesis of an increased risk.[5]

Pathology

The hallmark pathological features of SSc are a noninflammatory obliterative microangiopathy in multiple vascular beds and fibrosis of the skin and internal organs. In early-stage disease, cellular infiltrates may be prominent in many organs. In skin, inflammatory cells are located predominantly around blood vessels. With disease progression, these infiltrates become sparse.

Vascular injury is the earliest and possibly primary event in the pathogenesis of SSc. Patients with established SSc show widespread vascular lesions characterized by bland intimal proliferation in the small- and medium-sized arteries (Fig. 55.1). In late stages, perivascular adventitial fibrosis and generalized capillary rarefaction are prominent.

TABLE 55.1 Genetic Associations With Systemic Sclerosis (SSc)

Gene Locus	Gene Function	Genetic Polymorphisms Associated With SSc
IRF5	Activation of interferon	rs2004640, others
IRF8	Monocyte differentiation	rs11642837
IRF7	Activation of interferon	rs4963128
IL12R	Interleukin-12/T-cell signaling	rs3790567
STAT4	T-cell signaling	rs7574865, others
DNASE1L3	DNA clearance	rs35677470
ATG	Autophagosome biogenesis	rs9373839
PPARG	Adipogenesis	rs310746
CD247	T-cell receptor signaling	rs2056626
CSK	Src family tyrosine kinase	rs1378942
PTPN22	T-cell signaling phosphatase	rs2476601
BANK1	B-cell receptor signaling	rs10516487, others
BLK	B-cell receptor signaling	rs2736340
TNFAIP3/A20	Negative regulation of nuclear factor (NF)-κB inflammation	rs5029939, others
TNIP1	Negative regulation of NF-κB inflammation	rs2233287, others
TNFSF4	T cell–antigen-presenting cell interaction	rs1234314, others

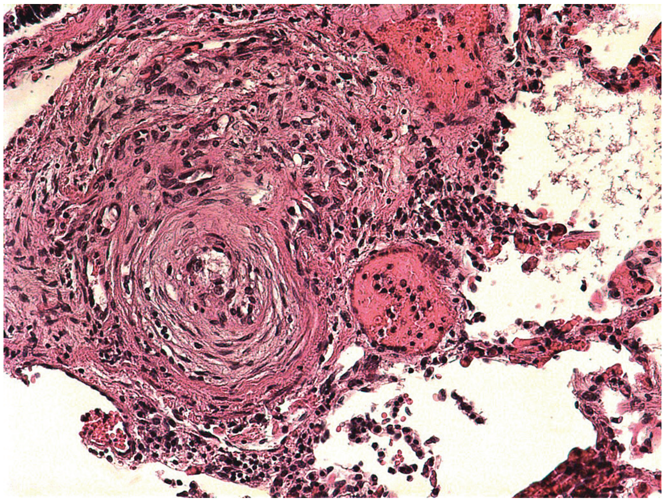

FIG 55.1 Pulmonary Arterial Involvement. Significant intimal layer hyperplasia is seen, leading to narrowing of the vascular lumen. (Courtesy of Dr. Anjana Yeldandi.)

Fibrotic changes are most prominent in skin, lungs, gastrointestinal (GI) tract, heart, tendon sheath, and perifascicular tissue surrounding skeletal muscle. Accumulation of collagen-rich connective tissue composed of fibulins; elastin; proteoglycans; matricellular proteins, such as tenascin-C and alternatively spliced fibronectin (EDA isoform), and other structural macromolecules in these organs leads to distortion of tissue architecture, resulting in progressive functional impairment. In skin, fibrosis causes massive dermal expansion with obliteration of hair follicles and sweat and sebaceous glands. Collagen deposition invades the subjacent adipose layer with entrapment and obliteration of adipocytes. Lungs show patchy infiltration of the alveolar walls with lymphocytes, plasma cells, macrophages, and eosinophils in early disease. In later stages, fibrosis and vascular damage predominate in the lungs, often coexisting in the same lesions. However, in patients with limited cutaneous SSc, the vascular lesions typically predominate. Intimal thickening of the pulmonary arteries, best seen with elastin stain, is a pathological hallmark of PH and at autopsy is often associated with multiple pulmonary emboli. Progressive fibrous thickening of the alveolar septae results in obliteration of the air spaces with a characteristic nonspecific interstitial pneumonia (NSIP) pattern and, less commonly, honeycombing, as well as loss of the pulmonary blood vessels. This process impairs gas exchange and contributes to worsening of PH. In the GI tract, pathological changes can occur at any level, from the mouth to the rectum. The esophagus shows atrophy of the lamina propria, submucosa, and muscular layers, with variable fibrosis. Replacement of the normal intestinal architecture leads to disordered peristaltic activity, resulting in gastroesophageal reflux, small bowel dysmotility, and bacterial overgrowth. Chronic gastroesophageal reflux leads to esophageal inflammation, ulcerations and stricture formation, and, in some cases, premalignant Barrett metaplasia.

The heart is frequently affected, with prominent myocardial contraction band necrosis, which reflects ischemia–reperfusion injury, and patchy areas of myocardial fibrosis. In the kidneys, vascular lesions predominate, and glomerulonephritis is rare. Chronic renal ischemia is associated with shrunken glomeruli and interstitial fibrosis. Scleroderma renal crisis (SRC) is associated with reduplication of elastic lamina, marked intimal proliferation, and narrowing of the lumen (onion skinning), often accompanied by microangiopathic hemolysis.

Pathogenesis

A comprehensive view of SSc pathogenesis must be capable of integrating the vasculopathy, immune dysregulation, and fibrosis of multiple organs, which are the hallmarks of the disease. As illustrated in Fig. 55.2, complex and dynamic interplay among these distinct pathomechanistic processes initiates, amplifies, and sustains tissue damage in SSc.[6] Animal models of disease (see Table 55.2) can be informative for identifying cell types, molecular mechanisms, and pathways contributing to SSc pathogenesis.

Microangiopathy

Evidence of vascular involvement is an early and widespread feature of SSc, and vascular damage has major impact on the course of the disease. Vascular endothelial cell injury is initially associated with largely functional and potentially reversible alterations. There is abnormal blood flow response to vasomotor or cold challenge and altered production of and responsiveness to factors mediating vasodilatation (nitric oxide and prostacyclins) and vasoconstriction (endothelins). Microvessels show loss of pericyte coverage, increased permeability, enhanced transendothelial leukocyte migration, activation of fibrinolytic cascades, and platelet aggregation culminating in thrombosis. Activated endothelial cells express elevated surface adhesion molecules and release endothelin-1, which further promotes leukocyte adhesion and smooth muscle cell proliferation, and might also drive endothelial–mesenchymal transition. Ensuing intimal and medial hypertrophy and fibrosis of the adventitial layers lead to vessel stiffening and luminal narrowing. Combined with endothelial cell apoptosis, the process culminates in the characteristically striking absence of blood vessels seen on angiograms of the

hands and kidneys in late-stage disease. Paradoxically, despite elevated levels of angiogenic signals, including vascular endothelial growth factor (VEGF), reflecting pervasive tissue hypoxia, the process of revascularization appears to be defective in SSc, possibly as a result of defects in the generation and maturation of bone marrow–derived $CD34^+$ endothelial progenitor cells.[7] Vascular injury in SSc is particularly prominent in the kidneys of patients with SRC, with evidence of complement activation and endothelin-1 deposition in the damaged small vessels.

Cellular and Humoral Immune Responses

In the early stages of SSc, activated T cells and monocytes/macrophages accumulate within lesional skin and the lungs, where they secrete proinflammatory and profibrotic mediators, including transforming growth factor-β (TGF-β), cytokines, and chemokines. These molecules can activate fibroblasts as well as endothelial cells, recruit further inflammatory cells, and initiate the fibrotic response. Because TGF-β, in particular, can induce its own production as well as that of other profibrotic growth factors, such as connective tissue growth factor (CTGF) and platelet-derived growth factor (PDGF), an initial cytokine burst could result in amplified cytokine production and sustained autocrine and paracrine signaling. Additionally, as the extracellular matrix (ECM) undergoes remodeling, it loses compliance and increases its stiffness, which, in itself, triggers biomechanical activation of resident stromal cells, in part by liberating and activating latent matrix-bound latent TGF-β. Alterations in the relative proportions and function of regulatory T cells (Tregs) and T-helper 17 (Th17) cells, and innate lymphoid cells (ILCs), have been documented and may play important roles in pathogenesis.

Virtually all patients with SSc have antinuclear and other autoantibodies in serum. These autoantibodies are generally highly specific for SSc and tend to be mutually exclusive (see below). Moreover, SSc-specific autoantibodies show strong association with individual disease subphenotypes, and their titers can fluctuate with disease activity. Multiple mechanisms have been proposed to account for autoantibody generation in SSc. In patients with SSc, B cells overexpress the surface receptor CD19, resulting in hyperresponsives.[8] Additionally, specific self antigens undergo posttranslational modifications, such as proteolytic cleavage, increased expression or misdirected subcellular localization that create neoepitopes recognized as nonself by the immune system. Although SSc-associated autoantibodies have well-established clinical utility as diagnostic and prognostic markers, their direct role in SSc-associated tissue damage remains uncertain.[9] Recent studies have indicated that patients with SSc also commonly have functional antibodies that are directed against fibroblasts and endothelial cells; the PDGF receptor; vascular receptors, such as endothelin-1 and angiotensin II receptors; and matrix metalloproteinases (MMPs).

Fibrosis: Cellular and Molecular Components

Interstitial and vascular fibrosis, the hallmarks of SSc, is characterized by replacement of normal tissue architecture with dense and noncompliant connective tissue. Although isolated organ fibrosis is a generalized and frequent sequel to any form of chronic or recurrent tissue injury, fibrosis concurrently affecting multiple organs is unique to SSc. Fibroblasts and related stromal cells of mesenchymal origin are key effector cells responsible for the development of fibrosis. In response to extracellular signals, such as TGF-β, CTGF, PDGF, Wnt, chemokines, endothelin-1, lysophosphatidic acid (LPA1), reactive oxygen species (ROS), and hypoxia, as well as integrin-mediated biomechanical signals from a stiff ECM, these cells proliferate; migrate; produce a broad array of matrix macromolecules; adhere to and remodel connective tissue; secrete growth factors, cytokines, and chemokines and express surface receptors for them; and undergo transdifferentiation into apoptosis-resistant contractile myofibroblasts. Under physiological conditions, the fibroblast repair program is tightly regulated and self-limiting to enable tissue regeneration, whereas under pathological conditions, fibroblast activation is sustained and amplified, resulting in exaggerated matrix deposition and disruption of tissue architecture. Uncontrolled activation of fibroblasts, combined with their relative resistance to apoptosis, is a fundamental pathogenetic alteration underlying fibrosis in SSc.

Fibroblasts explanted from lesional SSc tissues continue to display an abnormal phenotype when propagated *ex vivo*, with enhanced rate of synthesis of collagen and other ECM molecules, expression of α smooth muscle actin and cell surface adhesion molecules, and spontaneous generation of ROS through the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex pathway as well as from mitochondrial respiration. Additionally, explanted SSc fibroblasts show hallmarks of senescence. The persistent activated scleroderma phenotype is likely to reflect epigenetic modifications caused by chromatin remodeling, DNA methylation, or altered expression of noncoding regulatory RNAs, including microRNA and long noncoding RNAs.

TGF-β is a pleiotropic cytokine and a pivotal regulator of tissue repair and fibrosis (Chapter 9). Multiple abnormalities in TGF-β pathways have been identified in SSc, indicating a key role in pathogenesis. Lesional fibroblasts secrete TGF-β and exhibit TGF-β hyperresponsiveness caused by elevated expression of TGF-β surface receptors, and integrin-mediated activation of latent TGF-β. Furthermore, SSc fibroblasts show evidence of constitutive phosphorylation of Smad transcription factors and other key intracellular signaling pathways that, together with deficiencies in endogenous antifibrotic mechanisms, might contribute to the persistence and progression of fibrosis.[10] Therapies that selectively or nonselectively block growth factor signaling and abrogate fibrogenic pathways triggered by growth factors, chemokines, PDGF, Wnt, and CTGF are currently under development.

CLINICAL FEATURES

Overview

The term “scleroderma” is used to describe both systemic sclerosis and localized scleroderma, a disorder generally limited to skin. SSc is highly variable in its clinical expression and thus represents a broad spectrum of disease. The disease process can target skin, blood vessels, and the lungs, heart, GI tract, kidneys, and musculoskeletal system, subsets of patients exist with unique clinical features and distinct clinical outcomes. Raynaud phenomenon is virtually universal in SSc, suggesting that perturbation of the terminal arteries of the circulation is a fundamental process that links the different subsets of the disease. Thickening of the skin distinguishes SSc from other rheumatic diseases (Table 55.3); scleroderma (hard skin) is the most specific and prominent physical finding. Patients vary in the expression of the skin changes and are classified into two major subsets defined by the degree of clinically involved skin. In the diffuse skin variant called *diffuse cutaneous SSc* (dcSSc), fibrosis of skin is widespread, and the illness is more violent in expression, with rapid onset and increased risk of serious and internal organ disease. In contrast, the limited skin variant called *limited cutaneous SSc* (lcSSc) presents with long-standing Raynaud phenomenon, skin fibrosis limited to the fingers or distal limbs, and a generally indolent disease course. Limited SSc is less likely to be associated with organ failure or shortened life expectancy. Predictors of elevated mortality rates among patients with SSc include diffuse skin disease with a rapid rate of skin progression and internal organ involvement (especially the lungs or the kidneys, resulting in an SRC), male gender, black race, and later age of disease onset.[11,12]

KEY CONCEPTS

Clinical Patterns of Systemic Sclerosis

Limited Cutaneous Scleroderma

- Distal skin sclerosis (sclerodactyly)
- Severe Raynaud phenomenon with digital ischemia
- Numerous telangiectasia
- Isolated pulmonary arterial hypertension

Diffuse Cutaneous Scleroderma

- Rapidly progressing widespread skin involvement
- Scleroderma renal crisis
- Interstitial lung disease
- Severe gastrointestinal dysmotility
- Cardiomyopathy

TABLE 55.3 Classification of Systemic Sclerosis (SSc)

Diffuse cutaneous scleroderma—skin thickening on the trunk in addition to the face, proximal and distal extremities

Limited cutaneous scleroderma—skin thickening limited distal to the elbow and knee; may also involve the face and neck

CREST syndrome—subcutaneous *c*alcinosis; *R*aynaud phenomenon; *e*sophageal dysmotility; *s*clerodactyly; *t*elangiectasia

Sine scleroderma—no apparent skin thickening but characteristic visceral organ involvement, vascular and serological features

Overlap syndrome—criteria for SSc, coexisting with features of systemic lupus erythematosus, rheumatoid arthritis, or inflammatory muscle disease

Mixed connective tissue disease—overlap syndrome with anti-U1 ribonucleoprotein (RNP) antibodies

Early disease—Raynaud phenomenon (RP) with clinical and/or laboratory features of SSc; specific autoantibodies, abnormal nailfold capillaroscopy, finger edema, and ischemic injury

Although classification of SSc as diffuse and limited cutaneous has utility, disease expression is far more complex, and several distinct phenotypes are recognized within each of the two subsets. For example, 10–15% of patients with lcSSc develop severe pulmonary arterial hypertension without significant lung fibrosis. Other patients develop systemic features of SSc without appreciable skin involvement, a phenotype that is termed *systemic sclerosis sine scleroderma.* Unique clinical phenotypes of SSc are associated with specific autoantibodies (Table 55.4). For example, anticentromere antibodies are associated with lcSSc, whereas antitopoisomerase-I antibodies are associated with the presence of interstitial lung disease. The presence of anti-RNA polymerase antibodies is associated with rapid and widespread skin disease and an increased risk of an SRC. In some patients with SSc who have "overlap" features, SSc coexists with clinical and laboratory evidence of another autoimmune disease, such as polymyositis, autoimmune thyroid disease, Sjögren syndrome, polyarthritis, autoimmune liver disease, or SLE (see Table 55.4).

Instead of SSc, the term " localized scleroderma" is now properly used to describe a group of patients with disease generally limited to fibrosing skin disorders that occurs with similar frequency in both children and adults (Table 55.5). Localized scleroderma is infrequently associated with significant systemic involvement. Morphea, a form of localized scleroderma, can occur as solitary or multiple lesions (generalized morphea) of expanding circular patches of thickened skin. The most common form of localized scleroderma in children is linear scleroderma. It presents as a streak of thickened skin, generally in one or both lower extremities. Linear scleroderma often involves the subcutaneous tissues with fibrosis and atrophy of supporting structures, muscle, and bone, and radiographs may show melorheostosis of long bones. In children with linear scleroderma, the growth of affected tissues, muscles, and long bones can be retarded. When the lesions cross joints, significant contractures of the affected joint can develop. Linear scleroderma can occur on the

TABLE 55.4 Frequency and Clinical Correlations of Systemic Sclerosis (SSc) Autoantibodies

	% Frequency in SSc	Disease Subtype	Clinical Associations	Prognosis
Anticentromere	20–38	lcSSc	Pulmonary arterial hypertension	Better prognosis
Antitopoisomerase I	15–42	dcSSc	Pulmonary fibrosis Heart involvement	Worse prognosis
Anti-RNA polymerase III	5–31	dcSSc	Renal crisis Tendon friction rubs, synovitis, myositis, Joint contractures. Increased risk of malignancy	Increased mortality
Anti-U3 RNP (fibrillarin)	4–10	dcSSc	Renal crisis and cardiac involvement	Poor prognosis especially in African Americans
Anti-Th/To	1–13	lcSSc	Pulmonary fibrosis and renal crisis	Poor prognosis
Anti-U11/U12 RNP	3.2	—	RP Gastrointestinal involvement Lung fibrosis	Increased mortality
Anti-U1 RNP	2–14	lcSSc	RP, puffy fingers, arthritis, myositis, overlap syndrome (*i.e.,* MCTD)	Better prognosis
Anti-PM-Scl	4–11	Overlap with polymyositis lcSSc	RP, arthritis, myositis pulmonary involvement, calcinosis, and sicca symptoms	Better prognosis
Anti-Ku	2–4	—	Myositis, arthritis, and joint contractures	—
Anti-hUBF (NOR 90)	<5	lcSSc	Mild internal organ involvement	Better prognosis
Anti-Ro52/TRIM21	15–20	Association with other autoimmune diseases	Older age onset, pulmonary fibrosis	—

dcSSc, diffuse cutaneous SSc; lcSSc, limited cutaneous SSc; MCTD, mixed connective tissue disease; RNP; ribonucleoprotein; RP, Raynaud phenomenon; TRIM, tripartite motif.

TABLE 55.5 Classification of Localized Scleroderma

- Plaque types of morphea
  - Circumscribed plaques
  - Guttate
  - Keloid/nodular
  - Bullous
- Generalized morphea
  - Three or more locations
  - Pansclerotic morphea
- Linear scleroderma
  - Frontoparietal linear morphea (*en coup de sabre*)
  - Parry-Romberg syndrome (progressive hemifacial atrophy)
  - Linear streaks on limbs or trunk
- Deep morphea

head leaving severe facial deformity. When this occurs, it is called *en coupe de sabre.* This should be distinguished from Perry-Rhomberg syndrome, or facial hemiatrophy, which also affects the face, usually unilaterally, with atrophy of skin rather than fibrosis. Both *en coupe de sabre* and Perry-Rhomberg syndrome can be associated with central nervous system (CNS) involvement, presenting as headaches, visual disturbance, or a seizure disorder. Uncommon forms of localized scleroderma include pansclerotic morphea, keloid morphea, deep morphea presenting as a fasciitis, and bullous morphea with blistering. Morphea lesions can be seen in patients with SSc, and often lichen sclerosus is seen in association with morphea.

Symptoms

Characteristically, the earliest symptoms of SSc are nonspecific and include fatigue, musculoskeletal distress (stiffness or pain), and feeling ill. Cold sensitivity and Raynaud phenomenon occur early in the disease and may be the only clinical clue to the presence of active disease. Symptoms of esophageal dysfunction with dysphagia, heartburn, and periodic GI reflux are common problems, which, along with Raynaud phenomenon, can precede other manifestations of SSc by years. Visible capillary abnormalities easily seen at the nailfold (dilatation and loss or dropout of capillaries) are almost a universal finding in SSc. These nailfold capillary changes provide a clinical clue to presence of the underlying vascular disease in that changes occur early in the disease course and progress in association with other systemic involvement. An individual presenting with Raynaud phenomenon, abnormal nailfold capillaries, and the presence of an SSc-specific autoantibody can be suspected of having SSc even before other more obvious manifestations are noted.[13]

CLINICAL PEARLS

Clinical Features of Early Systemic Sclerosis

- Definite Raynaud phenomenon
- Gastroesophageal reflux with heartburn
- Swelling of the fingers and hands
- Musculoskeletal pain and stiffness
- Dilated nailfold capillaries
- Hyper- or hypopigmentary changes of skin

Diffuse SSc

In general, patients with dcSSc have a short interval between the onset of Raynaud phenomenon and other signs and symptoms.

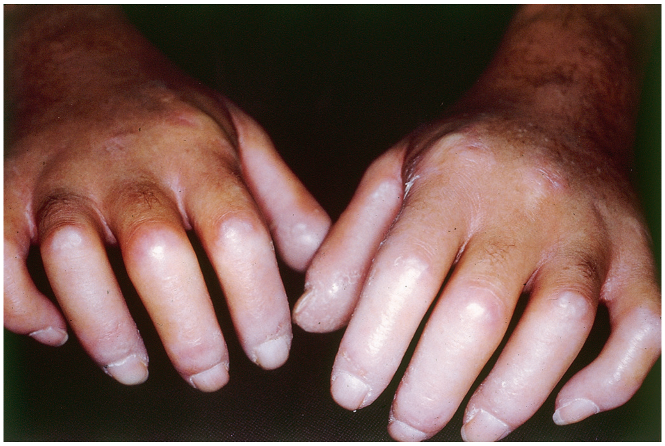

FIG 55.3 Skin Fibrosis in Systemic Sclerosis. Severe fibrosis of the skin of the hands and forearms causing joint contractures and skin ulcerations in a woman with diffuse cutaneous systemic sclerosis.

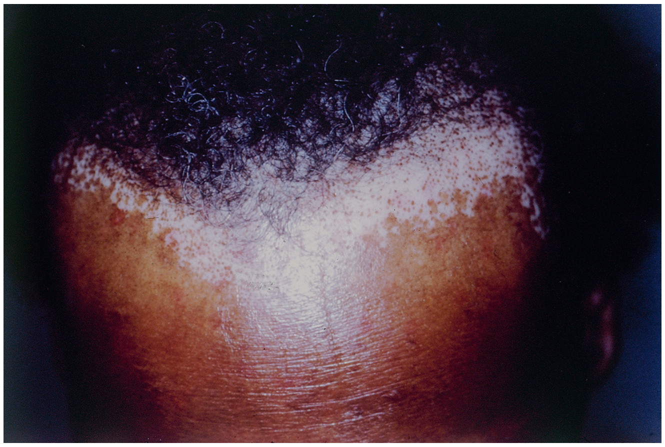

FIG 55.4 Pigmentation Changes in the Skin. Vitiligo (salt-and-pepper) appearance of the involved skin in a patient of African descent with diffuse cutaneous systemic sclerosis.

Soft tissue swelling, intense pruritus and burning, and nonpitting edema are signs of the early inflammatory or "edematous" phase of the diffuse cutaneous form of the disease. The skin of the fingers, hands, distal limbs, and face are usually affected first and more severely compared with other body areas (Fig. 55.3). Carpal tunnel syndrome can be present as a consequence of soft tissue inflammation around hands and wrists. Patients may note skin hyperpigmentation (patches or generalized tanning). Other early skin changes include vitiligo-like hypopigmentation ("salt and pepper" appearance), often on the chest or the back (Fig. 55.4). Escalating musculoskeletal symptoms are common and are associated with muscle weakness and decreased joint mobility. Significant finger and hand/wrist disease limits the patient from doing simple chores or performing self-care.

The early edematous phase of dcSSc has prominent inflammatory features, with significant skin edema and erythema, and is associated with inflammatory cell infiltration in the dermis. After a period of weeks to months, the inflammatory phase evolves into the "fibrotic" phase as increased collagen and extracellular material is deposited in skin, causing thickening and loss of flexibility. The fibrotic process starts in the dermis and is associated with loss of body hair, reduced production of skin oils, and a decline in sweating capacity as these cutaneous structures atrophy. Gradually, the subcutaneous tissue becomes affected, with atrophy of subcutaneous fat and fibrosis extending to the underlying fascia, muscle, and other soft tissue structures. During the fibrotic phase, patients note pain, progressive loss of flexibility, distressing disfigurement, and profound weight loss. Progressive flexion contractures of the finger joints ensue. Other joints, including wrist, elbow, shoulder, hip girdle, knees, and ankle, can also be affected as a result of fibrosis of the supporting joint structures (see Fig. 55.3). Thick ridges at the neck caused by firm adherence of skin to the underlying platysma muscle interfere with neck extension. Tendon friction rub is a prominent crepitation that can be felt or even heard over tendons of the lower and upper extremities. Tendon friction rubs are caused by fibrosis in the tissues surrounding the affected joints; they are associated with rapidly progressive skin disease and are linked to an overall poor prognosis. Fibrosis of the skin of the face yields a characteristic facial appearance with diminished oral aperture, loss of facial expression, vertical lines around the lips, loss of lip thickness, and protrusion of teeth.

The natural history of skin disease in dcSSc tends to be monophasic, and relapse is uncommon after the edematous and active fibrotic phase. The duration of active skin disease from the first signs of skin involvement to its maximal extent is characteristically less than 3 years; cutaneous inflammation and progressive fibrosis gradually subside, and regression of skin involvement begins. However, this time frame is highly variable from one patient to another, with many patients demonstrating rapid skin regression and others showing chronically active disease over years. In the late stages of dcSSc, skin remodeling can be dramatic, with return to normal-appearing skin in those areas spared from severe end-stage fibrosis. In more severely affected areas, the skin becomes thin or atrophic and can be bound down to underlying structures. Skin ulcerations or dystrophic calcification often complicate the fibrotic, atrophic, and avascular skin (Fig. 55.5).

Although the skin involvement is generally the most dramatic and visible manifestation of dcSSc, internal organ involvement occurs during the early active stage of advancing skin disease. Patients with dcSSc have a significant risk for interstitial lung disease, severe GI dysfunction, SRC, progressive heart disease, and recurrent digital ulcers during the initial active inflammatory and fibrotic phases of the skin disease. In practical terms, this means that in dcSSc, the initial 3–4 years is the period that the systemic process is most active; if organ failure does not occur during this period, the systemic process may stabilize without further progression.

Limited Cutaneous SSc

The disease course in the limited cutaneous variant of SSc is more indolent and often relatively benign. After the onset of Raynaud phenomenon, several years may pass before additional symptoms or signs are recognized. The most common non-Raynaud symptoms in patients with lcSSc are those of upper GI disease with dysphagia and gastroesophageal reflux. Dilated capillaries form visible erythematous vascular lesions (telangiectasia), seen most commonly on the fingertips, nailfold areas of the digits, palms, face, lips, and inside the oral cavity (Fig. 55.6). CREST (subcutaneous *c*alcinosis, *R*aynaud phenomenon, *e*sophageal dysfunction, *s*clerodactyly, and *t*elangiectasia) syndrome is a subtype of lcSSc, with distinctive features, an overall good prognosis, and an association with the presence of anti-centromere antibodies. Subcutaneous calcinosis caused by deposition of calcium hydroxyapatite crystals occurs commonly at sites of tissue ischemia and recurrent trauma, such as the fingertips, forearm, or elbow.

Although significant internal organ disease occurs with lower frequency in patients with lcSSc, isolated pulmonary arterial hypertension (PAH) develops in 10–15% of patients and may be life-threatening.[14] Significant interstitial lung disease can occur in about 20% of patients with lcSSc. Severe Raynaud phenomenon with macrovascular occlusive involvement occurs more frequently in lcSSc than in dcSSc and can be associated with critical digital ischemia, ischemic ulcerations, gangrene, and amputation. Overlap with other autoimmune syndromes, including the sicca complex, polyarthritis, cutaneous vasculitis, and autoimmune liver disease, such as biliary cirrhosis, is seen primarily in the lcSSc subset of SSc.

Raynaud Phenomenon

The skin has a unique vascular architecture that is designed to maintain a stable central body temperature. This system has superficial and deep vascular plexuses that allow shunting of

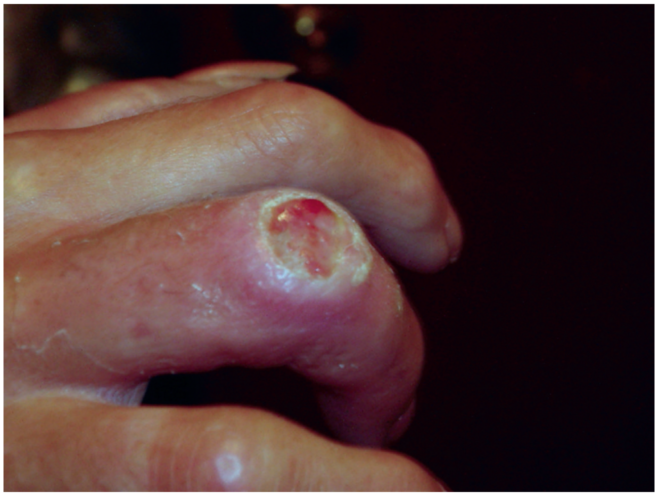

FIG 55.5 Traumatic Digital Ulcer. Ulceration of atrophic skin over the metacarpal joint of patient with diffuse scleroderma.

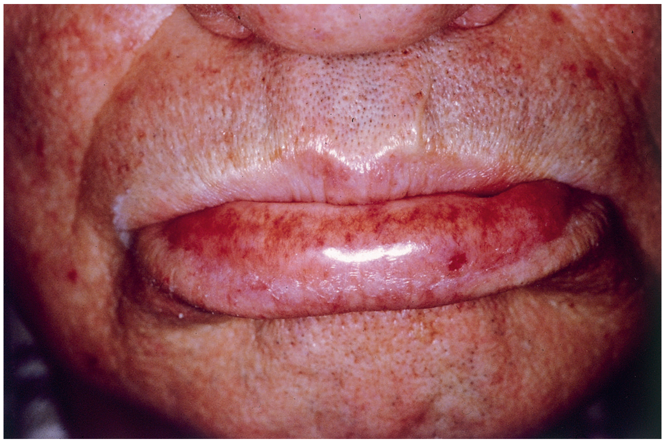

FIG 55.6 Telangiectasia. Characteristic telangiectasia on the lip in a woman with limited cutaneous systemic sclerosis.

blood away from the skin surface during cold exposure and increases surface blood flow during hot ambient temperatures. Arteriovenous anastomoses (AVAs) connecting arterioles and venules allow blood to bypass capillaries, thus allowing rapid and marked increases in cutaneous blood flow. Increased activity of the sympathetic nervous system via both the CNS (body chilling) and the peripheral nervous system (local cooling of skin) initiates vasoconstriction and heat conservation. Selective responses to cold by AVAs allow preservation of nutritional blood flow through skin capillaries. Raynaud phenomenon–associated increase in vascular tone results, in part, from a defect in the vascular response to normal sympathetic signals. Studies find that α_2 adrenergic receptors on the smooth muscle cells of cutaneous vessels mediate vasoconstriction in AVAs during a response to cold temperature. This response to sympathetic input is abnormally increased in patients with Raynaud phenomenon.[15]

Raynaud phenomenon is clinically defined as well-demarcated color changes of the digits induced by cold or emotional stress. Vascular constriction of AVSs, arterioles, and small arteries in the skin and tissues of the digits causes the pallor of the digits, the phase of complete loss of blood flow. The initial vasospasm and pallor is followed by cyanosis of the skin caused by venous pooling and low flow with deoxygenated blood. Finally, after rewarming, the recovery phase occurs with vasodilation manifested by hyperemia with blushed reddened skin as blood flow rebounds. Raynaud phenomenon affects as much as 3–5% of the general population. Raynaud phenomenon is considered to be primary when there is no other associated disease state. In these cases, it is thought to represent a genetic trait with cold sensitivity as a result of abnormal cutaneous vessel reactivity to environmental temperatures. In SSc, the disease process targets the peripheral vasculature, including AVAs or thermoregulatory blood vessels. This leads to not only the abnormal reactivity to ambient temperatures typical of Raynaud phenomenon but also significant structural disease of blood vessels, which causes tissue ischemia as a result of compromise to blood flow within capillaries or nutritional vessels. As a consequence of both an exaggerated response to cold and structural vascular disease, patients with SSc have severe Raynaud phenomenon with multiple, and often prolonged, daily episodes. The severe vascular disease can lead to critical ischemia with digital ulcerations or deep tissue infarction and gangrene. The vascular disease in SSc is not limited to skin but is systemic. There is evidence that abnormal vascular reactivity resulting in tissue injury occurs in the pulmonary, renal, GI, and coronary circulations.

Treatment of Raynaud phenomenon must be individualized and adjusted according to its severity. Initial therapy should include avoidance of cold exposure and use of methods of stress reduction. The best studied medications to treat Raynaud phenomenon are the calcium channel blockers (*e.g.*, nifedipine), which remain the recommended first choice of therapy. Other vasoactive drugs reported to be helpful include the phosphodiesterase inhibitors, such as sildenafil; serotonin reuptake inhibitors, such as fluoxetine; nitrates, such as topical nitroglycerine; and intravenous prostaglandins.[16] Bosentan, an endothelin-1 receptor inhibitor, was recently shown to reduce the incidence of new digital ulcers in patients with SSc but not to alter the frequency of Raynaud events.[17] Statins may also protect peripheral blood vessels and prevent ischemic digital ulcers, and antioxidants have the potential to reduce oxidative stress to tissues. Botulinum toxin injected locally at the base of the fingers is reported to be helpful, but a controlled clinical trial is needed to define its role. Digital sympathectomy is used when medical therapy has failed to reverse critical digital ischemia. In a few cases, macrovascular occlusive disease (particularly in the ulnar artery) can be surgically bypassed to improve distal blood flow.

Gastrointestinal Involvement

GI disease is a major cause of morbidity and mortality and accounts for one of the most frequent initial symptoms of scleroderma. Every part of the GI tract can be involved, including the oral pharynx, esophagus, stomach, and the small and large bowels. A reduced oral aperture (microstomia) is not only cosmetically unpleasant, but it also impairs daily hygiene and normal mastication. Periodontal disease is a consequence of several factors, including decrease salvia, difficulty in dental care, GI efflux disease, gum recession, and bone resorption. Caries and tooth loss can result. Initial symptoms are difficulty chewing and difficulty swallowing dry or a larger bolus of food.

Almost all patients with SSc demonstrate evidence of distal esophageal dysfunction. Clinically, this presents with dysphagia, heartburn, and regurgitation typical of gastroesophageal reflux disease (GERD). These symptoms are caused by peristaltic dysfunction of the distal esophagus, decreased lower esophageal sphincter (LES) pressure, and delayed gastric emptying, which is thought to be secondary to autonomic dysfunction. Pathological studies of the esophagus show that the smooth muscle (circular greater than longitudinal) of the bowel atrophies without significant fibrosis, vascular injury, or obvious inflammation.[18] Functional and pharmacological studies have shown that a neurogenic process precedes smooth muscle dysfunction. Autoantibodies directed against enteric neurons and antimuscarinic antibodies are found, suggesting that an immune process is involved in the pathogenesis of bowel dysmotility. Esophageal manometric evaluation reveals the characteristic triad of low or absent primary and secondary peristaltic activity in the distal esophagus, normal proximal esophageal (striated muscle) motility, and the loss of the LES tone. Complications include reflux esophagitis, esophageal strictures, mucosal erosions, and bleeding; Barrett metaplasia or, very rarely, adenocarcinoma may also develop.

Early satiety, bloating, nausea, periodic vomiting, and decreased appetite with weight loss are seen secondary to poor gastric emptying and retention of food and liquids in the stomach. Gastroparesis is commonly associated with esophageal dysfunction and aggravates GERD. Dilatation of mucosal capillaries in the GI tract is common, particularly in the gastric antrum. Gastric antral vascular ectasia (GAVE), also known as "watermelon stomach," is the major gastric manifestation, which may lead to occult bleeding and significant anemia. Intestinal dysmotility can involve the small and large bowels. Patients may note a change in bowel habits or present with episodes of pseudoobstruction with severe abdominal pain, bloating, abdominal distension, and vomiting. Persistent diarrhea may be a manifestation of malabsorption of fats as a result of bacterial overgrowth in the atonic small bowel and can be associated with dramatic weight loss and malnutrition. In the late stages, the bowel wall thins out and traps air (pneumatosis cystoides intestinalis). Wide-mouth diverticuli develop in the colon or the bowel and may rupture. Incontinence of stool can occur as a result of dysfunction of anal sphincters.

Pulmonary Involvement

Lung disease is now the leading cause of death in patients with SSc and accounts for significant lifetime morbidity. Lung involvement is often asymptomatic and nonprogressive, yet significant lung abnormalities can be detected in over 40% of patients with sensitive lung function testing or special imaging. In a subgroup of patients (10–20%), the disease process can lead to major pulmonary vascular disease or inflammation with progressive fibrosis and subsequent respiratory failure and death. A recent survey reported that 35% of all SSc-related deaths were directly attributable to pulmonary fibrosis or interstitial lung disease (ILD), and 26% of deaths resulted from PAH.[19] Additional pulmonary manifestations of SSc include aspiration pneumonitis, pulmonary hemorrhage, bronchiectasis, bronchiolitis obliterans with organizing pneumonia, pleural reactions, and pneumothorax. The risk of lung cancer is increased in patients with SSc.

Interstitial Lung Disease

Nonspecific interstitial pneumonia (NSIP) is the most common histopathological pattern in patients with SSc-related ILD (SSc-ILD). The prevalence of SSc-ILD is found in 50% of those with dcSSc compared with 35% in those with lcSSc. The presence of topoisomerase-I autoantibodies is strongly linked to the development of ILD, and the worst outcome is often seen in African Americans and Native Americans. Inflammatory alveolitis and subsequent tissue fibrosis causes restrictive ventilatory defect and an abnormal gas exchange. Patients with ILD usually experience rapid initial decline in lung function during the early period of active disease. About 20% of patients who eventually developed severe ILD (FVC ≤50%) have a fall in forced vital capacity (FVC) within 4 years of the onset of symptoms. If there is only minor impairment in FVC on lung function after more than 5 years of disease duration, then is it unlikely that the patient will ever develop severe lung fibrosis. In early disease, most patients have no respiratory symptoms. The most sensitive methods to detect early lung disease are pulmonary function testing and imaging with high-resolution computed tomography (HRCT). The presence of fibrosis and ground-glass opacities on HRCT is an indication of the activity of the disease process and correlates with subsequent decline in FVC. When the extent of disease defined by HRCT is <20%, the 10-year survival is reported to be 67%, whereas in the group with HRCT-defined disease extent of >20%, 10-year survival is considerably poorer at 43%.[20] Likewise, FVC of <70% is associated with a poor prognosis. Biological biomarkers that can detect active alveolitis and predict disease progression are needed. The presence of neutrophilia in fluid obtained from bronchoalveolar lavage (BAL) was thought to predict outcome, but neutrophilia does not clearly define prognosis or response to therapy. Both Krebs von den Lungen-6 (KL-6), a lung glycoprotein, and surfactant protein-D (SP-D) levels are elevated in patients with SSc compared with controls and higher in patients with alveolitis compared with those without alveolitis; thus SP-D levels are thought to be useful biomarkers of disease progression. Two multicenter clinical trials have been completed; one compared cyclophosphamide to placebo, and the other compared cyclophosphamide to mycophenolate.[21,22] Both studies demonstrated statistically significant stabilization or improvement of lung function along with improvement in scleroderma skin score and a variety of clinical measures. These studies suggest that immunosuppressive therapy can control active lung disease. A variety of other agents are now being tested in SSc-ILD, including rituximab (monoclonal antibody [mAb] to CD20 on B lymphocytes), pirfenidone (an antifibrotic/antiinflammatory agent used in idiopathic pulmonary fibrosis), and nintedanib (a tyrosine kinase inhibitor).[23,24]

Pulmonary Arterial Hypertension

PAH is detected in 8–15% of patients with SSc and may occur as the sole pulmonary manifestation of the disease or in association with ILD.[25] The natural history of PAH is highly variable. In many patients, it is clinically silent for years before it presents with exertional dyspnea and hypoxia secondary to altered gas exchange and right heart failure. It is most often a late (9–12 years after onset of Raynaud phenomenon [RP]) complication in patients with limited scleroderma; but PAH can occur within 5 years from the disease onset, particularly in patients older at the time of SSc diagnosis. Risk factors for PAH in SSc include disease onset at a later age, history of severe RP, numerous skin telangiectasias, abnormal nailfold capillaries, the presence of anticentromere, anti-U1 ribonucleoprotein (RNP), anti–U3 RNP (fibrillarin), or anti-B23 antibodies. Untreated, the estimated 3-year survival is approximately 50%. Although responses to current therapy are not as good among patients with SSc and PAH compared with patients with idiopathic PAH, there is evidence of improved survival on modern therapy compared with historical controls. Prognosis is poor among patients with PAH associated with ILD, and an even worse prognosis is associated with increased blood brain natriuretic protein (BNP), echocardiographic signs of right heart disease, and decreased diffusion capacity of the lungs for carbon monoxide (DLCO) on lung testing. PH can occur in SSc in the absence of PAH as a result of left heart disease or secondary to chronic hypoxia from severe ILD. Therefore patients need to undergo a right heart cauterization to confirm the presence of PAH or PH and characterize its severity. Current therapy for SSc-associated PAH is focused on supportive care, reduction of cardiac work load, and vasoactive drugs.[26] Short-acting prostacyclin analogues, including intravenous (epoprostenol or treprostinil) or inhaled (iloprost) prostaglandins, are used for treating severe disease. Selective and nonselective endothelin-1 receptor inhibitors (bosentan, ambrisentan, and macitentan), a phosphodiesterase type 5 inhibitor (sildenafil, tadalafil, and vardenafil), and a soluble guanylate–cyclase stimulator (riociguat) are helpful for treating milder disease. Early intervention and combination therapy may help achieve improved outcomes. In relatively short-term clinical trials, each of these treatments has been shown to improve exercise tolerance and hemodynamics, with variable benefit on disease progression. Early detection of PAH is important as it provides an opportunity for timely intervention. A systematic detection program in which periodic screening was performed in every patient with SSc detected less severe pulmonary vascular disease and showed better survival on therapy compared with that in patients managed by usual clinical practice.[27] Because of the complexity of life-threatening PAH, it is recommended that patients be referred to experts in pulmonary medicine, especially in PAH, to manage these cases. Lung transplantation remains an option for carefully selected patients with SSc, with survival following lung transplantation being similar to that of non-SSc patients with other lung diseases.

Cardiac Involvement

Cardiac involvement is common, but often there are no signs or symptoms until the heart has been severely affected. The reported prevalence of heart disease varies, depending on method of detection. Clinical criteria are insensitive, but modern sensitive tools, such as echocardiography, tissue Doppler imaging, speckle-tracking echocardiography, cardiac magnetic resonance imaging, or thallium scanning, can detect disease early and suggest that 40–60% of patients have heart disease. When heart disease is symptomatic, the prognosis is poor. SSc can affect virtually any cardiac structure, including the myocardium with fibrosis or inflammatory myocarditis, the myocardial microvasculature, or the pericardium with asymptomatic small effusions or large effusions leading to cardiac tamponade. As a consequence of cardiac tissue injury, left ventricular (LV) systolic dysfunction and/or LV diastolic dysfunction and/or right ventricular (RV) failure and/or conduction abnormalities with complex arrhythmias can occur, but valvular heart disease is unusual. Cardiac dysfunction can be primary to the disease process or secondary to other organ diseases, including PAH, ILD, or SRC. Cardiac disease occurs in both the limited and the diffuse subtypes but is more common in the patients with rapidly progressive diffuse skin disease, in those with anti-U3 RNP antibodies, and in association with peripheral muscle disease.[28] Heart disease is reported to be a cause of death in 20–30% of patients and is an independent risk factor for death. Optimal screening for heart disease is not well defined, but periodic clinical assessment coupled with echocardiography and blood levels of BNP is recommended. Modern techniques for detecting occult heart disease provide opportunities for early intervention and should be used for thorough evaluation of the patient when cardiac involvement is suspected. The ideal therapy is defined by the underlying situation (*e.g.,* vasodilator therapy to improve heart perfusion or antiarrhythmia therapy for a complex arrhythmia). A disease-modifying drug that specifically targets scleroderma heart disease has not yet been discovered.

Renal Involvement

Renal disease is an important clinical problem with both direct involvement and kidney compromise secondary to other organ dysfunction. The most dreaded renal complication is an SRC, which is defined as the new onset of accelerated arterial hypertension and/or rapidly progressive oliguric renal failure during the course of the disease. It is recognized that other causes of renal disease, including interstitial nephritis, glomerulonephritis, and antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis, can occur. SRC develops in 10–15% of patients with dcSSc, but in less than 5% of patients with lcSSc. It is generally a relatively early (<3–4 years) complication of the disease and is more likely to occur in males.[29] The presence of rapid progression of diffuse skin disease; tendon friction rubs; cardiac disease with clinically silent pericardial effusion, arrhythmias, or congestive heart failure; new unexplained anemia; or the use of corticosteroids are all associated with an increased risk of SRC. The autoantibody status is also helpful in identifying patients at risk for SRC. In approximately 30% of patients with anti-RNA polymerase III, seen almost exclusively in dcSSc, SRC develops; however, SRC occurs in only 10% of patients with antitopoisomerase antibodies and only rarely in patients with anticentromere antibody. SRC characteristically presents as sudden onset of malignant hypertension with rapidly progressive oliguric renal failure. Proteinuria, microhematuria, and evidence of a microangiopathic hemolytic process with thrombocytopenia are present. The exact mechanism triggering acute SRC is not known, but an autoimmune insult to the underlying SSc microvascular disease is thought to initiate a self-perpetuating process, which leads to glomerular hypoperfusion and a high renin state.

Patients with SRC who present with a creatinine >3 mg/dL have a poor outcome, with increased likelihood of permanent hemodialysis, need for renal transplantation, and/or high mortality. Prompt and aggressive intervention with angiotensin-converting enzyme (ACE) inhibitors to achieve blood pressure control before evidence of renal dysfunction is seen significantly improves the prognosis. Introduction of ACE inhibitors dramatically improved survival from a 1-year survival rate of 10% to a 5-year survival rate of 60%. All patients with SRC should be treated with an ACE inhibitor, but other vasodilators, including calcium channel blockers, endothelin receptor inhibitors, and prostaglandins, can be helpful. About 45% of patients whose blood pressure is normalized do not require dialysis. Reasonable kidney function can resume months after renal failure and the need for dialysis support. Despite ideal therapy, approximately 40% of patients still need long-term kidney support or have a poor survival. Overall survival on chronic dialysis is worse in patients with SSc compared with those without SSc, but renal transplantation is still an option with a long-term outcome similar to that of other causes of renal failure.

CLINICAL PEARLS

Recommended Approach to Systemic Sclerosis

- Determine scleroderma skin score to define clinical subtype
- Frequent clinical reassessment to define disease activity
- Careful clinical history to evaluate for gastrointestinal dysmotility
- Monitor for new onset hypertension: prevent renal crisis
- Pulmonary function test: early detection of interstitial lung disease
- Doppler echocardiography: screen for pulmonary arterial hypertension
- Obtain serology profile to help predict clinical outcome

Musculoskeletal Complications

Musculoskeletal impairment is a leading cause of disability and poor quality of life among patients with SSc. It is seen in the majority of patients, occurs early in the disease, and commonly has a dominant effect on hand function. There is a variety of associated clinical symptoms, including arthralgias, myalgias, stiffness, pain and loss of function as a result of joint contractures, inflammatory arthritis, myopathy, nerve entrapment (*e.g.,* carpal tunnel syndrome), fibrosis of tendons, and deconditioning from disuse. Loss of joint function is less likely to be secondary to synovitis but is usually caused by fibrosis of the overlying skin, the supporting joint structures, and the joint capsule itself. Flexion contractures associated with "friction rubs" most prominently felt over the ankles, knees, shoulders, and wrist are typical of advanced dcSSc. Muscle weakness is a common comorbid condition caused by deconditioning, muscle disuse, or malnutrition associated with weight loss. A scleroderma-related myopathy defined by weakness with elevated serum creatine kinase (CK) level; myopathic features on electromyography (EMG); and/or muscle biopsy is reported to occur in about 20% of patients. Most patients with skeletal myopathy have proximal muscle weakness on examination, and about 40% have one of the scleroderma/myopathy–associated autoantibodies (*i.e.,* anti-PM/Scl-75, anti-PM/Scl-100, or anti-CD1). The histopathological findings are highly variable, with fibrosis alone seen only in a small subset. When inflammation and/or necrosis are seen, immunosuppressive therapy has the potential to control the muscle disease.

Emotional Aspects

SSc impacts every aspect of a patient's life and is a disfiguring disease; therefore, it is not surprising that significant depression is common among patients with SSc.[30] Patients are frequently distressed by their appearance and avoid social interaction. Chronic pain and lack of social support are major causes of depression; therefore, family education, emotional support, pain control, and management of depressive symptoms are most important.

Treatment

THERAPEUTIC PRINCIPLES

Treatment of Systemic Sclerosis

Organ-Specific Therapy

- Vasodilator therapy for Raynaud phenomenon
- Proton pump inhibitor for gastroesophageal reflux
- Angiotensin-converting enzyme (ACE) inhibitor for scleroderma renal crisis
- Vasodilator therapy for pulmonary arterial hypertension
- Antiinflammatory therapy for arthritis
- Immunosuppressive therapy for interstitial lung disease

Disease-Modifying Agents

- No ideal treatment available; immunomodulatory, antiinflammatory, vasoactive, and antifibrotic agents are used and/or under study.

To date, no drug or intervention has been proven to be effective and safe for modifying the overall disease course. Most successful SSc treatments are directed to the specific organ(s) involved. Therapy is focused on an organ-specific disease process (*e.g.*, ACE inhibitor in SRC) or to aid a failing organ (*e.g.*, proton pump inhibitors for GERD). Therefore it is important to carefully characterize the patient's clinical phenotype, specific organ involvement, and level of disease activity before deciding on therapy. For example, a patient who has lcSSc but no evidence of visceral organ involvement is likely to have a benign course that requires only symptomatic therapy (*e.g.*, treatment of GERD and RP); use of systemic disease-modifying drugs would not be indicated. It is also important to distinguish disease activity from severity or advanced cumulative organ damage. For example, a patient with late-stage dcSSc with irreversible organ damage is unlikely to benefit from aggressive immunosuppressive or antiinflammatory therapy. Intervention with currently available drugs should be initiated early, ideally during the edematous active inflammatory phase of the disease. It is during the early stage of the disease that immunosuppression and antiinflammatory and antifibrotic agents have the greatest potential to control disease progression. Clinical experience teaches that once the edematous phase of the disease shifts to the more indolent fibrotic phase, current treatments are less likely to control the progression of disease and tissue damage. The primary outcome measure in clinical trials that focused on aggressive skin disease has been the modified Rodnan skin score; in current studies, however, composite scores that tally the burden of disease (activity and severity) as well as patient reported distress are included. Few well-designed controlled studies have been carried out for the treatment of early active disease; most reports are of anecdotal, uncontrolled experiences, complicated by investigator bias and the highly variable natural course of SSc.

Evidence-based management of SSc is helpful[31] while innovative therapies are being further studied in clinical trials.[32] Scleroderma is a multifaceted disease that includes active autoimmunity, vascular injury, and fibrosis and/or epithelial damage. Thus the major targets for therapy include regulating the immune system, controlling tissue fibrosis, and protection or prevention of progressive vascular disease. The majority of therapeutic interventions for scleroderma attempt to modify the disease process by immunomodulation in *early active* dcSSc because of the evidence that the SSc is an autoimmune disease initiated and/or propagated by an immune process. Drugs currently used for dcSSc include methotrexate, cyclophosphamide, and mycophenolate mofetil. Targeting specific immune cells is now a novel strategy that includes eliminating B cells with rituximab and suppressing activation of T cells with abatacept. In cases of severe life-threatening disease in highly selected cases not responding to low-dose immunosuppression, immunoablative therapy with high-dose cyclophosphamide alone or with radiation, followed by stem cell rescue, may be considered. Studies to evaluate the safety and efficacy of stem cell therapies are in progress.[33] Inhibiting proinflammatory and/or profibrotic cytokines or signaling pathways that may block tissue injury and fibrosis are being explored. These include antichemokines (CCR2) or inhibitors of CTGFs, recombinant humanized mAb to block TGF-β1 activity, modulation of interleukin-6 (IL-6) signaling, antagonists of the bioactive phospholipid LPA, and small-molecule inhibitors, such as tyrosine kinase inhibitors or pirfenidone. It is recognized that vascular disease also plays a fundamental role in the morbidity and mortality seen in scleroderma. Novel drugs targeting vascular disease, including endothelin receptor antagonists, agents that enhance nitric oxide production, prostacyclin analogs, antiplatelet agents, and statins, are currently being used.

ON THE HORIZON

Novel Therapeutic Approaches to Systemic Sclerosis (SSc) Management in Clinical Trials

- Targeted therapies to block transforming growth factor-β (TGF-β)
- Development of antifibrotic agents, including new approaches to blocking of fibrogenic pathways
- Use of biological agents, including anticytokines, antichemokines, and growth factor inhibitors

Other Fibrosing Diseases

Several disorders can cause skin fibrosis and mimic SSc.[34] SSc can be distinguished from these SSc-like fibrosing conditions by its characteristic clinical, pathological, and laboratory features. The most distinguishing clinical features of SSc include the presence of RP, nailfold capillary changes, the characteristic distribution, and characteristic skin changes. The skin pattern in SSc is noted for severe finger, hand, and distal limb involvement and sparing of the skin of the back of the trunk. SSc-specific serum autoantibodies also help define the presence of the SSc disease process.

Conditions that mimic SSC include localized forms of scleroderma (see Table 55.5), eosinophilic fasciitis, nephrogenic systemic fibrosis, scleromyxedema (papular mucinosis), scleredema, graft-versus-host disease (GvHD), toxic oil syndrome, and eosinophilia–myalgia syndrome (Table 55.6). Eosinophilic fasciitis presents with induration of subcutaneous tissues, particularly in the proximal limbs, without RP or systemic organ involvement. A peripheral eosinophilia with radiological and

TABLE 55.6 Differential Diagnosis of Systemic Sclerosis (SSc) and Scleroderma

Disorders Characterized by Similar Presentations

- Systemic lupus erythematosus
- Sjögren syndrome
- Rheumatoid arthritis
- Polymyositis/dermatomyositis
- Primary Raynaud phenomenon

Disorders Characterized by Similar Visceral Features

- Primary pulmonary hypertension
- Primary biliary cirrhosis
- Idiopathic intestinal hypomotility
- Idiopathic pulmonary fibrosis
- Malignant hypertension

Disorders Characterized by Skin Thickening

- Scleromyxedema
- Scleredema (of Buschke), diabetic scleredema
- Nephrogenic fibrosing dermatopathy
- Eosinophilic fasciitis/diffuse fasciitis with eosinophilia
- Eosinophilia–myalgia syndrome
- Generalized morphea
- Chronic graft versus host disease
- POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes)
- Amyloidosis
- Carcinoid syndrome
- Pentazocine-induced scleroderma
- Diabetic digital sclerosis
- Vinyl chloride disease
- Toxic oil syndrome
- Bleomycin exposure
- Werner syndrome
- Phenylketonuria
- Porphyria cutanea tarda
- Vibration white finger syndrome
- Chronic reflex sympathetic dystrophy

histological evidence of an inflammatory process in the fasciae is present. Nephrogenic systemic fibrosis is described in patients with end-stage renal disease who were exposed to gadolinium-based contrast agents.[35] Scleromyxedema, a condition of mucinous deposition in skin, is associated with the presence of monoclonal gammopathy that is characterized by a diffuse, papular skin eruption. Scleredema occurs with deposition of collagen and mucin in the dermis and primarily involves the upper back, neck, and face. It occurs in association with diabetes, a monoclonal gammopathy, or postinfection pharyngitis, particularly streptococcal pharyngitis. GvHD occurs after bone marrow or stem cell transplantation and is characterized by patchy areas of inflammatory and thickened skin with liver and GI involvement. Toxin exposure was linked to the toxic oil syndrome (adulterated rapeseed oil) and eosinophilia–myalgia syndrome (related to the presence of an impurity in the production process for L-tryptophan, a sleep aid). These syndromes have largely subsided by banning the agents involved, but sporadic cases of eosinophilia–myalgia syndrome continue to occur.[36]

MULTIPLE-CHOICE QUESTIONS

1. Which of the following complications is MOST frequent in systemic sclerosis (SSc)?
   A. Glomerulonephritis
   B. Scleritis
   C. Renal crisis
   D. Tendon rupture
   E. Pulmonary arterial hypertension

2. Characteristic thoracic involvement in SSc include all of the following EXCEPT:
   A. Pulmonary fibrosis
   B. Apical nodules
   C. Peripheral reticulations
   D. Enlarged pulmonary artery
   E. Patulous esophagus

3. Which of the scleroderma related autoantibodies are associated with the highest risk for developing a scleroderma renal crisis (SRC)?
   A. Anticentromere
   B. Antitopoisomerase
   C. Anti-RNA polymerase III
   D. Anti-U1 ribonucleoprotein (RNP)
   E. Anti-U3 RNP
   F. Anti-U11/U12 RNP

4. What is the major cause of mortality in scleroderma in the modern era?
   A. Scleroderma renal crisis
   B. Severe skin disease
   C. Scleroderma lung disease
   D. Gastrointestinal failure
   E. Complications of medications

Inflammatory Muscle Diseases

Arash H. Lahouti, Lisa Christopher-Stine

The idiopathic inflammatory myopathies (IIMs) are a group of rare systemic diseases. They consist of polymyositis (PM), dermatomyositis (DM), inclusion body myositis (IBM), and more recently described immune-mediated necrotizing myopathy (IMNM). Traditionally, they are believed to be autoimmune diseases, although recent studies suggest that there is a close resemblance between IBM and other neurodegenerative diseases. Similar to patients with other autoimmune diseases, those with IIM often have serum autoantibodies. Some of these antibodies are specific for myositis and are not seen in other rheumatic disorders. Our knowledge of the myositis-specific antibodies (MSAs) is incomplete. There has been considerable effort to better characterize antibodies associated with myositis and to discover new antibodies. Many MSAs are closely linked to a unique clinical phenotype. Thus they are useful in classifying the IIM. They can forewarn of particular extramuscular manifestations and guide appropriate treatment strategies.

IIM patients present with muscle weakness and elevated muscle enzymes. In patients with DM, skin manifestations may be the initial presentation. The differential diagnosis of muscle disease is broad and includes drug-induced myopathies, neuromuscular disorders, muscular dystrophies, and metabolic and endocrine myopathies. To add to the complexity, some DM patients do not develop muscle weakness, referred to as clinically amyopathic DM. The patient's age and gender, the pattern of the weakness, the severity of manifestations, and associated symptoms are commonly helpful in leading to the correct diagnosis. For example, IBM is distinguished from other IIMs by a characteristic involvement of the finger flexor and knee extensor muscles, which is often asymmetrical. IBM is more common in older men, whereas PM and DM are commonly seen in young to middle-aged women and children. DM is often associated with characteristic skin findings, which are not a feature of PM and IBM. However, in many patients differentiation between the IIMs cannot be made on clinical grounds, and further diagnostic testing is required. For example, both PM and IMNM present in the same fashion with a predominantly symmetrical proximal muscle weakness and elevated muscle enzymes. They can be distinguished only by pathological examination. On muscle biopsy, IMNM is associated with necrosis and regeneration of muscle fibers and a characteristic sparse inflammatory infiltrate. In contrast, PM is associated with the presence of cytotoxic inflammatory cells surrounding and invading muscle fibers. Electromyography is a valuable tool for differentiating between weakness originating from muscle rather than peripheral nerves. Magnetic resonance imaging (MRI) can be extremely helpful in identifying inflammatory changes in patients with subtle clinical muscle involvement. Moreover, MRI can help to better estimate the burden of disease and differentiate acute changes (edema) from chronic changes (atrophy). The role of new imaging modalities such as whole-body MRI needs to be further investigated.

Interstitial lung disease, gastrointestinal involvement, and arthritis are among the most common extramuscular manifestations of the IIM. Interstitial lung disease commonly occurs as part of the antisynthetase syndrome in a subset of patients who have antisynthetase autoantibodies. Gastrointestinal manifestations include dysphagia and aspiration pneumonia. Dysphagia is particularly common and can be seen in all forms of the IIMs. Certain forms of IIM, particularly DM, can be a paraneoplastic phenomenon. The most common cancers associated with myositis include gynecological (ovarian), pulmonary, gastrointestinal (pancreatic, stomach, and colorectal), and non-Hodgkin lymphoma. Also, the IIMs may be associated with other autoimmune diseases such as systemic lupus erythematosus (SLE), Sjögren syndrome, and systemic sclerosis.

Muscle biopsy is critical for the diagnosis of the IIMs. The presence of perifascicular atrophy is strongly suggestive of DM, whereas the finding of rimmed vacuoles in the appropriate context suggests IBM. Muscle biopsy also differentiates between the IIMs and other forms of myopathy such as drug-induced myopathies and muscular dystrophies.

Treatment of the IIMs is based largely on experience. Corticosteroids remain the mainstay of therapy. Steroid-sparing agents such as azathioprine, methotrexate, mycophenolate mofetil, and hydroxychloroquine are frequently initiated at presentation while a steroid taper is attempted. In patients with refractory disease, rituximab, intravenous immunoglobulin, and biological antirheumatic medications may be tried. IBM is the most resistant subset of the IIMs.

DM, PM, IBM, and IMNM constitute the largest subgroup of the acquired myopathies. They are a heterogeneous group and are rare among immunological illnesses. However, the IIMs share many clinical features and laboratory abnormalities, including related autoantibodies, and are closely related to major autoimmune diseases. Because their presentation and major clinical manifestations are weakness and/or rash, the differential diagnosis includes many more common diseases familiar to neurologists and dermatologists.

CLINICAL FEATURES

The clinical hallmark of PM, DM, and IMNM is the gradual onset of symmetrical proximal muscle weakness over weeks to months. In some cases, myalgia may be the presenting or most bothersome symptom, but more often the patient is evaluated for the physical limitations imposed by weakness: difficulty arising from a low chair or bed, or combing and brushing hair. Rash is the first feature in a considerable proportion of patients who have DM, but muscle weakness usually follows within a few months. A subset of patients with DM, clinically amyopathic dermatomyositis (C-ADM), may present only with rash in the absence of muscle weakness throughout the course of their illness. These patients are also at risk for pulmonary involvement, as are those with classic DM. The prevalence of interstitial pneumonitis in C-ADM can approach 5–10%, compared with 40% of patients with classic DM.[1] Arthritis, Raynaud phenomenon, fever, or lung disease presenting as cough or dyspnea may dominate the clinical picture. Cardiac and gastrointestinal symptoms, other than dysphagia in severe cases, are rarely early manifestations. Renal and central nervous system (CNS) involvement are almost never a part of the IIMs.

KEY CONCEPTS

Definition and Incidence of Idiopathic Inflammatory Myopathies (IIMs)

- Polymyositis (PM), dermatomyositis (DM), and related inflammatory muscle diseases are called IIM.
- Indistinguishable muscle inflammation may accompany other autoimmune connective tissue diseases or limb-girdle muscular dystrophies.
- The annual incidence in the US is 5–10 cases per million. DM and PM are more common in women than in men in all age groups; inclusion body myositis (IBM) is more common in men.

Some of the rashes of DM are virtually pathognomonic; others are not disease-specific (Fig. 56.1). The heliotrope rash, a violaceous discoloration of the eyelids, is sometimes no more than a line along the margin of the upper lid, but it may also affect both upper and lower lids completely and can be associated with edema mimicking thyroid disease. A reddish, sometimes raised and/or scaly, eruption over the metacarpophalangeal joints is known as Gottron papules. In some cases, the metatarsophalangeal joints, elbows, knees, and malleoli show a similar rash. Both heliotrope and Gottron rashes can occur rarely in cases of frank SLE without muscle involvement. Other common rashes include a flat, red blanching eruption of the upper chest (often in a V distribution), the upper back (where a shawl would touch), and sometimes the extensor surfaces of the upper arms and thighs. Another rash that mimics the malar rash of lupus on the face may be present; however, in contrast to lupus, it does not spare the nasolabial folds. Although found on sun-exposed parts of the body, these rashes are often not photosensitive in nature. As in other connective tissue diseases, nailfold capillary dilatation, infarcts, and cuticular overgrowth occur. Mechanic's hands, a roughening and cracking of the radial sides of the fingers and the palm, resembling a condition found in people who labor with their hands, is characteristic of a subset of myositis patients with the "antisynthetase syndrome" and can also be seen in patients with PM-Scl and U1-RNP autoantibodies.

CLASSIFICATION

In the past 40 years, several investigators have proposed diagnostic classification criteria for IIM. The criteria proposed by Bohan and Peter four decades ago remain the most familiar and accepted definitions of PM and DM (Table 56.1).[2,3] They combine clinical, laboratory, electrodiagnostic, and pathological features. These criteria currently serve as the gold standard for clinical diagnosis and for inclusion in clinical trials. However, they are limited by their poor specificity in distinguishing PM from other entities, including late-onset muscular dystrophies. The resultant misclassification limits the homogeneity of the patients included in previous observational and interventional studies. Additionally, the Bohan and Peter criteria completely omit the diagnosis of IBM, the most frequent type of IIM in patients over 50 years of age.

In 2004, more comprehensive criteria of IIM were proposed and approved by a group of international experts (Table 56.2). Unlike the previous criteria, these new criteria offer the advantage of classifying two rare forms of autoimmune myositis, *i.e.,* IMNM

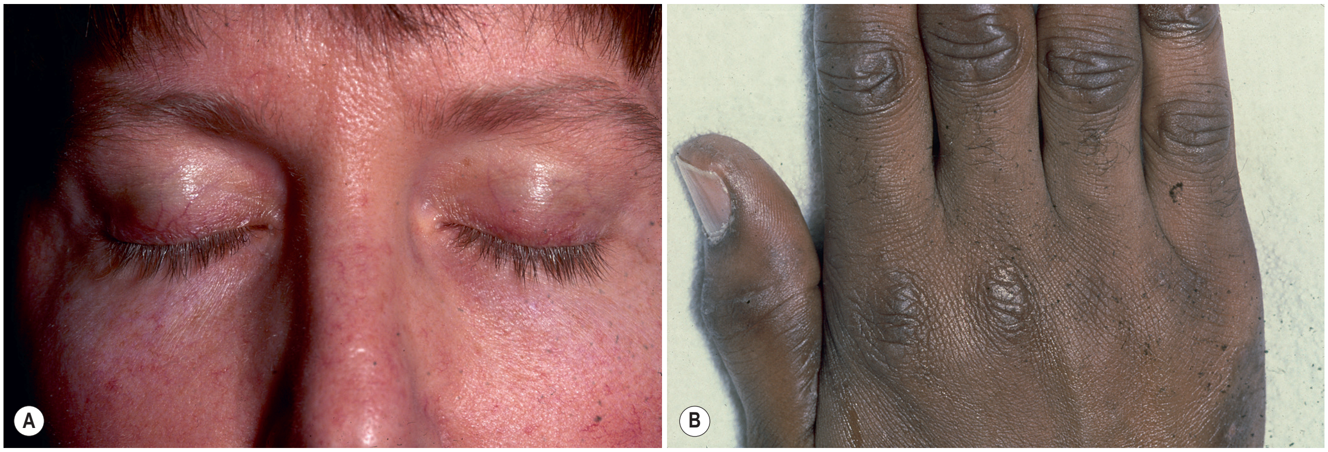

FIG 56.1 Dermatomyositis Rash. (A) In addition to the heliotrope rash on the eyelids of this patient with dermatomyositis, there is a flat, red rash on the nose and cheeks. (B) A raised, shiny-red rash—Gottron papules—is apparent on the interphalangeal and the second and third metacarpophalangeal joints of this man with dermatomyositis.

TABLE 56.1 Idiopathic Inflammatory Myopathy: Diagnostic Criteria

Bohan and Peter Criteria

1. Symmetrical proximal muscle weakness
2. Skeletal muscle enzyme elevation
3. Abnormal EMG[a]
4. Muscle biopsy abnormalities
5. Typical skin rash of DM[b]

[a] Polyphasic, short, small motor-unit potentials; fibrillation, positive sharp waves, increased insertional irritability; bizarre, high-frequency, repetitive discharges.

[b] Gottron sign, heliotrope rash.

Possible PM = any two of the first four criteria; possible DM = criterion 5 (rash) + any two criteria. Probable PM = any three of the first four criteria; probable DM = criterion 5 (rash) + any three criteria. Definite PM = all four of the first four criteria; definite DM = criterion 5 (rash) + all four other criteria.

DM, dermatomyositis; *EMG,* electromyography; *PM,* polymyositis.

and DM *sine* dermatitis, as separate categories (Table 56.2).[4] Separate classification criteria systems for IBM have been devised. According to most of the previous IBM criteria, characteristic muscle biopsy changes were necessary for a definite diagnosis of IBM. However, because selective involvement of finger flexors and knee extensors is almost exclusive to IBM among other forms of myopathy, the newly proposed *ENMC IBM Research Diagnostic Criteria 2011* entails a separate category for clinically defined IBM (Table 56.3).[5]

It has been useful for some purposes to divide cases into groups: PM, DM, juvenile myositis, myositis associated with another connective tissue disease (usually systemic sclerosis, SLE, or Sjögren syndrome), cancer-associated myositis (usually cases in which the diagnoses are made within 6–12 months of one another), IBM, and a miscellaneous group that includes such rare entities as eosinophilic myositis (Table 56.4). This classification has allowed recognition of unique clinical and pathogenetic features and response to therapy. In the case of cancer-associated myositis, a more rational approach to workup based on recognition of groups at risk is now possible.

KEY CONCEPTS

Characteristic Hallmarks of Inflammatory Myositis

- The clinical hallmark is proximal limb and neck weakness, rarely associated with muscle pain.
- The laboratory hallmarks are elevated serum levels of creatine kinase (CK), aldolase, lactic dehydrogenase, and the transaminases; a characteristic pattern ("irritable myopathy") is seen on electromyography (EMG). Elevated serum levels of autoantibodies are common.
- The pathological hallmarks are focal muscle necrosis, degeneration, regeneration, and inflammation.

Several autoantibodies, called "myositis-specific autoantibodies," are unique to myositis. These have allowed a useful alternative classification (Table 56.5). For example, patients with antibodies to the aminoacyl-tRNA (transfer RNA) synthetases, of which Jo-1 is the best known, have a characteristic syndrome called antisynthetase syndrome, which usually includes interstitial lung disease, nondeforming inflammatory arthritis, fevers, mechanic's hands, and Raynaud phenomenon, in addition to myositis. Those with antibodies to the signal recognition particle (anti-SRP) have an IMNM manifested by severe disease of abrupt onset, often in the autumn. According to some studies, cardiac involvement is less common and survival is better in patients with anti-SRP than has previously been reported.[6] Those with antibodies to the nuclear antigen Mi-2 almost always have the V and shawl rashes and cuticular overgrowth in addition to myositis. A recently discovered antibody, anti-3-hydroxy-3-methylglutaryl-coenzyme A reductase (anti-HMGCR), is tightly linked to IMNM.[7,8] Interestingly, the HMGCR is the pharmacological target of statin drugs, such as atorvastatin, and a subset of patients with anti-HMGCR antibodies develop this antibody in the context of previous statin exposure, although it is also seen in statin-naïve individuals, albeit to a lesser extent. Patients with anti-HMGCR antibodies present with profound proximal muscle weakness and a marked creatine kinase (CK) elevation. Further, compared with statin-exposed individuals, statin-naïve anti-HMGCR positive patients tend to be younger, have higher CK levels, and have a blunted response to immunosuppressive medications (Table 56.5).[2,8]

IBM is different from other inflammatory myopathies. Patients with IBM rarely improve in strength with immunosuppressive therapy. They tend to be older, and in contrast to patients with PM and DM, who are predominantly women, patients with IBM are more commonly men. They have gradual, painless, asymmetrical, progressive weakness and focal atrophy that develop over years, and they may complain of frequent falls. Two decades after onset, they are frequently wheelchair-bound. The forearms of these patients exhibit a scalloped appearance, attributed to muscle atrophy. Difficulty with swallowing can occur with any inflammatory myopathy and is frequently a major problem in patients with IBM. The CK and other skeletal muscle–associated serum enzymes are normal in about one-quarter of patients with IBM and only moderately elevated in the remainder. The electromyogram in IBM frequently demonstrates both myogenic and neurogenic features secondary to the effective denervation of some muscle cells by inflammation and necrosis.

Proposed criteria for the diagnosis of IBM rely on both pathological and clinical features. In the clinical setting of an inflammatory myopathy, the presence of the characteristic inclusions or rimmed vacuoles is diagnostic. Among the inflammatory myopathies, IBM is distinguished by substantial numbers of rimmed cytoplasmic vacuoles with tubulofilamentous material within myofibers. A variety of proteins have been found by immunohistochemistry in the muscle cells in IBM, including ubiquitin, β-amyloid precursor protein, and the transcription factor nuclear factor (NF)-κB. Many of the proteins accumulating in the IBM muscle are also involved in other neurodegenerative diseases. For example, aggregation of p62, an autophagy-related protein, has been shown in IBM muscle, in Lewy bodies in Parkinson disease, and in neurofibrillary tangles in Alzheimer disease, suggesting the possibility of a degenerative process in IBM. More recently, an autoantibody to cytosolic 5′-nucleotidase 1a (c5N1A) was discovered. Although this antibody has a good specificity to distinguish IBM against other forms of autoimmune myopathy, it is roughly positive in 60% of IBM patients.[9] In addition, anti-c5N1A can be detected in other connective tissue

TABLE 56.2 Proposed Diagnostic Criteria for Inclusion Body Myositis

The European Neuromuscular Centre (ENMC) criteria for the idiopathic inflammatory myopathies[4]

1. Clinical criteria
   a. Subacute onset
   b. Age >18 years (onset may be in childhood in DM and nonspecific myositis)
   c. Symmetrical proximal weakness
   d. Typical DM rash (including heliotrope, Gottron papules, Gottron sign, V sign, and shawl sign)
   e. Lack of features suggestive of IBM (asymmetry, finger flexor ≥ deltoid weakness, and knee extensors/ankle dorsiflexors ≥ hip flexors weakness), toxic myopathies, endocrine myopathies, amyloidosis, family history of muscular dystrophy or proximal motor neuropathies (*e.g.,* SMA)
2. Elevated serum creatine kinase level
3. Other laboratory criteria
   a. Abnormal electromyography
      Inclusion criteria
      I. Increased insertional and spontaneous activity in the form of fibrillation potentials, positive sharp waves, or complex repetitive discharges
      II. Morphometric analysis reveals the presence of short duration, small amplitude, polyphasic motor-unit action potentials (MUAPs)
      Exclusion criteria
      I. Myotonic discharges that would suggest proximal myotonic dystrophy or other channelopathy
      II. Morphometric analysis reveals predominantly long duration, large-amplitude MUAPs
      III. Decreased recruitment pattern of MUAPs
   b. MRI: diffuse or patchy increased signal (edema) within muscle tissue on Short T1 Inversion Recovery (STIR) images
   c. Myositis-specific antibodies detected in serum
4. Abnormal muscle biopsy
   a. Endomysial inflammatory cell infiltrate surrounding and invading nonnecrotic muscle fibers
   b. Endomysial CD8 T cells surrounding, but not definitely invading, nonnecrotic muscle fibers; or ubiquitous MHC-1 expression
   c. Perifascicular atrophy
   d. Membrane attack complex (MAC) depositions on small blood vessels, or reduced capillary density, or tubuloreticular inclusions in endothelial cells on EM, or MHC-1 expression of perifascicular fibers
   e. Perivascular, perimysial inflammatory cell infiltrate
   f. Scattered endomysial CD8 T-cell infiltrate that does not clearly surround or invade muscle fibers
   g. Many necrotic muscle fibers as the predominant abnormal histological feature. Inflammatory cells are sparse or only slight perivascular; perimysial infiltrate is not evident
   h. Rimmed vacuoles, ragged red fibers, cytochrome oxidase–negative fibers that would suggest IBM
   i. MAC deposition on the sarcolemma of nonnecrotic fibers and other indications of muscular dystrophies with immunopathology

Polymyositis–*Definite polymyositis:* 1. All clinical criteria with the exception of rash, 2. Elevated serum creatine kinase (CK), 3. Muscle biopsy criteria include a and exclude c, d, h, i; *Probable polymyositis:* 1. All clinical criteria with the exception of rash, 2. Elevated serum CK, 3. Other laboratory criteria (1 of 3), 4. Muscle biopsy criteria include b and exclude c, d, g, h, i. **Dermatomyositis–***Definite dermatomyositis:* 1. All clinical criteria, 2. Muscle biopsy criteria include c; *Probable dermatomyositis:* 1. All clinical criteria, 2. Muscle biopsy criteria include d or e, or elevated serum CK, or other laboratory criteria (1 of 3). **Amyopathic dermatomyositis–**1. Rash typical of DM: heliotrope, periorbital edema, Gottron papules/sign, V sign, shawl sign, holster sign, 2. Skin biopsy demonstrates a reduced capillary density, deposition of MAC on small blood vessels along the dermal-epidermal junction, and variable keratinocyte decoration for MAC, 3. No objective weakness, 4. Normal serum CK, 5. Normal electromyogram, 6. Muscle biopsy, if done, does not reveal features compatible with definite or probable DM. **Possible dermatomyositis sine dermatitis–**1. All clinical criteria with the exception of rash, 2. Elevated serum CK, 3. Other laboratory criteria (1 of 3), 4. Muscle biopsy criteria include c or d. **Nonspecific myositis–**1. All clinical criteria with the exception of rash, 2. Elevated serum CK, 3. Other laboratory criteria (1 of 3), 4. Muscle biopsy criteria include e or f and exclude all others. **Immune-mediated necrotizing myopathy–**1. All clinical criteria with the exception of rash, 2. Elevated serum CK, 3. Other laboratory criteria (1 of 3), 4. Muscle biopsy criteria include g and exclude all others.

TABLE 56.3 ENMC IBM Research Diagnostic Criteria 2011[5]

Clinical and Laboratory Features	Pathological Features
a. Duration >12 months	I. Endomysial inflammatory infiltrate
b. Age at onset >45 years	
c. CK no greater than 15 × ULN	II. Rimmed vacuoles
d1. Knee extension weakness > hip flexion weakness	III. Protein accumulation* or 15–18-nm filaments
d2. Finger flexion weakness > shoulder abduction weakness	IV. Upregulation of MHC class I

*Demonstration of amyloid or other protein accumulation by established methods (*e.g.*, for amyloid Congo red, crystal violet, thioflavin T/S, for other proteins p62, SMI-31, TDP-43). Current evidence favors p62 in terms of sensitivity and specificity, but the literature is limited, and further work is required.

Clinicopathologically defined IBM: clinical criteria include a–c and at least one of the d criteria plus the first three pathological features. **Clinically defined IBM**: All clinical criteria plus one or more pathological features. **Probable IBM**: clinical criteria include a–c and at least one of the d criteria plus one or more pathological features.

CK, creatine kinase; *IBM,* inclusion body myositis; *ULN,* upper limit of normal.

TABLE 56.4 Traditional Classification of Idiopathic Inflammatory Myopathies

Type I	Primary idiopathic polymyositis
Type II	Primary idiopathic dermatomyositis
Type III	Dermatomyositis or polymyositis associated with malignancy
Type IV	Childhood dermatomyositis or polymyositis
Type V	Myositis associated with another connective tissue disease
Type VI	Inclusion body myositis
Type VII	Miscellaneous: eosinophilic myositis, localized nodular myositis, etc.

TABLE 56.5 Clinical Features Associated With Myositis-Specific Autoantibodies

Autoantibodies	Association	Characteristic Clinical Features
Anti-Jo-1 and other antisynthetases	PM, DM, IMNM	Relatively acute onset of myositis, frequent interstitial lung disease, fever, Raynaud phenomenon, arthritis, mechanic's hands, moderate response to therapy, persistent disease. Patients sometimes meet criteria for SLE or RA, but muscle disease or lung disease dominate the clinical picture and prognosis.
Anti-SRP	IMNM	Very acute onset of myositis, often in autumn, severe weakness, no rash, palpitations, females predominate, poor response to therapy
Anti-Mi-2	DM	Relatively acute onset of myositis, classic dermatomyositis rashes with V sign and shawl sign, cuticular overgrowth, good response to therapy
Anti-HMGCR	IMNM	Necrotizing myopathy, may be preceded by statin therapy, very high CK levels, minimal muscle wasting
Anti-MDA5	DM, Clinically amyopathic DM	Clinically amyopathic dermatomyositis with rapidly progressive interstitial lung disease; characteristic skin findings include cutaneous ulcers and palmar papules
Anti-TIF1-γ (p155/140)	DM	Juvenile dermatomyositis and cancer-associated dermatomyositis
Anti-SAE	DM	Severe skin manifestations and dysphagia
Anti-NXP-2	DM	Associated with calcinosis and muscle contractures in children

DM, dermatomyositis; *IMNM,* immune-mediated necrotizing myopathy; *MDA5,* melanoma differentiation–associated protein 5; *NXP-2,* nuclear matrix protein; *PM,* polymyositis; *RA,* rheumatoid arthritis; *SAE,* small ubiquitin-like modifier activating enzyme; *SLE,* systemic lupus erythematosus; *SRP,* signal recognition particle; *TIF1-γ,* transcription intermediary factor 1-γ.

diseases (such as lupus, DM, and Sjögren syndrome) as well as in healthy subjects.[10]

IBM must be distinguished from other chronic myopathies. These include acquired myopathies, such as those caused by toxins, and genetically determined myopathies, such as some muscular dystrophies and the metabolic myopathies. There are several important differences between IBM and these other myopathies. The distinction, however, is not as well defined as might be expected. Although some of the familial forms of IBM have a distinctive clinical presentation, often early in life, there have been several families with the typical late onset and inflammatory picture of the presumed sporadic cases. Several genetic loci have been identified in familial IBM, so it will be important to assess any identified mutations in familial IBM–associated genes in sporadic cases.[11]

ETIOLOGY

Immunological Clues to Origin

The implications of myositis-specific autoantibodies that bind to and inhibit the function of native human enzymes involved in the formation of new proteins are tantalizing and probably significant. These autoantibodies appear to develop before symptomatic weakness or serum CK elevation, suggesting a close link to an initiating factor. Some of the clinical features, such as fever, arthritis, and lung disease, and the apparent seasonality in onset of disease in patients with anti-SRP, are reminiscent of some viral infections. In patients with autoantibodies against one of the aminoacyl-tRNA synthetases, such as Jo-1 (histidyl-tRNA synthetase), the possible connection to a viral inciting agent appeared compelling, as certain picornaviruses, which are closely related to viruses long suspected of causing myositis, such as coxsackie viruses, can mimic tRNA in acting as a substrate for an aminoacyl-tRNA synthetase.[12] Direct proof connecting picornaviruses to human myositis, however, has not been obtained.

In individuals infected with HIV or human T-cell lymphotropic virus (HTLV)-1, the development of IBM has been noted. However, it is not always the first manifestation in these cases. There is no evidence of viral replication within the muscles, but instead the chronic infection triggers an inflammatory response.[13]

Drugs and Toxins

A large number of environmental agents have been associated with myopathies. Drug-induced myopathy should be considered particularly in cases where no other cause has been identified. Sometimes the illness strikingly resembles the spontaneous disease. D-penicillamine, for example, can induce a variety of autoimmune phenomena, including an inflammatory myopathy that closely resembles PM. A number of drugs can also produce myopathies that can be clinically confused with IIM but are histologically distinct. This large group includes 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-coA) reductase inhibitors, corticosteroids, colchicine, and zidovudine (AZT).

In corticosteroid-induced myopathy, type II muscle fiber atrophy is prominent on muscle biopsy, and weakness improves when the dose is lowered. Colchicine can cause myopathy and painful neuromyopathy. The CYP3A4 system metabolizes colchicine, and taking another drug metabolized by the same pathway can result in myopathy.[14] Muscle biopsy shows autophagic vacuoles that stain for acid phosphatase. Discontinuation of colchicine usually results in improvement. AZT produces a characteristic mitochondrial myopathy. The myopathy associated with HIV infection can be distinguished from that caused by AZT by muscle biopsy, as characteristic mitochondrial abnormalities are found in the latter. Amiodarone rarely causes proximal and distal muscle weakness, or the accompanying tremor or distal sensory loss. Muscle biopsy reveals autophagic vacuoles with myeloid inclusions and debris. This is seen more commonly in patients with chronic kidney disease. The antimalarial drugs chloroquine and hydroxychloroquine produce a vacuolar myopathy, possibly by raising the intralysosomal pH so that the acid cathepsins that digest waste products in the lysosome are inoperable, so waste products accumulate in vacuoles.

Bacterial and Parasitic Diseases

Certain parasitic diseases can produce an illness by direct invasion of muscle. Weakness, fever, and eosinophilia are usually present. Bacterial pyomyositis is uncommon in North America but occurs more commonly in other parts of the world. It is attended by the signs of local infection and is often asymmetrical. A recent report, however, details two cases of pyomyositis initially diagnosed as PM. Patients presenting with disseminated pyomyositis may be difficult to distinguish clinically from those with IIM, especially in immunosuppressed individuals, who may not mount a systemic response.[15]

PATHOGENESIS

The precise mechanisms of cell damage and death in the IIMs are still unknown. T lymphocytes invading muscle fibers are predominantly lacking the costimulatory receptor CD28, indicative that they are chronically stimulated and end-differentiated. CD28^{null} lymphocytes are found in both muscle tissue and peripheral blood. They produce proinflammatory cytokines and release perforin and granzyme into targeted muscle cells. B cells and plasma cells are also present in myositis muscle infiltrates. The differentiation of B cells into antibody-producing plasma cells occurs within myositis muscle and is regulated by B cell–activating factor (BAFF). These antibodies are likely directed against autoantigens or cross-reacting viral antigens.

In addition to adaptive immune mechanisms, innate and nonimmune mechanisms also may be responsible for muscle cell damage and death. For example, Toll-like receptor (TLR)-3 and TLR-7 are expressed by infiltrating inflammatory cells and immature myoblasts in myositis muscle. TLR activation leads to production of inflammatory cytokines such as interleukin (IL)-6, thereby triggering or perpetuating inflammatory responses. Classic apoptosis is absent in IIM biopsies, but growing evidence suggests that autophagy could be responsible for myofiber death.

After damage, a muscle fiber, which is a syncytium, can regenerate. Initially, on light microscopy one can appreciate loss of striations leading to a homogeneous appearance, fiber size variation, atrophy, and centralization of the nuclei. In the inflammatory myopathies, cell-mediated cytotoxicity is a primary method of destruction. Macrophages and cytotoxic T cells invade the myofibers. The myocyte cytoplasm close to the invaginated cells appears vacuolated and swollen. Other regions of the same cell may show intense regeneration, as seen histologically by aggregates of nuclei with prominent nucleoli and fiber splitting. Thus degeneration and regeneration can coexist in the same fiber.

Cytokines and chemokines (Chapters 9 and 10) , which form an integrated network regulating inflammation, are produced by muscle fibers, immune cells, and endothelial cells. As an example, IL-1 is consistently found in myositis muscle. IL-1 facilitates transmigration of leukocytes by increasing the expression of adhesion molecules on endothelial cells. Further, IL-1 can decrease the proliferation of myoblasts. In some myositis patients, treatment with anakinra, an IL-1 receptor antagonist, results in improvement. This finding further supports a pathogenic role of IL-1. IL-1 acts in synergy with the other proinflammatory cytokines, tumor necrosis factor (TNF)-α and IL-17, to induce the production of IL-6 and CCL20 by myoblasts. The chemokine CCL20 recruits Th17 lymphocytes and immature dendritic cells into the muscle. IL-6 perpetuates inflammation by suppressing FOXP3$^+$ regulatory T cells. More recently, IL-15 has been reported to have a pathogenic role. IL-15 is expressed in muscle cells and myoblasts derived from PM and DM patients. IL-15 regulates T-cell activation and proliferation, and a higher expression of this cytokine at baseline may be associated with a poor response to immunosuppressive therapy.[16]

The role of type I interferons (IFN-Is) in the pathogenesis of DM has been extensively studied. The IFN-Is are a family of highly related glycoproteins, including IFN-α and IFN-β, that act on the type 1 IFN receptor. In DM muscle, the IFN-Is likely are produced by plasmacytoid dendritic cells (pDCs).[17] After activation of the IFN receptor, a cluster of IFN-I–inducible genes is transcribed, resulting in upregulation of several proteins, also known as the IFN signature, in the muscle and peripheral blood of patients with DM. Well known is the myxovirus resistance protein A (MxA), which, similar to other IFN-I–inducible proteins, has antiviral properties. This protein is overexpressed in both the muscle and skin in DM but not in PM or IBM. Further, decreased expression of MxA mRNA in peripheral blood mononuclear cells may correlate with decreasing muscle symptoms in juvenile DM patients. Indeed, some of the IFN-induced proteins may sustain autoimmunity in DM. For example, retinoic acid-inducible gene 1 (RIG-I) and melanoma differentiation-associated gene 5 (MDA-5) are IFN-I–induced proteins that induce IFN-I production in a positive feedback fashion. Both proteins contribute to IFN induction in response to measles virus infection,[18] nurturing the suspicion for a role of viral infections in myositis. Engel and colleagues[19] have demonstrated several important pathological distinctions between DM and PM and have suggested that in DM, the capillaries are the initial point of injury. A model of disease has been proposed in which primarily capillaries are damaged and myocytes are secondarily involved. Complement and immunoglobulins may be found in the capillary walls even where the remainder of the muscle is normal. The membrane attack complex of complement deposits there, and endothelial cells are swollen and pale. Even in unaffected regions of muscle, special staining reveals a marked decrease in capillary numbers. More advanced changes include microtubular endothelial inclusions and microvacuoles. Evaluation of lymphocyte populations in DM shows a high percentage of B cells and macrophages in the perivascular regions and an increasing frequency of CD4 T cells and pDCs toward the perimysium and endomysium. In DM, especially the juvenile-onset form, inflammation and necrosis followed by atrophy appear in a perifascicular pattern. Perivascular lymphocytic infiltrates, typical of later disease, have not been described as an early change. Consistent with the importance of immune complexes, histological abnormalities in the DM skin are indistinguishable from the changes in lupus.

In contrast to DM, PM and IBM do not demonstrate marked capillary changes, the perivascular infiltrates are less pronounced, and T-cell infiltrates in the perimysial and endomysial regions are more pronounced. Nonnecrotic fibers may be surrounded by T cells and macrophages. T cells are enriched for the CD8 subset. There is negligible evidence of natural killer (NK) cell presence. Should cytotoxic T cells prove to be the major effector cells, cloned T cells could lead to relevant antigenic targets. CD8 T cells recognize their antigenic peptide in association with major histocompatibility complex (MHC) class I molecules. Although resting normal muscle has very low class I expression, it is upregulated in regenerating and degenerating fibers found in both inflammatory and noninflammatory myopathies. Interestingly, in DM, class I expression is upregulated predominantly in the perifascicular regions, around sites of atrophy, and near sites of cellular invasion. In contrast, in PM, class I expression may be diffusely upregulated even where there is no cellular infiltrate. IBM shows a more focal class I distribution in regions of T-cell invasion. The presence of focal regions of MHC class I expression in nonnecrotic fibers at the site of activated CD8 T cells is compatible with cytotoxicity as a prime mechanism of myocyte necrosis in IBM and PM. A pivotal study using transgenic mice demonstrated that abnormal accumulation of MHC class I molecules in the endoplasmic reticulum (ER) of muscle may initiate the ER stress response.[20]

KEY CONCEPTS

Differential Histological Features of Myositis

- In dermatomyositis the earliest changes involve vessel walls, and B cells and CD4 T cells predominate in the muscle biopsy.
- In polymyositis and inclusion body myositis, the dominant pathological feature is targeting and invasion of muscle cells by CD8 cytotoxic T cells.

Proposed pathogenic mechanisms for the development of the sporadic forms of IBM are complex and include both autoimmunity and degeneration. Many proteins also found in other neurodegenerative diseases have been shown to accumulate in IBM muscle. In addition, IBM patients typically do not respond to immunosuppressive medications. These findings likely suggest that IBM is a degenerative disease. However, IBM is sometimes associated with other autoimmune diseases. In IBM biopsy specimens, inflammatory cells are predominantly composed of CD8 T cells, and a majority of patients express a circulating antibody to cytosolic 5′-nucleotidase 1A, supporting the role of autoimmunity in the pathogenesis of IBM.

In necrotizing autoimmune myositis (also known as IMNM), there is necrosis of muscle fibers with myophagocytosis and regeneration and paucity of T-cell infiltration. Complement deposition on blood vessels has been reported. In muscle biopsies from patients with statin-associated necrotizing autoimmune myositis, MHC class-I upregulation is frequently seen.[13]

The pathogenic role of autoantibodies found in IIM patients remains uncertain. MSAs are found in 60–80% of patients and appear to delineate specific clinical entities; each group has a strong but not absolute human leukocyte antigen (HLA) association. In a patient with myositis and antihistidyl-tRNA synthetase (Jo-1) autoantibodies, sera available from long before the onset of symptoms or biochemical damage to muscle tissue contained the autoantibodies, suggesting that the autoantibodies were not merely a response to release of tissue antigens. The extraordinary specificity of MSAs for IIM and the lack of evidence for strong polyclonal stimulation in these diseases suggest that MSAs are related to the fundamental causative process in IIM.

The structures bound by MSAs are mostly intracellular ribonucleoproteins involved in protein synthesis, such as the aminoacyl-tRNA synthetases and the SRP. These autoantigens are found in every nucleated cell. In general, the antibodies bind to conformational epitopes and, at least in the case of the antisynthetases, block enzymatic activity. It is possible that a structural property of muscle allows these particular proteins to be presented to the immune system when the cells are damaged; alternatively, the capacity of muscle fibers to degenerate alongside intense regeneration within the same fiber may allow these proteins to be efficiently displayed.[21] Experiments have suggested that some aminoacyl-tRNA synthetases have a direct proinflammatory role through a subsidiary chemokine-like action.

A landmark study determined that cultured myoblasts express high levels of autoantigens, which are strikingly downregulated as cells differentiate into myotubes *in vitro.* These data strongly associate regenerating rather than mature muscle cells as the source of continuous autoantigen supply in autoimmune myositis.[21]

GENETICS

The IIMs do not exhibit a simple mode of inheritance, and the rare familial cases mostly reflect IBM of early onset. As noted above, there are HLA associations for particular MSAs. Specifically, HLA-DR52 has a strong association (90%) with antisynthetase-positive myositis in people of both European and African descent.[22] HLA DRB1*11:01 was recently shown to be associated with an increased risk of anti-HMGCR myopathy.[23]

NATURAL HISTORY

The prognosis for patients with IIM varies greatly with clinical type, autoantibodies, extraskeletal muscle involvement, and the interval between diagnosis and the start of treatment.

Patients with DM or myositis accompanying another connective tissue disease are likely to recover most of their strength with prompt and adequate therapy. Although recurrences are common, persistent profound weakness does not usually occur. Most patients with anti-Mi-2 autoantibodies also usually respond well to therapy. Strength usually recovers well in patients whose myositis is cancer related, but overall mortality due to the tumor is high. Indeed, an accompanying tumor remains one of the most frequent causes of death in patients with an IIM. Among the MSAs, anti-TIF-1γ and anti–NXP-2 antibodies are found with increased frequency in patients with cancer-associated DM.[24]

Patients with PM fare less well, even when those with IBM are rigorously excluded. A return to normal strength is very unusual, and each recurrence is likely to be followed by greater residual weakness, even if inflammation is fully controlled. IBM has a poorer prognosis, but it is possible that the gradual decline in strength can be halted for long periods by corticosteroid and/or cytotoxic therapy if continuing inflammation is present. Severe muscle weakness and atrophy and very high CK levels are prominent features in patients with anti-SRP autoantibodies. Patients with anti-MDA5 antibodies are at increased risk for developing progressive interstitial lung disease. Those with anti-Jo-1 autoantibodies or antibodies to another synthetase are likely to respond to therapy initially, but they typically require continuing immunosuppression to treat frequent recurrences. In this group morbidity and mortality are heavily influenced by the progression of lung involvement. Longitudinal outcome studies in DM and PM are few. Cardiac involvement, respiratory involvement, and cancer were the main causes of death in several cohort analyses. Disease course is monocyclic in approximately 20% of patients, polycyclic in 20%, and chronic in the remainder. Relapses have been noted in the initial years of therapy and after prolonged disease-free intervals; therefore periodic surveillance is warranted for at least 2 years after remission.

PATIENT MANAGEMENT

The treatment of myositis is based on controlling skeletal muscle inflammation and damage. Immunosuppressive therapy is used in the initial stages of the disease to reduce inflammation and muscle damage. There are very few randomized controlled trials of any of the immunosuppressive agents used; thus therapeutic regimens and responses have remained largely anecdotal. After the initial inflammation is controlled, strengthening exercises are useful in improving functional capabilities.

Corticosteroids

Corticosteroids are the main immunosuppressive agents used in myositis treatment. An initial course of pulses of methylprednisolone may be helpful, particularly in disease of acute onset, and may also be helpful in managing disease flares. If active muscle inflammation persists or the side effects of corticosteroids are severe, other immunosuppressive treatments are employed.

Second-Line and Third-Line Immunosuppressive Therapies

The most frequently used second-line agents in the treatment of myositis are azathioprine and methotrexate. Azathioprine reduces long-term disability. Methotrexate is useful in patients with little or no response to corticosteroid therapy. Combination therapies, such as methotrexate with azathioprine, are useful even if patients have failed to respond to one of the agents alone. High-dose intravenous immunoglobulin (IVIG) is of proven benefit in DM.[25] Whereas patients with statin-associated anti-HMGCR myopathy may be particularly responsive to IVIG,[26] its usefulness in PM is less predictable. Apheresis proved ineffective in a controlled blinded study.[27] Both cyclosporine and tacrolimus have been effective in some cases, as have cyclophosphamide and chlorambucil. The most recent therapeutic options include mycophenolate and rituximab. Recently a large randomized placebo-phase clinical trial was conducted to elucidate the role of a 44-week course of rituximab therapy in adults and children with refractory PM and DM. In general, 83% of refractory myositis patients met the Definition of Improvement (DOI), and the presence of antisynthetase and anti–Mi-2 autoantibodies was associated with a shorter time to improvement.[28,29] In refractory patients who have not responded to the above-mentioned treatments, biological agents such as etanercept, adalimumab, anakinra, abatacept, and high-dose cyclophosphamide have been tried with variable success.[16,30–33] Thus far, there has been no effective therapeutic regimen for IBM. However, IVIG has been reported to provide a transient response.[13]

Monitoring Disease Activity

Improvement in strength and normalization of serum CK activity are the best indirect measures of disease activity. A decrease in serum CK activity may herald clinical improvement, but corticosteroid treatment alone can reduce CK activity without associated clinical improvement. A lack of improvement in strength in a corticosteroid-treated patient may be due to the resistance of the inflammatory process, the presence of a corticosteroid-induced myopathy, muscle atrophy, and/or misdiagnosis. A diagnostic and therapeutic taper of the corticosteroids may then be warranted. If inflammation is present concurrently, other immunosuppressive agents are useful as the dosage of corticosteroids is lowered. If the CK value begins to rise, even if it is still within the normal range, and the symptoms of myositis are worsening in a patient whose disease has previously been controlled with corticosteroids, an increase in the dose may be warranted.

Treatment-Resistant Myositis

Some treatment-resistant PM patients have another disease. In such cases IBM or a liED-girdle muscular dystrophy should be suspected. Unlike other myositis patients, those with IBM rarely, if ever, improve in strength with immunosuppressive therapy, but stabilization of strength can be achieved in some IBM patients with immunosuppressive agents.[34,35] Patients with limb-girdle muscular dystrophies may mimic PM clinically. They may have inflammation on muscle biopsy and may occasionally have associated autoantibodies. Thus patients with a suspected IIM who do not respond to immunosuppressive therapy should undergo further evaluation, including genetic testing, to search for a limb-girdle muscular dystrophy.

Nonskeletal Muscle Involvement

Other organs frequently involved in myositis include the skin, lungs, and joints. Such organ involvement and the systemic features of myositis (fever and weight loss) usually improve with immunosuppressive therapy that controls inflammation in the skeletal muscle. Hydroxychloroquine and other antimalarials are useful in controlling the rashes associated with myositis.

DIAGNOSTIC TOOLS, EVALUATION, AND DIFFERENTIAL DIAGNOSIS

CLINICAL PEARLS

Clinical Features That Suggest a Non-Idiopathic Inflammatory Myopathy Diagnosis

- Family history of a similar illness
- Weakness related to exercise, eating, or fasting
- Sensory, reflex, or other neurological signs
- Cranial nerve involvement
- Fasciculations
- Muscle cramping (severe)
- Myasthenia (increasing weakness with repeated contractions)
- Myotonia (difficulty relaxing a contracted muscle)
- Significant atrophy or hypertrophy early in the illness
- Marked asymmetry
- Dyspnea due to diaphragmatic weakness with normal chest x-ray

Clinical, laboratory, pathological, and electrodiagnostic findings contribute to the proper diagnosis of IIM. Even in individuals with typical clinical features, it is essential to exclude other diseases that may have similar symptoms and signs (Table 56.6). Certain clinical features should suggest a different diagnosis. These include a family history of a similar illness; sensory, reflex, or other neurological changes; fasciculations; a relationship of the weakness to exercise, food intake, or fasting; major muscle cramping, myotonia (difficulty relaxing a contracted muscle), or myasthenia (increasing weakness with repeated contractions); significant early muscle atrophy or hypertrophy; marked asymmetry; weakness in the distribution of the cranial nerves; and dyspnea due to diaphragmatic weakness rather than lung fibrosis.

The single most useful laboratory feature of muscle destruction is elevation of the serum CK, although this is nonspecific, and a small proportion of patients—probably <5%—have a bonafide inflammatory muscle disease without ever having an elevated CK. Elevations of the serum levels of aldolase, serum glutamic-oxaloacetic transaminase (SGOT), serum glutamate pyruvate transaminase (SGPT), and lactate dehydrogenase (LDH) are as frequent but less specific for muscle disease. Unlike inflammatory markers for other autoimmune inflammatory diseases, those such as the erythrocyte sedimentation rate (ESR) and C-reactive protein are often not elevated. Although some studies have shown ESR to be elevated in 50% of patients, most experts find a substantially lower proportion of IIM patients to have an elevated

TABLE 56.6 Differential Diagnosis of Idiopathic Inflammatory Myopathy

Neuromuscular Disorders

Genetic muscular dystrophies
Metabolic myopathies
Disorders of carbohydrate metabolism: McArdle disease, phosphofructokinase deficiency, adult acid maltase deficiency, and others
Disorders of lipid metabolism: carnitine deficiency, carnitine palmitoyl transferase deficiency
Disorders of purine metabolism: myoadenylate deaminase deficiency
Mitochondrial myopathies
Spinal muscular atrophies
Neuropathies: Guillain–Barré and other autoimmune polyneuropathies, diabetes mellitus, porphyria
Myasthenia gravis and Eaton–Lambert syndrome
Amyotrophic lateral sclerosis
Myotonic dystrophy and other myotonias
Familial periodic paralysis

Endocrine and Electrolyte Disorders

Hypokalemia, hypercalcemia, hypocalcemia, hypomagnesemia
Hypothyroidism, hyperthyroidism
Cushing syndrome, Addison disease

Toxic Myopathies (Partial List)

Alcohol
Amiodarone
Chloroquine and hydroxychloroquine
Cocaine
Colchicine
Corticosteroids
D-penicillamine
Ipecac
Statins and other lipid-lowering agents
Zidovudine (AZT)

Infections

Viral: HIV, human T-lymphotropic virus 1 (HTLV-1), influenza
Bacterial: *Staphylococcus, Streptococcus, Clostridia*
Parasitic: toxoplasmosis, trichinosis, schistosomiasis, cysticercosis

Miscellaneous

Polymyalgia rheumatica
Vasculitis
Eosinophilia myalgia syndrome
Paraneoplastic syndromes

ESR, even with active disease.[36] Likewise, hematological abnormalities, including anemia, are uncommon and rarely related to the underlying myopathy. If a significant abnormality is found, the physician should be alert to another cause for it.

Electromyographic (EMG) abnormalities are frequently present. Although the test is useful for excluding some neurological diseases that resemble IIM, it is painful for many patients and not useful for following the course of the illness.

MRI, especially a combination of the T1 and the fat-suppressed T2 (STIR) sequences, is remarkably useful in defining the extent of involvement and in planning a biopsy (Fig. 56.2). Whole-body MRI has been shown to facilitate the characterization of inflammatory myopathy, as certain patterns of muscle and subcutaneous tissue inflammation were predictive of the IIM subset (DM, PM, or IBM). In a recent study in juvenile DM, whole-body MRI was able to reveal inflammatory changes of subcutaneous and fascial tissue that was undetectable on clinical examination.[37] MRI can also help differentiate active disease from chronic disease, with active myositis being notable for changes consistent with muscle edema on T2-weighted images, and chronic myositis revealing a decrease in muscle bulk and replacement by adipose on T1-weighted images.[38] Although not specific, the changes of inflammatory myopathy on imaging can provide considerable assistance in confusing cases, as well as help in choosing a site to biopsy.

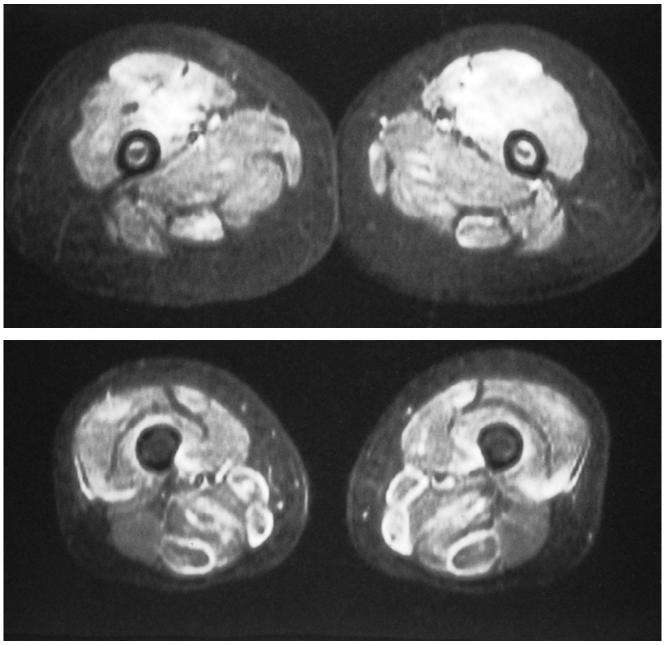

FIG 56.2 Magnetic Resonance Images of the Upper and Lower Thighs of a Patient With Dermatomyositis Using the Fat-Suppressed T2 (STIR) Technique. With this technique inflammation appears as a bright signal; normal muscle is gray; bone, fat, fascia, and normal skin are dark. Blood vessels may appear as bright spots. Note the remarkable symmetry of the inflammation. In this patient most of the involvement is in the quadriceps in the upper thighs and around the periphery of the hamstring muscle group.

A muscle biopsy should be performed in every suspected case of myositis (Fig. 56.3). Although the patchy involvement means that the biopsy can occasionally miss inflammation, certain confounding diagnoses—for example amyloidosis, eosinophilic myositis, dystrophy, or some metabolic myopathies as well as the important variant IBM—can be diagnosed definitively only by biopsy. The identification of autoantibodies, particularly the myositis-specific autoantibodies, has distinct clinical and prognostic use.

ON THE HORIZON

- Development of revised and updated classification criteria for inflammatory myopathies is needed.
- Improved diagnostic classification of cases through novel autoantibodies as well as immunohistochemistry.
- Long-term studies are needed to better characterize the prognosis of idiopathic inflammatory myopathies, particularly in relation to recently discovered autoantibodies.

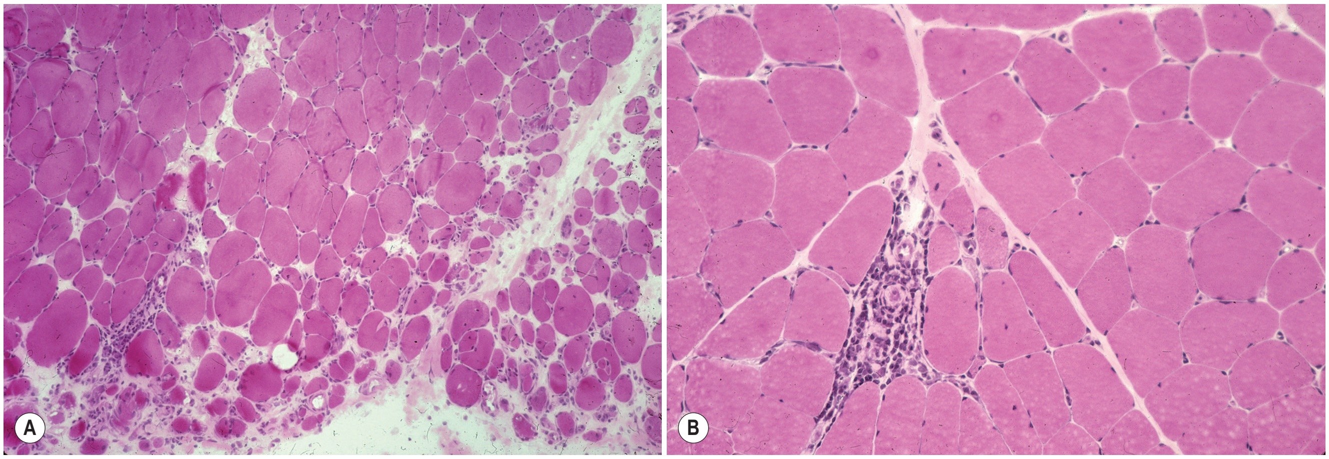

FIG 56.3 Biopsy in Dermatomyositis. (A) Low-power (original magnification ×100) view of a muscle biopsy from a patient with dermatomyositis. Note the marked variation in fiber size and the large number of atrophic myocytes, particularly at the periphery of the fascicles. (B) High-power (original magnification ×200) view of inflammation around the vessels in the muscle biopsy of a patient with dermatomyositis. There are nearby atrophic cells and cells whose nuclei have moved away from the periphery of the cell (centralized nuclei).

PITFALLS

It is increasingly apparent that the boundary between IIM and some genetically determined myopathies cannot be cleanly drawn. Recently dystrophies with an extraordinary variety of clinical manifestations (with regard to age and distribution of weakness) have also been described.[39] Not only can inflammation be seen on biopsy in some patients, but a partial clinical response to corticosteroids also can occur. Furthermore, it is increasingly recognized that mitochondrial abnormalities can be limited to groups of skeletal muscles, leading to confusion with IIM. Toxic myopathies, of course, will continue to occur with the release of new drugs and thus will continue to be a possible source of diagnostic confusion.

Thus not only must the history, physical examination, and biopsy be performed and interpreted with compulsiveness and care, but molecular diagnostic techniques also must be employed by clinicians in pursuit of an accurate diagnosis and appropriate therapy. The correct response to disease that persists in the face of powerful immunosuppressive therapy is a careful rethinking of the diagnosis, including, on occasion, rebiopsy and molecular consultation.

MULTIPLE-CHOICE QUESTIONS

1. A 42-year-old Asian woman comes to your office complaining of a rash on her face and upper back that started 2 months ago. Around the same time, she developed joint pain and swelling in both hands. Approximately a week ago, she noticed mouth sores as well as weakness, with difficulties walking upstairs. Other medical problems include an episode of pulmonary collapse resulting in intensive care unit admission and requiring intubation and treatment with antibiotics and steroids 3 years ago, but she had full recovery after this. Otherwise, she has been healthy. She has never smoked and does not drink alcohol. Her mother has rheumatoid arthritis. She takes no medications. Physical examination reveals heliotrope rash, Gottron sign, shawl sign, nail bed erythema, dilated capillary loops, and swelling of the hands. There is extensive ulceration and necrosis of the fourth digit. Neurological examination demonstrates symmetrically reduced hip flexion (4/5) muscle strength. Further evaluation reveals a serum CK level of 100 U/L (normal range: 24–170 U/L) and an aldolase level of 15.6 U/L (normal = <8.1 U/L). Which of the following antibodies is most likely to be detected in this patient's serum?
   A. Anti-Jo-1
   B. Anti-SRP
   C. Anti-RNP
   D. Anti-MDA5
   E. Anti-La

2. A 58-year-old Caucasian man began noticing progressive weakness with bilateral foot slapping 3 years ago. He began struggling with stairs and progressive weakness in his handgrip about 1 year later. He also began having difficulties walking on uneven ground. He has not had any difficulty swallowing. His past medical history is significant for elevated serum CK levels of 1400 (normal range: 24–170 U/L) 5 years ago and hypercholesterolemia. His family history includes breast cancer in his mother. He has a 33-pack-year smoking history, but he quit 2 years ago. He has no other medical problems. Neurological examination reveals reduced triceps strength (right: 4+/5, left: 4/5), finger flexion (2/5 bilaterally), knee extension (4+/5 bilaterally), and left wrist flexion (4+/5) muscle strength. The patient's laboratory tests show an elevated CK level of 1030 U/L. Electromyography reveals positive waves, fibrillations, and mixed neurogenic and myopathic motor units in the involved muscles. A quadriceps muscle biopsy is performed. Which of the following findings is most likely present on biopsy?
   A. Many necrotic muscle fibers and sparse inflammatory cells
   B. Perifascicular atrophy
   C. Endomysial inflammatory infiltrate and rimmed vacuoles
   D. MAC depositions on small blood vessels

3. Which of the following antibodies is associated with the disease presented in question 2?
   A. Anti-HMGCR
   B. Anti-SAE
   C. Anti-c5N1A
   D. Anti-Mi-2
   E. Anti-SRP
   F. No recognized antibodies are associated with this condition.

57

Spondyloarthritis

John D. Reveille

The term *spondyloarthritis* (SpA) (otherwise known as *spondyloarthropathy*) encompasses a heterogeneous group of inflammatory diseases characterized by spinal and peripheral joint arthritis, inflammation of the attachments of ligaments and tendons to bones (enthesitis), and, at times, mucocutaneous, ocular, and/or cardiac manifestations. These disorders show familial aggregation and are typically associated with genes of the major histocompatibility complex (MHC), particularly human leukocyte antigen (HLA)-B27 (Chapter 5). The SpA spectrum includes *(i)* axial spondyloarthritis (AxSpA), including ankylosing spondylitis (AS); *(ii)* reactive arthritis (ReA), known previously as *Reiter syndrome; (iii)* psoriatic arthritis (PsA) and/or spondylitis; *(iv)* enteropathic arthritis and/or spondylitis associated with the inflammatory bowel diseases (IBD), ulcerative colitis (UC), or Crohn disease (CD); and *(v)* undifferentiated SpA, which encompasses patients expressing elements of, but failing to fulfill, accepted criteria for one of the above diseases. In addition, isolated acute anterior uveitis (AAU)[1] and spondylitic heart disease (complete heart block and/or lone aortic regurgitation)[2] associated with HLA-B27 may also be classified within the spectrum of SpA.

CLASSIFICATION OF SPONDYLOARTHRITIS

There are no diagnostic criteria for any of the SpA types. Classification criteria have been developed to provide greater specificity in clinical studies. The European Spondyloarthropathy Study Group (ESSG) criteria for SpA were developed in 1991, have been validated in numerous population groups, and remain the basis of many clinical and epidemiological studies (Table 57.1).[3] The modified New York criteria, developed in 1966 and modified in 1984, remain the "gold standard" for AS.[4] However, this depends on the presence of radiographic sacroiliitis, which takes up to 10 years to develop after the onset of inflammatory back pain. For PsA, the classification criteria for psoriatic arthritis (CASPAR) (see Table 57.1)[5] have stemmed from the perception that the ESSG criteria were not "sensitive" enough.

The International League Against Rheumatism (ILAR) juvenile idiopathic arthritis (JIA) classification criteria for enthesitis-related arthritis (ERA) have been proposed for juvenile SpA (JSpA; see Table 57.1). No criteria have been validated for enteropathic arthritis.

New criteria have been developed by the Assessment of SpondyloArthritis International Society (ASAS) for axial SpA based on the presence of inflammatory back pain that take advantage of imaging innovations, such as magnetic resonance imaging (MRI) and HLA-B27 typing.[6] More recently, criteria for peripheral spondyloarthritis based on the presence of peripheral arthritis, enthesitis, or dactylitis have also been developed utilizing these innovations.[7] The result of this is a reclassification of all the various spondyloarthritides under the diagnoses of axial and peripheral SpA.

EPIDEMIOLOGY

The frequency of SpA in general and AS in particular varies in different populations and parallels the frequency of HLA-B27. The prevalence of AS varies from 0.2% to 0.7% among people of European ancestry[8-10] and has been reported in similar frequencies in eastern Asia (Table 57.2). Higher rates of prevalence have been reported in Eskimo groups from Siberia and Alaska as well as in groups from Scandinavia and as high as 4.3% in male Haida Native Canadian groups, where the frequency of HLA-B27 is 50%.[8] AS is much less frequent in persons of African and Japanese descents, in whom HLA-B27 is rare.

The prevalence of ReA is unknown and probably varies over time, depending on endemic rates of the sexually acquired (*Chlamydia*) and enteric (*Shigella, Salmonella, Campylobacter*) infections that trigger it. It appears that the frequency of ReA has dramatically declined following the adoption of safer sexual practices and better sanitation, at least in Western countries, in the wake of the human immunodeficiency virus (HIV) epidemic.

Psoriasis affects 1–3% of the general population.[9] The frequency of PsA is less clear and is higher in those with more severe disease; population studies among Caucasians estimate a frequency of approximately 0.1%.[8]

The prevalence of IBD is 100–200 per 100 000 among Caucasians, with an equal male-to-female ratio.[8,10] It is rare in people of African and Asian descents. The risk of spondylitis and peripheral arthritis varies in different reports, perhaps reflecting the subspecialty of the observer. Spondylitis occurs in as many as 15–20% of those with IBD. In general, peripheral arthritis occurs less frequently in those with UC (up to 10%) than in those with CD (up to 20%), although its frequency tends to be higher in series where the assessor was a rheumatologist.[8,10]

PATHOGENESIS

Genetics of Spondyloarthritis

Familial Aggregation

Susceptibility to AS is clearly attributable to genetic factors, with a sibling recurrence risk ratio as high as 82 and twin-based studies

TABLE 57.1 **Current Classification Criteria for Spondyloarthritis**

A. European Spondyloarthropathy Study Group (ESSG) Criteria for Spondyloarthritis

1. Inflammatory back pain or synovitis (asymmetrical, lower extremity) *plus* one of the following:
   - (a) Alternating buttock pain
   - (b) Sacroiliitis
   - (c) Heel pain (enthesitis)
   - (d) Positive family history
   - (e) Psoriasis
   - (f) Crohn disease, ulcerative colitis
   - (g) Urethritis or cervicitis or acute diarrhea in the preceding 4 weeks

B. The Modified New York Criteria for Ankylosing Spondylitis[4]

1. Clinical criteria:
   - (a) Low-back pain and stiffness for more than 3 months which improves with exercise, but is not relieved by rest
   - (b) Limitation of motion of the lumbar spine in both the sagittal and frontal planes
   - (c) Limitation of chest expansion relative to normal values correlated for age and gender
2. Radiological criterion:
   - (a) Sacroiliitis grade 2 bilaterally or grade 3–4 unilaterally
   - (b) *Definite ankylosing spondylitis* if the radiological criterion is associated with at least one clinical criterion

C. The Classification Criteria for Psoriatic Arthritis (CASPAR) Criteria for Psoriatic Arthritis

1. Inflammatory joint disease plus at least three points from the following features:
   - (a) Current psoriasis (assigned a score of 2; all others assigned a score of 1)
   - (b) History of psoriasis
   - (c) Family history of psoriasis
   - (d) Dactylitis
   - (e) Juxtaarticular new bone formation
   - (f) Rheumatoid factor seronegativity
   - (g) Nail dystrophy

D. ASAS Criteria for Axial Spondyloarthritis in Patients With Chronic Low Back Pain for at Least 3 Months

1. Sacroiliitis on imaging (either MRI findings of inflammatory disease in the sacroiliac joints or sacroiliitis on standard pelvic X-rays by New York criteria) plus ONE of the following OR HLA-B27 positivity plus TWO of the following:
   - (a) Inflammatory low back pain
   - (b) Arthritis
   - (c) Enthesitis
   - (d) Dactylitis
   - (e) Psoriasis
   - (f) Crohn disease or ulcerative colitis
   - (g) Good response to nonsteroidal antiinflammatory agents
   - (h) Positive family history of SpA
   - (i) Presence of human leukocyte antigen (HLA)-B27
   - (j) Elevated cross-reactive protein

E. ASAS Criteria for Peripheral Spondyloarthritis—Arthritis or Enthesitis or Dactylitis With at Least One of:

a. Uveitis
b. Psoriasis
c. Crohn disease or ulcerative colitis
d. Previous infection
e. Presence of HLA-B27
f. Sacroiliitis on imaging
OR
with at least two of:
a. Inflammatory low back pain
b. Arthritis
c. Enthesitis
d. Dactylitis
e. Positive family history of SpA

F. The International League Against Rheumatism (ILAR) Juvenile Idiopathic Arthritis Classification Criteria for Enthesitis-Related Arthritis (ERA)

Arthritis and enthesitis
OR
Arthritis or enthesitis with at least two of:

1. Sacroiliac joint tenderness and/or inflammatory spinal pain
2. Presence of HLA-B27
3. Family history in at least one first- or second-degree relative of medically confirmed HLA-B27-associated disease
4. Anterior uveitis that is usually associated with pain, redness, or photophobia
5. Onset of arthritis in a boy after 8 years of age

Exclusions

- Psoriasis confirmed by a dermatologist in at least one first- or second-degree relative
- Presence of systemic arthritis

estimating disease heritability to exceed 90%.[11] The concordance rate for AS in identical twins has been reported to be as high as 63% compared with 23% in nonidentical twins.[11] The concurrence rate for psoriasis in monozygotic twins is 70 versus 15–30% in dizygotic twins. Recurrence risk for parents and sibs of patients with CD is 4.8% and 7%, respectively, and for UC 0.9 and 1.2%, respectively.[11]

HLA-B27 and Spondyloarthritis

HLA-B27, which is encoded in the MHC class I region (Chapter 5), confers the greatest known risk for AS and is found in up to 90% of AS patients of European ancestry[11-13] (Table 57.3), as opposed to 6–8% of healthy Caucasians.[12,14] The estimated prevalence of HLA-B27 in the United States is 6.1% overall, is highest in younger individuals (7.5% before age 50 years), and falls rapidly over age 50 years (3.3%).[14]

KEY CONCEPTS

The Genetic Basis of Spondyloarthritis

- Human leukocyte antigen (HLA)-B27 comprises nearly 80% of the overall genetic susceptibility to ankylosing spondylitis (AS) and contributes heavily to susceptibility to reactive arthritis, psoriatic arthritis, and enteropathic spondylitis.
- Additional influences seem to come from other major histocompatibility complex (MHC) genes, including *HLA-A*02, B*40* for AS and *C*0602* for psoriasis, whose identification has been confounded by linkage to HLA-B27.
- Genome-wide association studies (GWAS) utilizing dense single nucleotide polymorphism (SNP) mapping have located at least 70 genes or genetic regions in AS susceptibility.
- Over 60 genes have been identified thus far in psoriasis pathogenesis.
- GWAS utilizing dense SNP mapping will likely locate many of the remaining genes in AS susceptibility.

TABLE 57.2 The Epidemiology of Spondyloarthritis

AS, ankylosing spondylitis; HLA, human leukocyte antigen; n.a., not available; PsA, psoriatic arthritis; SpA, spondyloarthritis; NY (New York) and mNY (modified New York criteria for AS); ESSG (European Spondyloarthropathy Study Group Criteria)

Approximately 70% of patients with ReA have HLA-B27, except in Africa, where no association of HLA-B27 is seen in those with HIV-associated SpA.[13]

HLA-B27 is found in 60–70% of patients with psoriatic spondylitis and in 25% of those with peripheral PsA.[12,13] Up to 70% of those with IBD-associated spondylitis have HLA-B27, although no HLA-B27 association is seen with asymptomatic sacroiliitis. Approximately 50% of patients with AAU alone are HLA-B27 positive.[12]

Over 146 molecular subtypes of HLA-B27 have been described this far (http://www.ebi.ac.uk/ipd/imgt/hla/nomenclature/index.html). The most common subtypes (HLA-B*27:05, B*27:02, B*27:04, B*27:07, B*27:14) are clearly associated with SpA. Two subtypes of HLA-B27—HLA-B*27:06 and B*27:09—found in Southeast Asia and Sardinia, respectively, appear not to be associated with AS,[13] possibly in part as a result of amino acid differences in the "B" pocket of the HLA antigen-binding cleft at positions 114 and 116 that could alter the composition and anchoring of peptides presented by these HLA-B27 subtypes. The other subtypes of HLA-B27 are too rare to have had disease associations established. These subtypes evolved from the parent allele HLA-B*27:05 along three lines (Fig. 57.1) in three distinct geographical regions.

The exact mechanism underlying the effect of HLA-B27 on disease susceptibility has still not been determined. One theory suggests that SpA results from a unique set of antigenic peptides, either bacterial or self, that are bound and presented by all disease-associated HLA-B27 subtypes (but not by other HLA class I molecules) to CD8 T cells, resulting in an HLA-B27–restricted cytotoxic T-cell response found only in joints and other affected tissues (the so-called arthritogenic peptide hypothesis). However, such peptides have not been reproducibly identified to date. In fact, gene association data showing interaction between HLA-B27 and a gain-of-function (GOF) variant of endoplasmic reticulum (ER)–associated aminopeptidase I (ERAP1) suggest that aberrant antigen processing may play a central role in AS susceptibility.[15] The same has been described for HLA-C*06:02 and psoriasis.[16] An alternative concept focuses on self-association as a unique property of the HLA-B27 molecule. HLA-B27 heavy chains can form homodimers *in vitro* that are dependent on disulfide binding through their cysteine-67 residues in the extracellular α_1 domain (as well as other cysteine residues in other domains) (Fig. 57.2).[13,16] This occurs as a result of B27 misfolding within the ER. The accumulation of misfolded protein results in a proinflammatory intracellular stress response through the stimulation of secretion of type 1 interferon (IFN). Also, HLA-B27 homodimers are detectable at the cell surface in patients with SpA, are capable of peptide binding, and are more abundantly expressed when the cell's antigen-presenting function is impaired. They are ligands for a number of natural killer (NK) and related cell surface receptors. Populations of synovial and peripheral blood monocytes, NK cells, and B and T lymphocytes from patients with SpA and controls carry receptors for HLA-B27 homodimers, including killer immunoglobulin-like receptor (KIR)3DL1 and KIR3DL2 and immunoglobulin (Ig)–like transcript 4 (ILT4).[13,15] These homodimers may act as a

TABLE 57.3 Genetic Factors Implicated in Spondyloarthritis

HLA-B27	AS = 90%, reactive arthritis = 70%; psoriatic spondylitis = 70%; peripheral psoriatic arthritis = 24%; IBD-associated arthritis = 60%. No association with psoriasis, Crohn disease, ulcerative colitis, or peripheral enteropathic arthritis

HLA, human leukocyte antigen; MHC, major histocompatibility complex; *IL23R*, interleukin-23 receptor; *ADCY3*, adenylate cyclase 3; *CDKAL1*, CDK5 regulatory subunit-associated protein 1-like 1; *CCL21*, chemokine; CC motif, ligand 21; *IL12B*, The Interleukin-12 p40 subunit; *ZMIZ1*, zinc finger MIZ-domain containing 1; *ETS1*, V-ETS avian erythroblastosis virus E26 oncogene homologue 1; *SH2B3*, SH2B adaptor protein 3; *FOS*, V-FOS FBJ murine osteosarcoma viral oncogene homologue; *TNP2*, transition protein 2; *RPS6KB1*, ribosomal protein S6 kinase, 70-kDa, 1; *TYK2*, tyrosine kinase 2; *DNMT3B,* DNA methyltransferase 3b; *UBE2L3,* ubiquitin-conjugating enzyme E2L; *SP140*, nuclear body protein 140; *FUT2*, fucosyl transferase 2; *CD28*, CD28 antigen; *IRF5*, interferon regulatory factor 5; *RORC,* RAR-related orphan receptor C-3; *HMGN2P18,* high mobility group nucleosomal binding domain 2 pseudogene 18; *ITLN,* intelectin 1; *FCGR2A*, Fcγreceptor 2A; *DNMT3A,* DNA methyltransferase 3b; *IL1R2,* interleukin-1 receptor, type II; *CXCR2,* chemokine, CXC motif, receptor 2; *GPR35,* G protein–coupled receptor 35; *MST1*, macrophage stimulating 1; *ANTXR2*, anthraxin receptor receptor 2; *PTGER4*, Prostaglandin E receptor 4, EP4 subtype; *ERAP2*, endoplasmic reticulum–associated aminopeptidase 2; *C5orf56,* chromosome 5 open reading frame 56; *IRGM,* immunity-related GTPase family, M; *BACH2*, basic leucine zipper transcription factor 2; *C7orf72*, chromosome 7 open reading frame 72; *JAK2*, Janus kinase 2; *TLR4*, Toll-like receptor 4; *ZNF365,* Zinc finger protein 365; *NKX2-3*, NK2 homeobox 3; *OR5B21,* olfactory receptor family 5 subfamily B member 21; *SMAD3*, Mothers against decapentaplegic, Drosophila, homologue of, 3; *NOD2*, Nucleotide-binding oligomerization domain protein 2; *IL27*, interleukin-27; *ZPBP2*, zona pellucida–binding protein 2; *PTPN2*, protein tyrosine phosphatase, non–receptor type, 2; *IL6R*, interleukin-6 receptor; *ANKRD55,* ankyrin repeat domain–containing protein 55; *FGFR1OP*, fibroblast growth factor receptor 1 oncogene partner; *TNFSF8*, tumor necrosis factor ligand superfamily, member 8; *NOTCH1,* NOTCH, Drosophila, homologue of, 1; *TFRSF1A/LTBR*, tumor necrosis factor receptor superfamily, member 1A/ lymphotoxin B receptor; *RIC8B,* RIC8, *C. elegans*, homologue of, b; *LSM14*, LSM Protein A; *ASAP2*, development-and differentiation-enhancing factor 2; *ITGAL*, integrin, alpha-L; *FAM118A*, family with sequence similarity 118 member A; *ERAP1*, endoplasmic reticulum aminopeptidase I; *TNFAIP3,* tumor necrosis factor-α-induced protein 3; *ZC3H12C*, zinc finger CCCH domain-containing protein 12C; *PPP2R3C*, protein phosphatase 2, regulatory subunit B-double prime, γ; *NOS2,* nitric oxide synthase 2A; *PARK7*, Parkinson disease 7, autosomal recessive early-onset; *OSMR,* oncostatin M receptor; *RN7SKP226,* RNA, 7SK small nuclear pseudogene 226; *IL2RA*, interleukin-2, receptor alpha; *PLAU*, plasminogen activator, urinary; *TSPAN14*, tetraspanin 14; *NFKBIA,* nuclear factor of κ light chain gene enhancer in B-cell inhibitor, α; *STAT3,* signal transducer and activator of transcription 3; *FIBP,* fibroblast growth factor, acidic, intracellular binding protein; *TAGAP*, T-cell activation GTPase-activating protein; *GNA-12*, guanine nucleotide-binding protein, α-12; *HDAC7A*, histone deacetylase 7A; *SDF4*, stromal cell-derived factor 4; *PTPN22*, protein tyrosine phosphatase, non–receptor type, 22; *DENND1B*, DENN/MADD domain-containing protein 1B; *GCKR*, glucokinase regulatory protein; *FOSL2*, FOS-like antigen 2; *THADA*, thyroid adenoma-associated gene; *PUS10*, pseudouridylate synthase 10; *IL18R1*, Interleukin-18 receptor; BANK1, B-cell scaffold protein with ankyrin repeats 1; *IL21*, interleukin-21; *DAP*, death-associated protein; *NDFIP1,* NEDD4 family-interacting protein 1; *PRDM1*, PR domain-containing protein 1;*SKAP2*, SRC kinase associated phosphoprotein 2; *TNFSF15*, tumor necrosis factor ligand superfamily, member 15; *CREM*, cAMP response element modulator; *GLYAT,* glycine N-acyltransferase; *CD6*, CD6 molecule; *IFNG-AS1*, interferon gamma antisense RNA 1; *LINC00284*, long intergenic non–protein coding RNA 284; *FNDC3A*, fibronectin type III domain containing 3A; *UBAC2,* UBA domain containing 2; *CLEC16A*, C-type lectin domain family 16, member A; *PRKCB*, protein kinase C, subunit B; *ORMDL3,* ORM1-like protein 3;*CD226*, CD226 antigen; *KEAP,* KELCH-like ECH-associated protein 1; *PKIG*, protein kinase, cAMP-dependent catalytic, inhibitor gamma; *CD40*, CD40 antigen; *ZNF831*, zinc finger protein 831; *TNFRSF6B,* tumor necrosis factor receptor superfamily, member 6B; *UQCR10,* ubiquinol-cytochrome c reductase complex, 7.2-kDa subunit; *IL1R1*, interleukin-1 receptor, type I; CMC1, COX assembly mitochondrial protein 1, *S. cerevisiae*, homologue of; NPM1P17, nucleophosmin 1 (nucleolar phosphoprotein B23, numatrin) pseudogene 17; *ACTA2*, actin, α_2, smooth muscle, aorta; *NPEPPS*, aminopeptidase, puromycin-sensitive; *ERN1*, endoplasmic reticulum-to-nucleus signaling 1; *HIPK1,* homeodomain-interacting protein kinase 1; *GBAP1*, glucosylceramidase β pseudogene 1; *TEX41,* testis expressed 41 (non–protein coding); *ATG16L1*, autophagy 16-like1; *GAL3ST2*, galactose-3-O-sulfotransferase 2; *CPEB4,* cytoplasmic polyadenylation element-binding protein 4; *CCR6*, chemokine, cc motif, receptor 6; *JAZF1*, juxtaposed with another zinc finger gene 1; *MYRF*, chromosome 11 open reading frame 9; *LRRK2*, leucine-rich repeat kinase 2; *KSR1*, kinase suppressor of RAS 1; *C17orf67*, chromosome 17 open reading frame 67; *NFATC1*, nuclear factor of activated T-cells 1; *SBNO2*, strawberry notch, Drosophila, homologue of, 2; *STK11*, serine/threonine protein kinase 11; *PPP5C*, protein phosphatase 5, catalytic subunit; *IFNGR*, interferon-γreceptor 1; *TNFRSF14,* tumor necrosis factor receptor superfamily, member 14; *RNF186*, Ring finger protein186; *HSPA6*, heat-shock 70-kDa protein 6; *NR5A2*, nuclear receptor subfamily 5, group A, member 2; *IL8RA*, interleukin-8 receptor A; *LSP1*, lymphocyte specific protein 1; *NXPE1*, neurexophilin and PC-esterase domain family member 1; *SLC39A11*, solute carrier family 39 (zinc transporter), member 11; *HNF4A*, hepatocyte nuclear factor 4-α; *UBASH3A,* ubiquitin-associated and SH3 domain-containing protein A; *IFNLR1*, interferon-λ receptor 1; *LCE3B*, late cornified envelope protein 3b; *IL36RN*, Interleukin-36 receptor antagonist; *STAT4*, signal transducer and activator of transcription 4; *IL17RD*, interleukin-17 receptor D *FBXL1*, S-phase kinase-associated protein 2; *IL4/IL13*, Interleukin-4/interleukin-13; *TNIP1*, TNFAIP3-interacting protein 1; *TRAF3IP2*, TRAF3-interacting protein 2; *DEFB4*, Defensin β, 4A; *IL23A,* interleukin-23; *IL22*, interleukin-22; *GJB2*, gap junction protein, β_2; *SETD1A*, SET domain-containing protein 1A; *CARD14,* caspase recruitment domain-containing protein 14; *SOCS3*, suppressor of cytokine signaling 3; *STARD6*, START domain-containing protein 6; *ILF3,* interleukin enhancer–binding factor 3; *CARM1*, coactivator-associated arginine methyltransferase 1; *SLC9A8,* Solute carrier family 9 (sodium/hydrogen exchanger), member 8; *RNF114*, ring finger 114 protein.

FIG 57.1 The six major families of human leukocyte antigen (HLA)-B27 subtypes (HLA- B*27:59, B*27:64, B*27:65 and B*27:94 represent truncated genes with deletions of most of exons 2 and 3 and are not included above) are denoted in relationship to the "parent" subtype HLA-B*27:05. The ethnic or geographic origin of the subtypes is indicated in parentheses next to the allele: EU, European; NA, North American; SA, South American; EA, East Asian; SEA, Southeast Asian; NEA, Northeast Asian; ME, Middle East; Afr, African; UK, British Isles; Tur, Turkish; Mex, Mexican mestizo. Where no parentheses are given, the origin of the cell line from which the sequence came is unknown. Most B27 subtypes have evolved through five patterns of evolution along geographic lines. The first group, with HLA-B*27:02-B*27:23 (and B*27:30), appears to have evolved in Europe and the Middle East, entails anywhere from one to seven amino acid substitutions in the first (α_1) domain, and has the second (α_2) domain identical to B*27:05. The second group, including HLA-B*27:04 as the most common allele, evolved in Eastern Asia and includes a uniform amino acid substitution in the α_1 domain and anywhere from one to seven substitutions in the α_2 domain. The third and fourth groups seem to have evolved directly from HLA-B*27:05, from mutations in either exon 2 or 3, respectively. The fifth group, including HLA-B*27:07 as its leading member, evolved in southern and eastern Asia, the Middle East, and Sardinia with patterned amino acid substitutions in the α_2 domain. Finally, the sixth group, with HLA-B*27:08 as its common member evolved largely in East Europe, has different characteristic pattern of amino acid substitutions in the α_2 domain. Notable exceptions include HLA-B*27:13, B*27:109 and B*27:112-27:115, which have amino acid substitution outside α_1 and α_2 in the membrane proximal (α_3) domain. (Data are derived from http://www.ebi.ac.uk/cgi-bin/imgt/hla/allele.cgi.)

proinflammatory target or receptor for humoral or cell-mediated autoimmune responses. However, it is not yet known whether HLA-B27 homodimer formation is specific for, or even correlates with, the presence of SpA; in fact, disease does not develop in most HLA-B27–positive individuals.

Other MHC Genes and SpA Susceptibility

HLA-B27 is not the only genetic factor involved in AS and SpA susceptibility (see Table 57.3). Fewer than 5% of HLA-B27–positive individuals in the general population become affected,[11,13] whereas SpA will develop in up to 20% of HLA-B27–positive relatives of patients with AS. Family studies have suggested that HLA-B27 contributes less than 40% of the overall genetic risk for SpA,[12] whereas the entire effect of the MHC is about 50%.[11,13]

HLA-B60, a serologically defined HLA specificity that correlates with *HLA-B*40:01* on DNA analysis, has been described as augmenting the risk for AS in both HLA-B27–positive and HLA-B27–negative individuals from Europe and Taiwan.[11,13] Other MHC genes have also been implicated in AS in addition to B27, although their identification is complicated by the tight

FIG 57.2 After transcription of the human leukocyte antigen (HLA)-B27 heavy chain on ribosomes, it is inserted into the endoplasmic reticulum (ER), glycosylated, and two pathways ensue. (A) The B27 heavy chain is retained through binding with calnexin and ERp57, folded into its tertiary structure, and bound to β_2 microglobulin. After that calnexin releases the complex and it is associated with calreticulum, which, in turn, chaperones the formation of the peptide loading on to the complex of heavy chain, β_2 microglobulin and antigenic peptide, via the TAP proteins and tapasin. The antigenic peptide is derived from intracellular proteins from viruses, bacteria, tumors, and so on, that have been degraded in proteasomes, and then the peptides are trimmed for optimal length for peptide loading by endoplasmic reticulum-associated aminopeptidases (ERAP1 and ERAP2). Then the trimolecular peptide complex (HLA-B27 heavy chain, β_2 microglobulin and peptide) travels through the Golgi apparatus (A1) to the cell surface, where the antigenic peptide is presented either to the α: β T-cell receptor on CD8 T lymphocytes or to the killer immunoglobulin (KIR) receptor on natural killer (NK) cells (A2); or (B) the HLA-B27 heavy chain misfolds in the ER, forming B27 homodimers and other misfoldings which are bound to the ER chaperone BiP. Then, they either (B1) accumulate there, causing either ER-associated degradation (ERAD) or a proinflammatory ER unfolded protein response (UPR); or (B2) the B27 homodimers migrate to the cell surface, where they either become antigenic themselves or present peptide to receptors on T cells and NK cells.

linkage disequilibrium found within the MHC, and many of the associations may reflect linkage to B27. These include the epithelial "stress" marker MICA, located adjacent to HLA-B27, which acts as a ligand for cells expressing a common activator NK receptor (NKG2D), as well as the tumor necrosis factor (*TNF*), heat shock protein (*HSP*)*-70*, *LMP-2* and *LMP-7*, *HLA-DRB1*01*, and *DRB1*04* alleles.[13] In addition, *HLA-DRB1*08* has been implicated both in susceptibility to uveitis in the setting of AS and to juvenile-onset AS.[1,13] In psoriasis, the primary MHC association is with HLA-Cw6 (*HLA-C*06:02*). Both *HLA-DRB1*04* and **07* alleles have been implicated in PsA. There is not a significant MHC association with IBD *per se*, although *HLA-DRB1*01:03* has been associated with enteropathic peripheral arthritis.[13]

Non-MHC Genes in Susceptibility to Spondyloarthritis

Recent genome-wide association studies (GWAS) in AS from the United Kingdom and North America[15,17] have implicated up to 70 genes in AS susceptibility (see Table 57.3). These genes fall into the following functional networks:

1. Genes involved in IL-17–mediated immunity (*IL23R*, *TYK2*, *IL6R*, *IL7R?*, *IL27*, *IL1R2/IL1R1*, *IL12B*, *JAK2*, *RORC*, *PTGER4*) (*Note:* Gene symbols are explained in the legend to Table 57.3.)

2. Genes involved in CD8 T-cell function (*RUNX3, EOMES, IL7R, ITGAL*)
3. Genes involved in peptide processing and presentation (*HLA-B, ERAP1, UBE2L3, NPEPPS, ERN1, ASAP2*)
4. Genes involved in microbial sensing (*CARD9, NOS2, NOD2, IRGM*)
5. Genes involved in nuclear factor (NF)-κB (NF-κB) activation (*TLR4, NOD2, NOTCH1, TNFAIP3*)
6. Others (*ZMIZ1, FCGR2A, KIF21B, SH2B3, TNFRSF1A, GPR65, SULT1A1, GPR35, BACH2, ICOSLG, NKX2-3*)

The most consistent (and best replicated) association is with ERAP1, which acts as a molecular ruler in the ER in trimming peptides processed in proteasomes to optimal length of nine amino acids for MHC class I binding and presentation. HLA-B27–negative patients with AS lack an association with ERAP1,[15] although an association with ERAP2 is seen.

A number of genes whose products are operative in the Th17 pathway have also been associated with AS susceptibility: the IL-23 receptor (*IL23R*), which pairs with the *IL12RB1* gene product to confer IL-23 (but not IL-12) responsiveness on cells expressing both subunits; prostaglandin E receptor 4 (*PTGER4*), which stimulates dendritic cell (DC) production of IL-23 and, in turn, Th17 expansion and is overexpressed in SpA synovium; signal transducer and activator of transcription 3 (*STAT3*), a key regulatory factor in Th17 responses; and IL-12β (*IL12B*), which encodes the IL12p40 protein, a component of both IL-12 and IL-23.

GWAS in psoriasis and PsA have identified over 60 genes implicated in disease susceptibility outside the MHC.[18] These include genes in common with those for AS (*IL23R, IL12B, CDKAL1,* and *ERAP1,* the last showing interaction with HLA-Cw6 similar to that seen with HLA-B27). Detailing all the non-MHC genes associated with psoriasis is outside the scope of this chapter. Non-MHC genes implicated in PsA susceptibility include *IL-1A,* as well as the *IL-2/IL-21* and the *IL-4/IL-13* gene complexes (both important in Th2-associated autoimmunity).

The first gene to be implicated in IBD susceptibility was *NOD2/CARD15,* which accounts for about 20% of CD susceptibility and whose protein product serves as a receptor for bacterial products in monocytes that transduces signals leading to NF-κB activation. A number of GWAS conducted since then have implicated over 130 genes in IBD susceptibility,[17] including 113 for CD and 100 for UC, and at least 83 shared genes between CD and UC. The autophagy 16-like 1 gene (*ATG16L1*), which is highly expressed in intestinal cell lines, is linked to CD susceptibility. DCs from patients with CD with susceptibility variants in *NOD2* or *ATG16L1* are deficient in autophagy induction, suggesting that these genes influence bacterial degradation and interact with the MHC class II antigen-presenting machinery. What is especially striking is the number of genes shared in common with the various types of SpA, suggesting a common pathogenesis.

Genes and Severity of SpA

Disease severity in AS also has a hereditary component. By defining severity on the basis of radiographic involvement, two genes have been identified in a large candidate gene study.[19] One was the gene for cyclooxygenase I (COX-I), the target of nonsteroidal antiinflammatory drugs (NSAIDs), the other for the receptor activator of NF-κB (RANK). No evidence was found for an MHC contribution to radiographic severity.

Infection

A role for triggering infections has been better documented in SpA than in most other rheumatic diseases. In developed countries, the most frequent type of ReA occurs following urogenital infections with *Chlamydia trachomatis* (endemic ReA). Postdysenteric ReA, more commonly encountered in "less technologically advanced countries," occurs after various *Shigella* and *Salmonella* (especially *S. typhimurium* and *S. enteriditis*), *Campylobacter jejuni* and *C. fetus,* and, in Europe, *Yersinia enterocolitica* species. Microorganisms implicated in ReA share common biological features: *(i)* They can invade mucosal surfaces and replicate intracellularly; and *(ii)* they contain lipopolysaccharide (LPS) in their outer membrane. Of particular note, antigens from *Salmonella, Yersinia,* and *Chlamydia* have been found in the synovial tissues and fluids of patients with ReA, often many years after the initial infection. Although only bacterial fragments of the enteric pathogens have been found, evidence for viable *C. trachomatis* and perhaps *C. pneumoniae* have been demonstrated in several studies. *Chlamydia* and other organisms have also been reported in the joints of healthy individuals, and this has led to questioning of the pathogenic significance of these findings. Other data, however, support the likelihood that bacterial persistence plays an important role in ReA, including the finding of specific IgA antibodies and synovial T-cell proliferation to the initiating infectious agent.

The Gut and Spondyloarthritis

In studies from Belgium and from Scandinavia, up to 50% of patients with AS have microscopic ileal inflammation seen on ileocolonoscopy. Moreover, two-thirds of patients with undifferentiated SpA have histological gut inflammation. Gut inflammation in AS appears to be immunologically related to that seen in CD. These observations have raised the speculation that the inciting event in the SpA may be a breakdown of the gut–blood barrier to intestinal bacteria, although such has yet to be proven. It has been established that patients with AS and their relatives have increased intestinal permeability compared with healthy controls.

The bacterial population inhabiting human intestines, referred to as the gut microbiota (Chapter 14), is a vast microbial community. The number of bacteria in the human gut outnumbers the cells in the body 10-fold, and they contain 100 times more genes than in the entire body.[20] In fact, there is a beneficial relationship between the gut microbiome and the human system. The human gut provides nutrients and the microbiome provides metabolic and physiological capacities, which possibly affect the education of the adaptive immune system. Many studies, from early antibody and fecal carriage studies suggesting a role for gut *Klebsiella pneumonia* in the pathogenesis of SpA (which has not been confirmed by modern sequencing studies)[20] to more recent findings showing an interplay between host genetics (*e.g.,* HLA-B27) and intestinal bacterial composition and others suggesting a link between intestinal dysbiosis and SpA, are suggesting that upsetting the homeostasis between the gut microbiome and the host immune systems.[20] This is clearly an area where more work needs to be done.

PATHOLOGY OF SPA

One of the biggest problems with studies of the synovium in SpA and PsA is that most lesions are examined late in the course of disease (*i.e.*, in the hips), and this only at joint replacement. Few data exist from early disease, and the difficulty with tissue access further complicates this.[21,22] For the most part, the synovium in SpA resembles that of rheumatoid arthritis (RA), with some notable differences. The synovium in SpA displays a tortuous vascular morphology compared with the rheumatoid synovium, which is linear and has diminished lymphoid aggregates. This may be caused by vascular endothelial growth factor (VEGF) and the angiogenic growth factor Ang2, the messenger RNA (mRNA) of which have been observed at higher levels in the synovium in PsA compared with RA. VEGF is particularly interesting because it can synergize with RANK ligand (RANKL) to induce bone resorption and also synergize with bone morphogenetic proteins to trigger bone formation, both processes typical of the altered bone remodeling seen in PsA and SpA.[21,22]

Increased production of the scavenger receptor CD163 by macrophages in both the lining and sublining layers is seen in SpA compared with RA.[20] Local production of soluble CD163 inhibits synovial T-cell activation, and levels of synovial CD163 fall with effective treatment. Increased expression of Toll-like receptors 2 and 4 (TLR2, TLR4) has been shown in SpA on CD163$^+$ peripheral blood mononuclear cells in patients with synovitis, which decreases with TNF-α blockade. This leads to the speculation that SpA represents an exaggerated inflammatory response of the innate immune system in genetically susceptible patients.[22]

Osteoclasts also appear to have a role and have also been observed at the bone–pannus junction in PsA. In addition, CD14$^+$ monocytes that are committed to becoming osteoclasts or osteoclast precursors are increased in the circulation of patients with PsA compared with healthy controls and decline rapidly following treatment with TNF antagonists. The clinical improvement is accompanied by an MRI-defined reduction of bone marrow edema.

Even fewer data exist on enthesitis (the enthesium being the insertion of tendons, ligaments, joint capsules, or fascia into bone). Pathological examination of enthesitis in AS demonstrates local inflammation, fibrosis, erosion, and ossification. Immunohistochemical staining for phosphorylated SMAD1/5 in entheseal biopsies of patients with SpA reveals active bone morphogenetic protein signaling.[21]

The pathology of psoriasis consists of an inflammatory cell infiltration in the dermis, with localized increased cytokine production and hyperproliferation of keratinocytes (Chapter 64). CD4 cells are prominent in the dermis, CD8 in the epidermis; Langerhans cells function as antigen-presenting cells (APCs). The synovium is infiltrated with CD8 T cells but demonstrates less pronounced intimal lining layer hyperplasia and fewer synovial T cells. It is more vascular than the synovium in RA, contains numerous B cells and macrophages, and has upregulation of adhesion molecules, such as intercellular adhesion molecule (ICAM)-1 and E-selectin, and overexpression of proinflammatory cytokines, such as TNF-α, IL-1β, IL-6, and IL-18.[22]

CLINICAL FEATURES

Ankylosing Spondylitis

Musculoskeletal Symptoms

KEY CONCEPTS

Clinical Features of Inflammatory Back Pain

- Low-back pain that is present every day for at least 3 months
- Age of onset <45 years
- Morning stiffness in the back lasting at least 30 minutes
- Pain that is relieved by exercise and worsened by rest
- Alternating buttock pain
- Relief with nonsteroidal antiinflammatory agents

The first symptoms of AS usually appear in adolescence or early adulthood and usually start before the age of 45 years. The hallmark of AS is the presence of inflammatory back pain,[5] a dull, persistent ache, usually in the buttocks or hips, that is worst in the early-morning hours (between 2 and 5 A.M.) and is associated with morning stiffness lasting >30 minutes (and sometimes several hours to all day). The pain is classically worsened by rest or recumbency and improves with activity. One important component of inflammatory back pain is the striking improvement that results from the use of NSAIDs (usually in high doses). Although the pain may be unilateral or intermittent at first (in fact, alternating buttock pain is a cardinal feature of the disease),[5] within a few months it usually becomes persistent and bilateral, and the lower lumbar area becomes stiff and painful.[4,5] Occasionally, the first symptom of AS comes from extraspinal sources, such as AAU, peripheral arthritis, or enthesitis, especially in patients with disease onset in childhood.

In patients with AS, the most commonly affected joints outside the spine are the hips (in up to 50% of patients),[22] with rapidly progressive destructive arthritis that necessitates joint arthroplasty at an early age. A characteristic radiographic finding is a fairly characteristic osteophytic collar that forms at the junction of the femoral head and the neck.[23] Peripheral arthritis other than in the hips and shoulders is uncommonly seen in patients with AS but, when present, is typical of that seen in other types of SpA, with an asymmetric oligoarthritis presenting predominantly in the lower extremities.

Chest pain, often pleuritic, can be seen in patients with AS as a result of involvement of the costovertebral and manubriosternal joints. This and progressive thoracic spinal involvement may result in fusion of the costovertebral joints, with loss of chest expansion and a mechanical restrictive ventilatory defect.

Enthesitis is a classic feature of AS and other SpA (Fig. 57.3). The most common (and most disabling) sites for enthesitis are in the foot, at the insertion of the Achilles tendon, and of the plantar fascia on to the calcaneus.[24]

Three physical measurements have been validated and recommended by an ASAS Working Group as useful for evaluating patients with AS specifically and with inflammatory back pain in general. The Schober test is measured as the increase with maximal forward spinal flexion with locked knees of a 10-cm segment marked on the patient's back with the inferior mark at the level of the posterosuperior iliac spines. The measured distance should increase from 10 cm to at least 13.5 cm in an adult. Chest wall expansion with inspiration is measured with a tape measure placed circumferentially around the chest wall

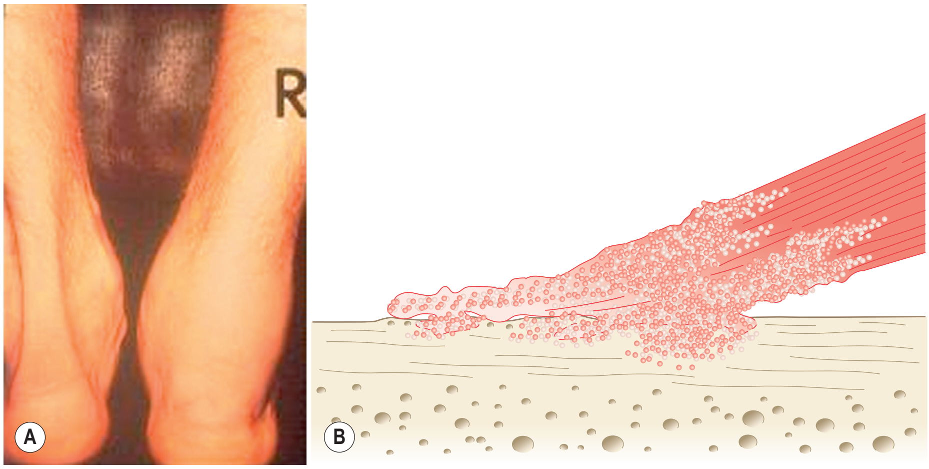

FIG 57.3 (A) Achilles tendinitis/enthesitis in a patient with reactive arthritis. (B) Schematic drawing of enthesitis, showing periosteal new bone formation, and subchondral bone inflammation and resorption.

at the fourth intercostal space. Normal chest expansion in an adult is >5 cm, although this may vary with age and gender. An occiput-to-wall distance of >2.5 cm is definitely abnormal. To measure the occiput-to-wall distance, the patient stands with the heels and buttocks touching the wall behind and with the knees straight. The patient is asked how far back he or she can move the head, still keeping the chin in the normal position. In the straight position, the distance between the posterior convexity of the occiput and the wall is measured to the nearest 0.1 cm. The better of two attempts is recorded. Anything >0 is regarded as abnormal.

Another commonly employed measurement is lateral bending. Here, the patient stands with the heels and back against the wall. There is no flexion of the knees or bending forward. The distance between the patient's middle fingertip and the floor is measured. The patient then bends sideways without bending the knees or lifting the heels. A second reading is taken, and the difference between the two is recorded. The best of two tries is recorded for the left and right sides. The mean of left and right gives the final result (in centimeters to the nearest 0.1 cm). Normal is >10 cm.

Extraarticular Manifestations

Uveitis. The anterior portion of the uvea consists of the *iris* and *ciliary body,* and the posterior portion is known as the *choroid.* Inflammation of the anterior uveal tract is known as *anterior uveitis* or *iritis* (Chapter 74). When the adjacent ciliary body is also inflamed, the process is known as *iridocyclitis.* AAU represents the typical uveitis found in SpA, occurring in up to 40% of patients with AS,[1] of whom approximately 90% are HLA-B27 positive (see Table 57.2).[1] Typically, AAU presents unilaterally with sudden onset, is self-limiting, and tends to be recurrent. Symptoms may include redness, pain, blurred vision, increased lacrimation, photophobia, and miosis. The diagnosis is characteristically confirmed by slit-lamp examination, which is also useful in monitoring response to treatment.

Prognosis is favorable in AAU, with resolution of symptoms within a few weeks. However, if treatment is delayed or inadequate, complications may occur; these include anterior synechiae (adherence of the iris to the cornea), posterior synechiae (adherence of the iris to the lens), which can lead to cataracts, and cystoid macular edema.[1] Rarely, increased ocular pressure is seen.[1] Macular edema has been shown to be the main factor that determines visual outcome in cases of uveitis.[1] Although AAU is the most common uveitis associated with AS, posterior uveitis has been reported and tends to be more severe, especially in those with coexistent IBD.[1]

Cardiac manifestations. The characteristic cardiac abnormalities in AS are aortitis, aortic regurgitation, and conduction abnormalities. Less commonly associated cardiac conditions include pericarditis, cardiomyopathy, and mitral valve disease. HLA-B27 is an important genetic risk factor for these cardiac conditions. Aortic regurgitation is well characterized and distinguished from aortic valvular dysfunction in other disorders. Three factors contribute to the development of incompetent aortic valves: dilatation of the aortic root, fibrotic thickening and downward retraction of the bases of the cusps, and inward rolling of the edges or margins of the cusps. Aortic regurgitation is present in 2–10% of patients with AS and increases in likelihood with greater disease duration.

Cardiac conduction abnormalities, including atrioventricular and intraventricular blocks, have been regarded as the most common cardiac complication in patients with AS. Complete heart block has been found in 1–9% of patients with AS. Electrophysiological studies show that the preferential level of block is in the atrioventricular node itself, which is in contrast to most cases of acquired complete heart block, where 80% are within or below the bundle of His. Rare complications include myocardial involvement, mitral regurgitation, and pericarditis.

Pulmonary manifestations. The incidence of pleuropulmonary involvement in AS is estimated to be 1%. The most frequently recognized manifestations are upper-lobe fibrosis, mycetoma formation, and pleural thickening. Fusion of the costovertebral joints caused by inflammation and ankylosis of the thoracic spine may lead to restrictive ventilatory impairment on pulmonary function testing. The upper-lobe fibrosis tends to be progressive. Another common finding is the presence of bilateral symmetric apical pleural thickening. Several recent studies have demonstrated that high-resolution computed tomography (HRCT) is more sensitive than chest radiography in detecting the presence of pulmonary abnormalities in AS, suggesting that pulmonary involvement in AS is more common than once thought. The clinical implications of these observations remain unclear as lung involvement in AS is usually asymptomatic.

Renal manifestations. Renal involvement in AS, although uncommon, can include secondary renal amyloidosis (AA type), NSAID nephropathy, and glomerulonephritis.

Osteoporosis. Measuring bone mineral density in patients with spondylitis is complicated by false increases in spinal density from dense syndesmophyte formation, leading some to recommend quantitative CT over standard dual-energy X-ray absorptiometry (DEXA) for bone mineral density measurements. Nevertheless, up to half the patients with long-standing AS have been reported as having osteopenia or osteoporosis,[25] which has been attributed to the impact of inflammation on bone remodeling as a result of aberrant activation of bone morphogenic protein and Wnt signaling. This may be further worsened by treatment factors and decreased mobility or physical activity, in addition to osteoclast/osteoblast imbalance.[25]

Spondylodiscitis and spinal fractures. An uncommon but well-recognized complication of AS is spondylodiscitis, a destructive discovertebral lesion also called *Andersson lesion.*[26] Typically, these lesions are confined to the thoracolumbar spine, sometimes with multiple-level involvement. Pain and tenderness localized to the affected disk are the most common presenting features of spondylodiscitis, although it can be asymptomatic and only detected on routine radiographic examination many years later. Spondylodiscitis usually occurs at an advanced stage of AS under the form of an erosive condition related to both mechanical factors and osteoporosis. However, early spondylodiscitis may occur as a result of the inflammatory process. Patients may or may not have a history of preceding trauma.

Even trivial falls can be catastrophic for AS patients, who are at risk for spinal fractures because of their spinal rigidity and osteoporosis. The estimated prevalence of vertebral fractures in AS varies from 4% to 18%. Fractures through the disk space, the weakest point in the ankylosed spine, are most common, with the cervical spine being the most frequently affected region, followed by the thoracolumbar junction, and may or may not be complicated by injury to the spinal cord, ranging from mild sensory loss to quadriplegia. Spontaneous atlantoaxial subluxation is also rarely seen.

Neurological manifestations. Neurological involvement in AS is most often related to spinal fracture, atlantoaxial subluxation, or cauda equina syndrome. The cauda equina syndrome in AS is characterized by a slow insidious progression and a high incidence of dural ectasia, although a rapid onset secondary to a traumatic event has been reported. It tends to be a late manifestation of AS, often when the disease is no longer active. The prevalence of neurological findings in cauda equina syndrome in AS is very high, presenting with a prodrome of sensory, motor, or reflex loss before the progression to sphincter disturbance. About half the patients have pain in the rectum or lower limbs that is presumably neurogenic in origin. Case reports have also been published about the occurrence of AS with a multiple sclerosis (MS)–like syndrome and transverse myelitis, although the association is not conclusive.

Fatigue and psychosocial manifestations. Fatigue is a common problem in AS and seems to be associated with more severe disease. Sleep disturbance has been reported to be as high as nearly 81% of female patients with AS and 50% of male patients. The disturbance is closely related to pain during the night characteristic of active disease. A high level of depressive symptoms has been reported in approximately one-third of patients with AS, with women reporting more depression than men. Pain was found to be a major determinant of depression for women but was of lesser importance for men.

AS in women. AS in women may not be as severe as it is in men and may present with isolated neck pain in the absence of typical back pain.[26] There tends to be a greater delay in the diagnosis of AS in women compared with that in men. Women tend to have less severe involvement of the spine, with peripheral joint involvement. A large review of the impact of AS on reproductive events on women concluded that AS did not adversely affect the ability to conceive, pregnancy outcome, or neonatal health.[27]

Reactive Arthritis

The classic triad of arthritis, urethritis, and conjunctivitis, representing what was formerly known as *Reiter syndrome,* is a presenting feature of only a minority of patients with ReA (comprising only a third of the cases in some series). In ReA, the clinical features are nowadays viewed more as a spectrum ranging from the classic triad to undifferentiated SpA. In fact, the manifestations vary among patients, depending on the genetic makeup, the triggering event, and the sequential immunological reaction.

Typically, the features start 1–4 weeks after a triggering event, frequently identified as an enteric or urogenital infection, but often the event passes unnoticed without any specific symptoms. The syndrome starts with constitutional symptoms, such as fatigue, malaise, and fever, and then is typically manifested by asymmetrical, additive lower-extremity oligoarticular inflammatory arthritis along with an array of different extraarticular features, including a sterile oligoarticular or monoarticular and asymmetrical arthritis of the lower extremities, especially knees, ankles, and, occasionally, hips. Upper-extremity involvement is encountered less commonly. Dactylitis occurs in the toes or fingers, resulting in the "sausage digits," which represent inflammation not only of the interphalangeal joints of the hands and feet but also of the surrounding soft tissue structures, including tendons and subcutaneous tissue.

Sacroiliitis and spondylitis are less common than peripheral arthritis, although inflammatory back pain does occur. Unilateral and bilateral sacroiliac involvement and even spondylitis occur, especially in those with chronic or long-standing disease. The most common sites for enthesitis are the Achilles tendon and plantar fascia insertions, although tenderness over the symphysis pubis, iliac crest, ischial tuberosity, greater trochanters, and thoracic cage ribs may also occur.

Mucocutaneous lesions may be difficult to distinguish from PsA, especially circinate balanitis and keratoderma blennorrhagica. Circinate balanitis is an ulcerative mucosal lesion over the glans or shaft of the penis that is demarcated by a serpiginous erythematous border. The lesion is usually painless and sterile unless a superimposed infection occurs. Keratoderma blennorrhagica is a painless desquamative psoriatic-like papulosquamous eruption and is sometimes referred to as *pustulosis palmoplantaris* and occurs on the palms and soles of the feet. Oral lesions have been described as shallow, painless ulcers or patches on the palate and tongue, or mucositis of the soft palate and uvula. Conjunctivitis and AAU also occur, as described in AS. Conjunctivitis may be unilateral or bilateral and is usually an early feature manifesting with irritation, erythema, and lacrimation. It is usually associated with a sterile discharge unless a superimposed infection occurs because of eye rubbing. It can be severe and occasionally progresses to episcleritis, scleritis, or keratitis. Other findings seen in AS, such as cardiac involvement, rarely occur. Although renal involvement is mainly described in the context of the urogenital triggering infectious process, sterile pyuria in conjunction with proteinuria and microscopic hematuria are sometimes encountered. Documented glomerulonephritis is rarely described.

Juvenile Spondyloarthritis

There are two clinical subsets of JSpA: *(i)* undifferentiated JSpA, which includes peripheral arthritis and enthesitis, primarily affects the lower limbs, may also present with sacroiliac tenderness and/or inflammatory spinal pain, and also includes isolated episodes of arthritis, enthesitis, tendinitis, dactylitis, and seronegative enthesopathy and arthropathy (SEA) syndrome[28]; *(ii)* differentiated JSpA (juvenile AS, PsA, IBD-related arthropathy) includes peripheral arthritis and enthesitis plus evidence of structural changes in juvenile AS (radiographic sacroiliitis, spinal disease, or tarsal ankylosis) and/or specific extraarticular symptoms (*e.g.,* psoriasis or IBD). SEA syndrome was originally referred to the combination of enthesitis and arthritis or arthralgia as an idiopathic disease or as part of a well-defined SpA.[27]

Psoriatic Arthritis

Skin involvement exhibits four clinical patterns.[29] The most common type is psoriasis vulgaris. Nearly as common is guttate psoriasis. The most severe type is the erythrodermic variety. Finally, pustular psoriasis is the type most closely associated with HLA-B27. Usually, the disease appears coincident with or after the onset of skin manifestations, although approximately 15–20% of patients will have preexisting arthritis. The joint disease likewise occurs in different subtypes, as defined by the Moll and Wright classification (Fig. 57.4), including oligoarticular, asymmetrical, polyarticular, symmetrical, distal interphalangeal (DIP)-predominant, spondylitis (sacroiliitis), arthritis mutilans, inflammation of DIP joints (often with nail involvement (≈80%)), dactylitis (“sausage digits”), and enthesitis.[26] Extraarticular features include nail pitting (which correlates best with DIP involvement) and uveitis (which occurs in some series as high as 33% but in most far less). Radiographically, large eccentric erosions are encountered.

Enteropathic Arthritis

The arthritis associated with IBD (enteropathic arthritis) is most commonly nondestructive and reversible. Two patterns have been recognized (Table 57.4). Type 1 is oligoarticular, involving the knees and ankles more than the upper extremities. It tends to resolve in <6 weeks. The second type has a polyarticular presentation, is more likely to involve the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints than the lower extremities, and is more likely to have a chronic course. The symptoms of peripheral arthritis tend to coincide with activity of the bowel disease in UC but not in CD. Total colectomy is associated with remission of arthritis in half the patients. In contrast, axial

TABLE 57.4 Extraintestinal Manifestations of Inflammatory Bowel Disease

Feature	Crohn Disease (%)	Ulcerative Colitis (%)
Peripheral arthritis	15	10
Axial arthritis	15–20	10–15
Septic arthritis	Rare	No association
Skin	<9	<1
Aphthous ulcers	Rare	8
Nephrolithiasis	<15	No association
Liver disease	3–5	7
Uveitis	13	4
Vasculitis	Takayasu arteritis	<5
Clubbing of fingers	4–13	1–5

TABLE 57.5 Frequencies of Different Symptoms and Signs in Patients With Undifferentiated Spondyloarthritis

Feature	Percent (%)
Demographic	
Males	62–88
Mean age at onset (years)	16–23
Clinical	
Low-back pain	52–80
Peripheral arthritis	60–100
Polyarthritis	40
Enthesopathy	56
Heel pain	20–28
Mucocutaneous involvement	16
Conjunctivitis	33
Genitourinary disease	28
Inflammatory bowel disease	4
Cardiac abnormalities	8
Laboratory	
Elevated erythrocyte sedimentation rate	19–30
Human leukocyte antigen (HLA)-B27 positive	80–84
Radiographic	
Sacroiliitis	16–30
Spinal radiographic changes	20

Adapted from Chen CH, Lin KC, Yu DT, et al. Serum matrix metalloproteinases and tissue inhibitors of metalloproteinases in ankylosing spondylitis: MMP-3 is a reproducibly sensitive and specific biomarker of disease activity. Rheumatol (Oxf) 2006; 45: 414–420.Table 56.6 Measurements of disease outcome in spondyloarthritis.

involvement may precede the development of IBD, has no gender predilection, and resembles the development of AS. The axial symptoms do not parallel activity of IBD. In addition to spondylitis, an isolated sacroiliitis occurs that is often asymmetric and not associated with HLA-B27.

Mucocutaneous complications of IBD include erythema nodosum, which occurs in fewer than 10% of those with CD and is rare in UC; pyoderma gangrenosum, seen in slightly over 1% of those with CD and rarely occurring in those with UC; and, rarely, erythema multiforme. Painful aphthous ulcers occur in about 8% of those with UC and are rare in CD.

The uveitis with IBD that is bilateral, posterior, insidious in onset, and/or chronic in duration contrasts with the uveitis associated with other types of SpA, which is predominantly anterior, unilateral, sudden in onset, and limited in duration. Only 46% of patients with uveitis associated with IBD are HLA-B27 positive, as opposed to 89% of the patients with SpA. Episcleritis, scleritis, and glaucoma are more common among patients with IBD than in those with SpA.

Undifferentiated Spondyloarthritis

Patients who do not meet criteria or clinical features of the "classic" spondyloarthritides are regarded as having undifferentiated SpA. Generally, at presentation, about 40% of patients will be classified as having undifferentiated SpA,[30] and the frequency of HLA-B27 reaches around 80% in Caucasians (Table 57.5). Follow-up studies suggest that over time about one-third will go into remission and more than half will develop a "classic" SpA, usually AS.[30]

LABORATORY INVESTIGATIONS

The most useful investigations in SpA come from musculoskeletal imaging, but some laboratory tests are informative.

Data on the correlation of erythrocyte sedimentation rate (ESR) and cross-reactive protein (CRP) in the assessment of disease activity in SpA show ambiguous results, although most studies suggest that CRP performs better. A recent literature review on the validity of ESR and CRP in AS concluded that ESR and CRP do not comprehensively represent the disease process and thus do not have the same validity as in RA.[13,30] Generally, it is felt that patients with peripheral joint involvement or with IBD more often have elevated ESR and CRP than patients with axial disease.[13] However, the presence of clinically active AS is not excluded by normal ESR and/or CRP levels. Synovial fluid does not differ in appearance or cytology from that of any inflammatory joint disease.

DIAGNOSIS

In most cases, SpA is largely diagnosed, or at least initially suspected, on clinical grounds. Current criteria for AS demand that the patient have radiographic sacroiliitis (at least grade II bilaterally or grade III unilaterally) in conjunction with clinical signs of inflammatory back pain and limitation of spinal mobility. However, given that up to 10 years can pass from the onset of inflammatory back pain and the development of radiographic sacroiliitis, many of those with inflammatory back pain might not have radiographic evidence of sacroiliitis. With the development of effective treatments (*i.e.,* anti-TNF blockers), criteria have been developed for earlier diagnosis of axial SpA that take into account recent advances in MRI scanning as well as the added benefit provided in HLA-B27 testing.[5,6]

Measures of SpA Activity and Severity

In the past few years, outcome measures have been developed and validated to quantitate disease activity and severity; these are summarized in Table 57.6. These instruments are extensively validated and easy to administer in clinical practice and have been shown to perform well in clinical trials. The Ankylosing Spondylitis Disease Activity Scale (ASDAS) has recently been developed to gauge disease activity.

TABLE 57.6 Measurements of Disease Outcome in Spondyloarthritis

Ankylosing Spondylitis

1) Disease activity
    (a) Bath Ankylosing Spondylitis Disease Activity Index (BASDAI)
    (b) Ankylosing Spondylitis Disease Activity Score (ASDAS)
    (c) Patient and Physician Global Assessments
2) Function
    (a) Bath Ankylosing Spondylitis Functional Index (BASFI)
    (b) Dougados Functional Index
3) Quality of Life
    (a) SF-36
    (b) Ankylosing Spondylitis Quality of Life Index (ASQOL)
    (c) ASAS Health Index
4) Metrometry
    (a) Schober test (lumbar flexion)
    (b) Chest expansion
    (c) Occiput-to-wall distance
    (d) Lateral bending
    (e) Bath Ankylosing Spondylitis Metrology Index (BASMI) lateral ending
5) Imaging
    (a) Standard radiography
    (b) Computed tomography
    (c) Magnetic resonance imaging
6) Assessment in Ankylosing Spondylitis (ASAS) 20
    (a) An improvement of 20% and absolute improvement of 10 units on a 0–100 scale in three of the following four domains:
        i. Patient global assessment (by visual analogue scale [VAS] global assessment)
        ii. Pain assessment (the average of VAS total and nocturnal pain scores)
        iii. Function (represented by BASFI)
        iv. Inflammation (the average of the BASDAI's last two VAS concerning morning stiffness, intensity, and duration)
        v. Absence of deterioration in the potential remaining domain (deterioration is defined as 20% worsening)

Psoriatic Arthritis

1) Arthritis
    (a) ACR response criteria
    (b) Psoriatic Arthritis Response Criteria (PsARC)
    (c) Ritchie Articular Index
2) Skin response
    (a) Psoriasis Area and Severity Index (PASI)
    (b) Target lesion score
    (c) Static global assessment
3) Quality of life (HAQ, SF-36, DLQI)
4) Radiographic

CLINICAL RELEVANCE

Utility of Human Leukocyte Antigen (HLA)-B27 Testing in the Evaluation of Inflammatory Back Pain and Spondyloarthritis

- Not indicated where the diagnosis is unquestionable, as it has little value in prognosis.
- Although patients with spondyloarthritis of African and Middle Eastern ancestry are more likely to be HLA-B27 negative, the finding of HLA-B27 in these patients has higher predictive value.
- Most useful in patients with either inflammatory back pain without radiographic changes or with other features of spondyloarthritis (unexplained lower extremity arthritis in a young adult, uveitis, etc.).
- If serological testing is used to ascertain HLA-B27, it must be ensured that the blood sample arrives in the laboratory within 24 hours of being drawn (false negatives will be caused by cell death).

Radiographic Imaging of Spondyloarthritis

Axial Spondyloarthritis

The bottom line in the diagnosis of AS is the demonstration of radiographic sacroiliitis (Fig. 57.5).[4] Two outcome instruments have been introduced in the assessment of disease damage and progression in AS: the Bath Ankylosing Spondylitis Radiographic Index (BASRI) and the modified Stokes Ankylosing Spondylitis Scoring System (mSASSS).[31] As a rule, these instruments have a low sensitivity to change (7.5% over 2 years), have been validated in long-duration disease only, and their predictive effect for disease activity is not yet ascertained.

One problem with radiographic imaging is the average decade-long interval from the onset of inflammatory back pain to the appearance of radiographic sacroiliitis.[5] The introduction of MRI imaging of the spine and entheses has allowed not only correct anatomical description of spinal structures but also differentiation of AS-related and unrelated inflammatory spinal lesions earlier than is possible with standard radiography.[32] MRI of the sacroiliac joints and spine is currently the only imaging tool to localize and quantify spinal inflammation accurately (Fig. 57.6) and is being developed as a measure of disease activity and treatment response.

Psoriatic Arthritis

PsA has some characteristic radiographic manifestations, including asymmetrical involvement, involvement of the DIP joints, and the classic "pencil-in-cup" deformities. Also seen are periostitis, bony ankylosis, and bony erosions with new bone formation. Radiographic severity is quantitated by the modified Sharp scoring method used in RA.

The measures used in PsA to assess disease severity include the ACR response criteria, the Psoriatic Arthritis Response Criteria (PsARC), which entail improvement in at least two of the following four criteria: *(i)* physician; and *(ii)* patient global assessments (on 0–5 visual analogue scales); *(iii)* tender and swollen joint scores (>30% improvement), with improvement in at least one of these two joint scales; and *(iv)* no worsening in any criteria. The Ritchie Articular Index is also used. The Psoriasis Area and Severity Index (PASI) is used to assess the extent of skin involvement, as well as general measures, such as the target lesion score, and the static global assessment. The PASI is a composite index of skin disease severity, including an overall evaluation and quantitation of the extent of scaling, erythema, and induration weighted: *(i)* by severity; and *(ii)* by body surface area. A target lesion is a single lesion >2 cm in diameter that is evaluated over time by a dermatologist and is graded for size, elevation, erythema, and scaling.

DISEASE COURSE AND PROGNOSIS

Ankylosing Spondylitis

AS significantly impacts the lives of those affected. Recent data suggest that patients with AS are more likely to be work disabled or even not participate in the labor force compared with population controls, especially in older patients and in those with longer disease duration. Moreover, in the same study, patients with AS were more likely to have never married or to be divorced. Women with AS were less likely than expected to have had children.[32]

Although AS is a chronic condition that can frequently have an unpredictable course, some studies suggest that those with higher levels of disease activity early in the course of the disease are more likely to have active disease in the future (Fig 57.7).[33]

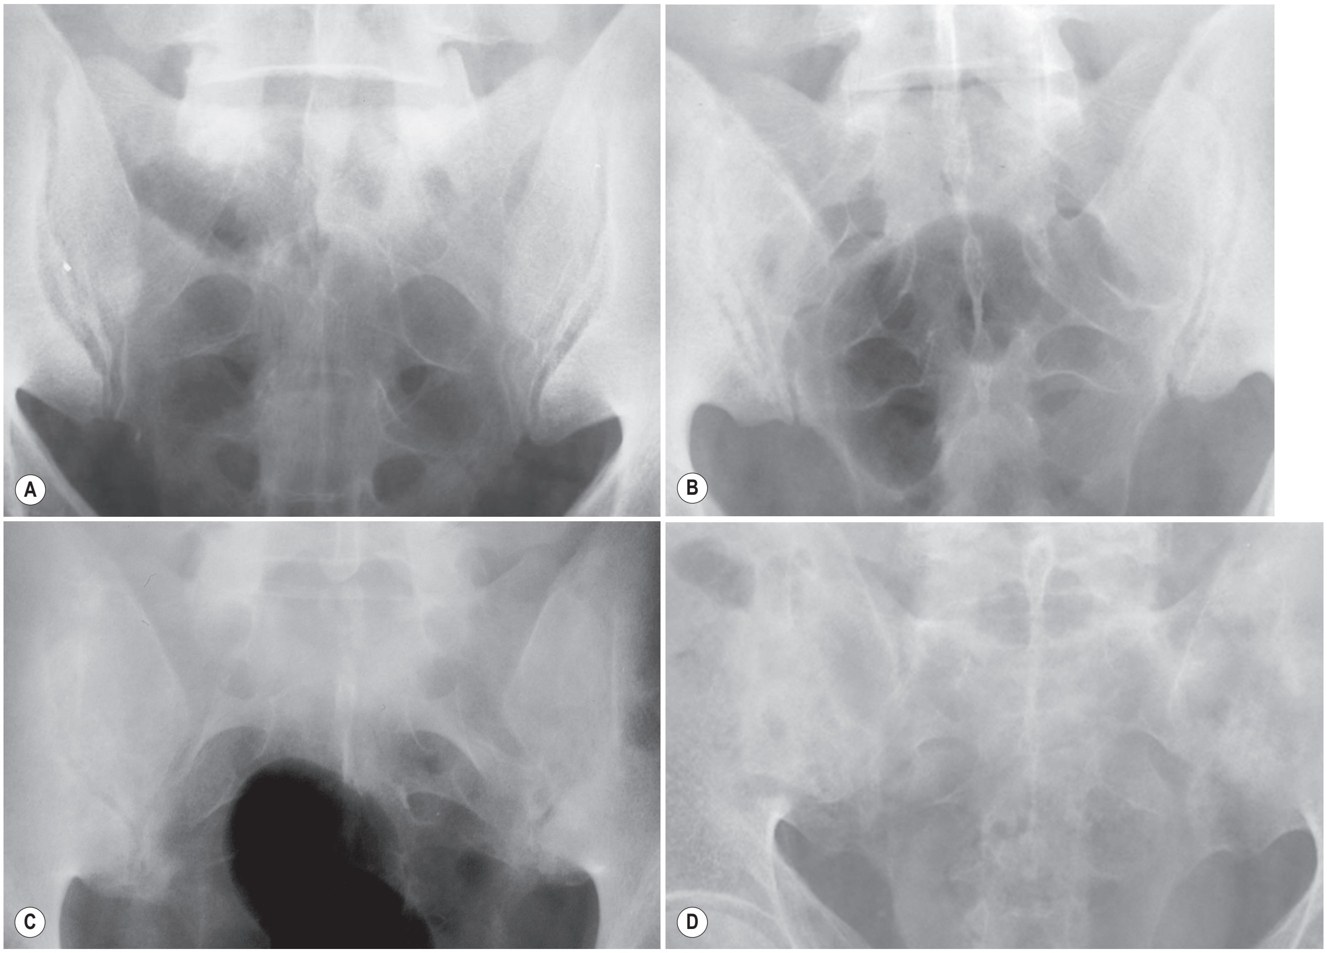

FIG 57.5 Grading of radiographic sacroiliitis, including (A) grade 0–1 (normal); (B) grade 2–3, with sclerosis and small erosions; (C) advanced grade 3, with joint space narrowing and large erosions; and (D) grade 4 (total sacroiliac fusion).

Hip involvement is a predictive factor for severe disease.[32] Other factors that may suggest severe disease and severe outcome include ESR >30 mm/hr; unresponsiveness to NSAIDs; limitation of lumbar spine; "sausage" digits; oligoarthritis; or onset at <16 years.[33] Longitudinal studies in patients with AS revealed that deformities and disability occurred during the first 10 years of disease and correlated significantly with the occurrence of peripheral arthritis, radiographic changes of AS in the spine, and the development of "bamboo" spine.[33]

Significant risk factors for work disability from several studies include older age, longer disease duration, lower level of education, reduced physical functioning, pain, and more physically demanding jobs. Patients with AS have an overall frequency of disability and economic costs similar to that of RA, with a threefold greater rate of disability than the general population, a higher rate of sick leave episodes (up to 50% more), and an overall 8% loss of productivity.[34] Moreover, a growing body of data has shown that patients with AS are at risk for early mortality as a result of cardiovascular disease.[35] However, the impact of newer agents, such as anti-TNF and anti–IL-17 drugs, on the natural history of this disease remains to be seen.

Reactive Arthritis

Early studies of outcome in ReA suggested a relatively poor prognosis. More recent studies, however, have found that, in general, the prognosis of ReA is fairly good.[36] Most cases appear to remit within 6 months of onset. Given the introduction of highly effective biological agents, such as anti-TNF blockers, it is likely that the long-term prognosis in ReA will improve even further.

Psoriatic Arthritis

Recent studies—although before the introduction of biological treatments—showed that the prognosis of PsA is worse than previously suggested.[29,37] In one large cohort, 40–57% of patients had deforming arthritis, 17% had[3] five deformed joints, and up to 19% of patients had disability. Overall, more rapidly progressive disease was associated with a greater number of actively inflamed joints, the early use of disease-modifying agents, and the presence of HLA-B27 and -B39. Patients with PsA have also been shown to have increased mortality, which is associated with a high ESR, high "advanced" medication use, and early radiographic damage.

Juvenile Spondyloarthritis

Although not extensively studied, the prognosis in JSpA is guarded.[28] Available data suggest that children with disease activity for >5 years are more likely to be disabled. In fact, the probability of remission was only 17% after 5 years of disease. Nearly 60% of children with JSpA have moderate to severe limitation after 10 years of disease. What is not clear is the extent to which the

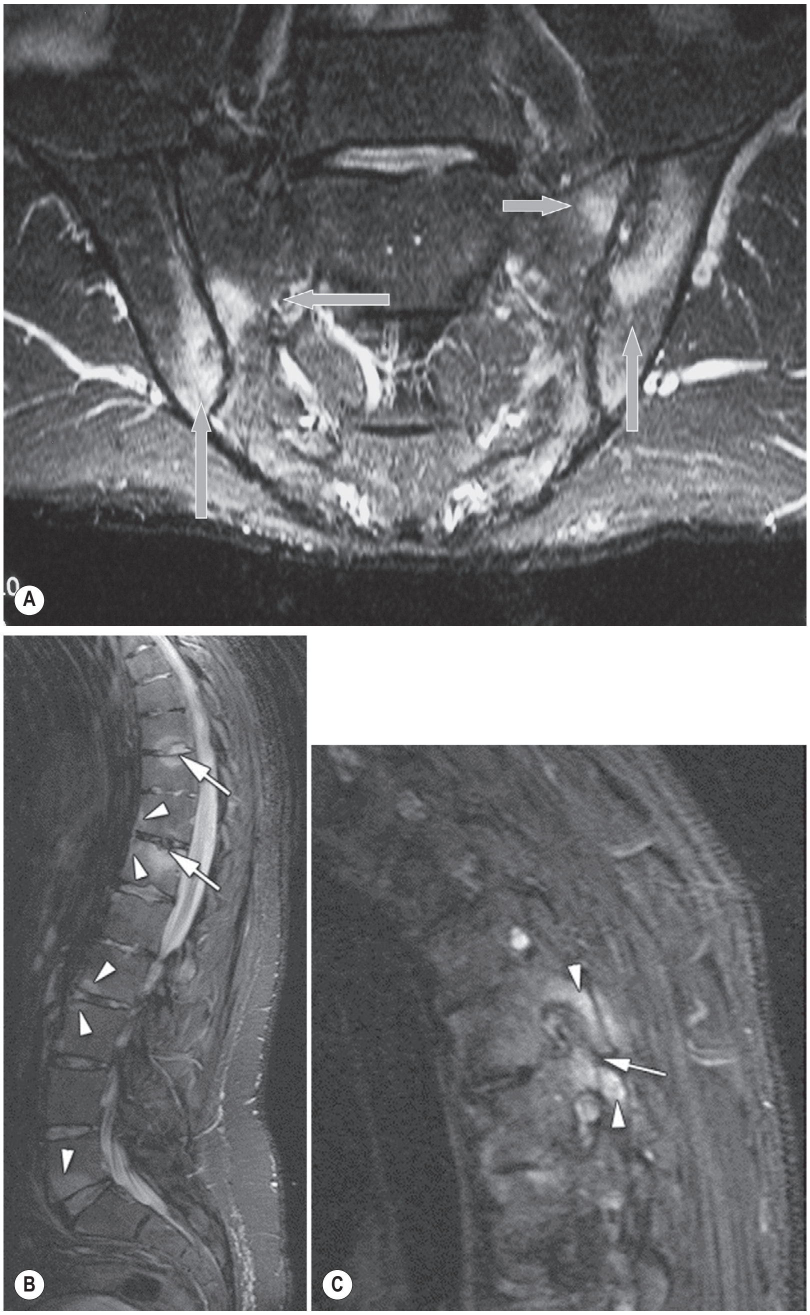

FIG 57.6 (A) Magnetic resonance imaging (MRI) of the sacroiliac joints, showing areas of marrow edema (indicated by arrows) on STIR sequences. (B) Lateral spine, showing enhancement of the insertion of the annulus fibrosis on the disk (arrowheads) and subchondral bone (arrows). (C) Involvement of the subchondral bone of the apophyseal joints.

outcome in juvenile-onset AS is different from that in adult-onset disease.

TREATMENT

Recent guidelines for treatment of SpA have been put forth by the American College of Rheumatology and the European League against Rheumatism based on current literature and clinical trials (Table 57.7).[38,39]

Patient Education and Physiotherapy

A great deal of educational information is available for patients (http://www.spondylitis.org and http://www.arthritis.org). Unsupervised recreational exercise improves pain and stiffness, and back exercise improves pain and function in patients with AS and other types of SpA, but these effects differ with disease duration. Health status is improved when patients perform recreational exercise at least 30 minutes per day and back exercises at least 5 days per week.

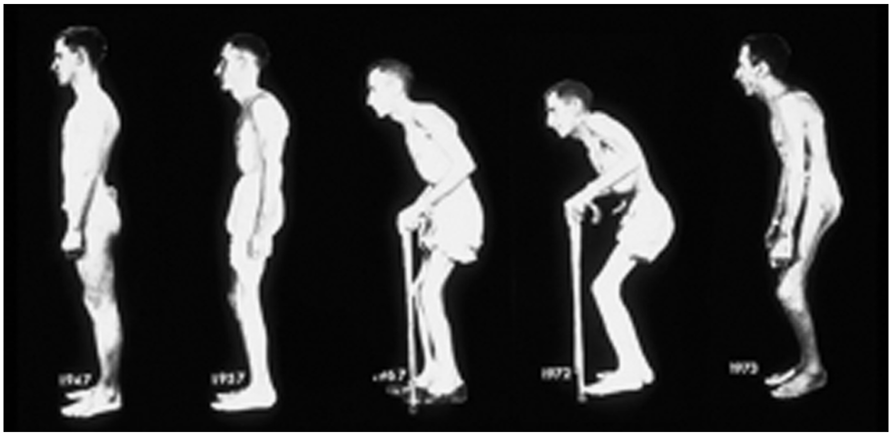

FIG 57.7 The "classic" course of ankylosing spondylitis, showing disease progression from shortly after disease onset in 1947 until just before the patient's death in 1973. The slight improvement between 1972 and 1973 was as a result of his having undergone total hip arthroplasties.

TABLE 57.7 Treatment of Spondyloarthritis

- Patient education
- Physiotherapy
- Medications
- Nonsteroidal antiinflammatory drugs
- Disease-modifying antirheumatic drugs
    - Sulfasalazine (especially for peripheral arthritis)
    - Methotrexate (especially for psoriatic arthritis, psoriasis)
    - Leflunomide
- Corticosteroids
    - Systemic
    - Intraarticular, intralesional
- Biological agents
    - Tumor necrosis factor blockers
    - Interleukin (IL)-17/-IL-23 blockers
- Treatment of osteoporosis
- Surgery
- Hip replacement
- Corrective spinal surgery

Medical Treatment

Nonsteroidal Antiinflammatory Drugs

NSAIDs remain the starting point of treatment, and many patients will attain satisfactory symptom control with these agents alone. There are no strong data to suggest the superiority of any specific NSAID in patients with SpA. NSAIDs when taken regularly (not on an as-needed basis) and at full antiinflammatory doses retard the radiographic progression of AS,[40] an observation that has recently been replicated.[41] COX-2 antagonists are recommended mainly for patients with proven peptic ulcer disease. Of concern is the association of the use of NSAIDs with flares of colitis, suggesting they should be used with care in this setting.

Disease-Modifying Antiinflammatory Drugs

Sulfasalazine. The efficacy of sulfasalazine in the treatment of peripheral joint involvement in AS and other SpA has been shown in several controlled trials, including two large multicenter studies in the United States and France.[42] It is not efficacious in axial disease. Coincident with improvement in peripheral arthritis is a fall in acute-phase reactants, such as the ESR and CRP.

THERAPEUTIC PRINCIPLES

Treatment Principles for Medical Management of Spondyloarthritis

- Patient education, regular exercise, smoking cessation, and physiotherapy should be initiated early in the disease course.
- Nonsteroidal antiinflammatory drugs (NSAIDs) remain the "first-line" treatment.
- Disease-modifying antirheumatic drugs (DMARDs: sulfasalazine, methotrexate) are used for peripheral arthritis.
- Intraarticular/intralesional corticosteroid injections are administered.
- Biological (anti–tumor necrosis factor [TNF], anti–interleukin-17 [IL-17] agents) for axial disease refractory to NSAIDs, peripheral arthritis refractory to DMARDs, and entheseal lesions refractory to NSAIDs.
- It is important to remember to treat coexistent/complicating conditions (inflammatory bowel disease [IBD], psoriasis, osteoporosis, premature atherosclerosis).

Other DMARDs. Although less well studied than sulfasalazine, methotrexate has been shown to be effective in some but not all studies of peripheral arthritis and psoriasis in patients with AS and other SpA. Its efficacy in treating axial SpA has not been established.

The use of leflunomide in patients with SpA has not been well examined. Limited data suggest that it may be useful in the treatment of peripheral joint involvement in SpA as well as PsA, although not for axial involvement. Apremilast, an oral phosphodiesterase 4 inhibitor, has been shown to be effective in psoriatic arthritis but not in AS.[43]

Corticosteroids. Although not well studied in patients with AS, many clinicians add low-dose glucocorticoids to the management of active SpA where NSAIDs or DMARDs fail to achieve a satisfactory response. On occasion, pulse steroids have also been utilized. Given the lack of controlled data as to their effectiveness, the side effects of long-term glucocorticoid therapy (including osteoporosis, a major cause of morbidity in AS patients, and possible worsening of psoriasis), and the emergence of more effective treatments, their use is not recommended unless more effective treatments are not available.

Intraarticular/Intralesional Corticosteroids

Intraarticular and peritendinous injections of depot steroid preparations are frequently employed by clinicians for symptomatic relief of local flare-ups, although they have not been extensively studied in controlled trials. Injecting around the Achilles tendon is generally not recommended because of the risk of tendon rupture.

Antibiotics

Early data suggested that a 3-month course of antibiotics in the acute phase after disease onset may have a beneficial effect on the course of ReA, specifically in those with *Chlamydia trachomatis*–triggered ReA, but not in other patients. Recent long-term follow-up data, however, suggest that tetracycline treatment did not change the natural history of the disease. In another recent study, however, a 6-month course of azithromycin and rifampin in the acute phase was found to have a beneficial effect on the long-term prognosis, although this has not been reproduced in all studies.[44] It is clear that early antibiotic therapy for chlamydial genital infections can prevent ReA, although the same is not true for enteric pathogens. For patients at risk for enteric infections and ReA, prophylactic antibiotics should be considered. There is no evidence that antibiotics have any place in the management of other SpA.

TNF-α Blockers

This category of medications has been shown to be effective in controlling inflammation and improving function in patients with AS (Table 57.8). The use of TNF blockers in the treatment of AAU is less clear, however. Recent data suggest they are useful, at least those comprising monoclonal antibodies (mAbs).[1] Currently five agents that have been approved for use by the Food and Drug Administration (FDA) are in clinical use for the treatment of AS in the United States, including infliximab, an infusion of a chimeric mAb to TNF-α (infliximab) at 5 mg/kg of infliximab every 6–8 weeks; etanercept, given 50 mg subcutaneously weekly; adalimumab, which is used at a dose of 40 mg administered subcutaneously every other week; golimumab, at a dose of 50 mg administered subcutaneously monthly; and certolizumab, at either 200 mg administered subcutaneously every other week[45] or 400 mg once a month. The onset of action is quite rapid, usually following the first infusion or injection. These agents are effective also in PsA[46] and axial SpA.[45,47] Improvement was seen not only clinically but also radiographically, with clearing of lesions suggestive of disease activity on MRI, and, in studies extending >4 years, radiographically. Although earlier studies following up patients for 2 years did not demonstrate that anti-TNF agents affect radiographic severity in AS, data from observational cohorts from North America and Europe spanning longer periods have shown they do, indeed, slow radiographic progression, especially in those with shorter disease duration treated for an extended period.[48]

TABLE 57.8 International Assessment in Ankylosing Spondylitis (ASAS) Consensus Statement for the Use of Anti–Tumor Necrosis Factor (TNF) Agents in Patients With Ankylosing Spondylitis (AS) and Axial Spondyloarthritis (ASpA)*

1. For the initiation of anti–TNF-α therapy:
    (a) A diagnosis of definitive AS by modified NY criteria or axial SpA by ASAS criteria
    (b) Presence of active disease for at least 4 weeks as defined by both a sustained Bath AS Disease Activity Index (BASDAI) of at least 4 *and* an expert opinion based on clinical features, acute-phase reactants, and imaging modalities
    (c) Presence of refractory disease defined by failure of at least two nonsteroidal antiinflammatory drugs during a single 4-week period, failure of intraarticular steroids if indicated, and failure of a disease-modifying antirheumatic drug, preferably sulfasalazine, in patients with peripheral arthritis
    (d) Application and implementation of the usual precautions and contraindications for biological therapy
2. For the monitoring of anti–TNF-α therapy: both the BASDAI and the ASAS core set for clinical practice should be followed regularly
3. For the discontinuation of anti-TNF-α therapy: in nonresponders, consideration should be made after 12 weeks' treatment. Response is defined as improvement of:
    (a) At least 50% or 2 units (on a 0–10 scale) of the BASDAI
    (b) Expert opinion that treatment should be continued

*van der Heijde D, Sieper J, Maksymowych WP, et al. 2010 Update of the international ASAS recommendations for the use of anti-TNF agents in patients with axial spondyloarthritis. Ann Rheum Dis 2011; 70 :905–8.

Interleukin-17 Blockers (Secukinumab)

Secukinumab is an anti–IL-17A mAb that has been shown to control the symptoms of active AS in one phase II trial and two phase III clinical trials[49] and has been approved by the FDA. The impact of this medication on other disease features, such as radiographic progression, remains to be determined.

Surgical Treatment of AS Complications

Because the hip is the joint most commonly involved in patients with AS, total hip arthroplasty is the most common surgical procedure.[24] Heterotopic new bone formation may be a potential problem.

Limited prevalence data suggest that patients with AS, even those with mild disease, are at increased risk for vertebral fracture, often resulting in neurological compromise.[25] In general, halo vest immobilization is recommended. Surgical intervention may be necessary when neurological impairment is seen. The fixed kyphotic deformities seen in patients with advanced AS are of considerable distress to patients and may result in substantial functional impairment. A small minority of patients with AS will seek surgical correction of their spinal deformities. In general, open, polysegmental, and closing wedge osteotomies are employed. Loss of correction is seen least commonly in closing wedge osteotomy. In a meta-analysis of the literature between 1945 and 1998, an average correction of 37°–40° was seen, with perioperative mortality of 4% as a result of pulmonary, cardiac, and intestinal problems.[50]

CONCLUSIONS AND RESEARCH OPPORTUNITIES

ON THE HORIZON

Research Opportunities in Spondyloarthritis (SpA)

- Improved understanding of pathogenetic mechanisms of SpA
- Elucidation of the roles of non–major histocompatibility complex (MHC) genes in SpA
- Definition of the link between gut inflammation and ankylosing spondylitis (AS) triggering
- Improved measures of treatment outcomes
- Advances in biological therapies of SpA

Progress has been made in the classification and epidemiology of SpA, particularly in the elucidation of the factors involved in SpA pathogenesis in recent years. It has become clear that HLA-B27, the primary genetic factor, functions in a variety of roles, including "classic" antigen presentation. GWAS have identified a vast number of susceptibility genes for SpA, including those in the antigen processing and Th17 pathways, some of which are shared by some or all SpA and others that are specific for a given disease. Their specific roles and how they interact are currently being elucidated, and with larger-scale studies and whole-genome sequencing, new candidates are being identified.

However, less progress has been made with regard to nongenetic factors. Despite what has been learned in ReA, no infectious trigger has been identified in AS (and, in fact, there might be no specific trigger). The link of gut inflammation to the triggering of AS is strongly suggested by data thus far, especially its possible link to the gut microbiome. This is clearly an area of further investigation.

Novel outcome measures have been developed that will help provide better care to patients, especially in the area of imaging. The advances in treatment have been most exciting, particularly the development of biological treatments, which hold promise for a better future for patients with these diseases.

Small- and Medium-Vessel Primary Vasculitis

Raashid Ahmed Luqmani, Ana Águeda, Lorraine O'Neill

Small- and medium-vessel vasculitides are characterized by inflammation of the blood vessel wall resulting in end organ failure or irreversible tissue damage and necrosis. In some cases, this is relatively trivial and may lead to minor inconvenience for the patient. However, in many forms of vasculitis, the consequences of rapid onset of ischemia and occlusion of blood vessels are devastating, leading to organ failure and death.

The distinction between small- and medium-vessel vasculitis entities is arbitrary, with three main patterns of vasculitis: small, medium, and large. Although there is merit in this classification, there are different patterns of involvement for patients with predominantly small-vessel involvement (characterized by capillaritis) compared with, but overlapping with, patients with medium-vessel involvement typified by small arteriolar inflammation. For example, in the kidney, small-vessel involvement leads to inflammation of glomeruli (glomerulonephritis); by contrast, medium-vessel inflammation of renal arterioles results in infarction of the kidney with tissue loss. Therefore patterns of disease are well recognized, with typical dominance of kidney, lung, and upper airway involvement in patients with granulomatosis with polyangiitis (GPA), previously termed Wegener's granulomatosis. In microscopic polyangiitis (MPA), there is lack of upper airway involvement but significant renal and lung involvement. Finally, in eosinophilic glomerulonephritis with polyangiitis (EGPA), previously termed Churg-Strauss syndrome, the pattern of clinical involvement is dominated by upper and lower airway disease combined with neurological (peripheral nerve) features. These three entities are grouped together by their association with the presence of antineutrophil cytoplasmic antibody (ANCA) in most, but not all, cases.

In patients with polyarteritis nodosa (PAN), one of the main forms of medium-vessel vasculitis, the most characteristic findings are bowel ischemia or infarction and peripheral neuropathy. In a childhood onset form of medium-vessel vasculitis (Kawasaki disease [KD]), the clinical features are diverse and include mucocutaneous inflammation and systemic upset with fever, and in 2–4% of cases, there is coronary artery dilatation and/or aneurysm development, which can potentially rupture, leading to fatal consequences.[1]

The diversity of different forms of vasculitis with overlapping features suggests that the underlying mechanisms are varied, but some pathways are likely to be shared. This is reflected in treatment approaches, which, with some exceptions, are often very similar across diseases.

EPIDEMIOLOGY

Despite improvement in our understanding of the epidemiology of the systemic vasculitides, patients are often not diagnosed as having vasculitis for extended periods. The discovery of antibodies to neutrophil cytoplasm (ANCA) and their association with small-vessel vasculitis has improved recognition.[12] Greater awareness of vasculitis may be a factor that explains an apparent increase in incidence from 1.5/million/year to 6.1/million per year.[2] The incidence of ANCA-associated vasculitides (AAV) is 10–20 new cases per million per annum.[3] In southern Europe, the number of cases of MPA is greater than those of GPA.

MPA is also more common than GPA in Japan. ANCA directed against myeloperoxidase is the predominant antibody detected in patients with AAV in Japan, whereas autoantibodies directed against proteinase 3 (PR3) are rarely seen in Japanese patients but are the most frequent ANCA antibody in patients in northern Europe.

The epidemiology of EPGA is less well understood compared with other forms of AAV. EGPA is characterized by an elevated eosinophil count in patients with late-onset asthma. Around 50% of cases have ANCA, usually directed against myeloperoxidase. EGPA is less common than either GPA or MPA, with an incidence of around 0.6/million per annum. There is a potential overlap condition called *hypereosinophilic syndrome* (HES), and it is not clear whether some cases of HES are really cases of EGPA, or vice versa. Indeed, if patients are ANCA negative, distinguishing the two conditions can be challenging.[4] Furthermore, because bronchospasm is a key feature of EGPA, it is possible that some cases of asthma, an extremely common condition, may, in fact, represent mild forms of EGPA. This has been brought more to light in cases of drug-induced EGPA, specifically in the setting of the use of montelukast, a leukotriene inhibitor, as a treatment for moderate to severe asthma. It has been suggested that these patients probably had underlying EGPA, which had previously been suppressed with systemic glucocorticoids, but when these were withdrawn, features of EGPA became more apparent.

AAV typically affects older individuals in their 60s or 70s but can occur at any age. Most patients survive their initial illness as a result of effective immunotherapy, and therefore the prevalence of these diseases is growing. In southern Sweden, estimates of prevalence are 160 per million (95% confidence interval [CI] 114–206) for GPA, 94 (58–129) for MPA, 31 (11–52) for PAN,

TABLE 58.1 **Diagnosis, Incidence and Prevalence in KD, PAN, AAV and Leukocytoclastic Vasculitis**

Diagnosis	Incidence	Prevalence	References/ Reviews
KD	For children <5 years old: 2431/million (Japan) 1131 per million (Korea) 690 per million (Taiwan) 36–185/million (Italy)	Not applicable	Makino N, et al., 2015[96]
PAN	3.6/million adults	2.6–14/million adults	Nesher G, et al., 2016[5] Mohammad AJ, et al., 2007[4]
ANCA-associated vasculitides	9.5–16/million/year (Germany) 22.6/million (Japan) 21.8/million (UK)	149/million	Reinhold-Keller E, et al., 2005[10] Herlyn K, et al., 2014[11] Fujimoto S, et al., 2011[94]
Leukocytoclastic vasculitis	45/million (equal male and female; increased incidence with age)	No data	Arora A, et al., 2014[7]

AAV, ANCA-associated vasculitis; *ANCA,* antineutrophil cytoplasmic antibody; *KD,* Kawasaki disease; *PAN,* polyarteritis nodosa.

and 14 (0.3-27) for EGPA.[6] However, these are based on a relatively small population size and are higher than those reported from a Spanish series, where the prevalence of all forms of AAV was under 45/million.

The two main forms of medium-vessel vasculitis are PAN and KD. PAN is extremely rare. There is very wide misconception among many physicians that PAN is the most common form of vasculitis, and this is partly encouraged by the older literature, which refers to all forms of vasculitis as PAN (initially called *periarteritis nodosa* and subsequently *polyarteritis nodosa*). In fact, the majority of patients with so-called PAN probably did not have this disease but were more likely suffering from one of the forms of small-vessel vasculitis, particularly MPA and GPA. PAN has been associated with infection, especially hepatitis B and hepatitis C. The epidemiology of hepatitis B has been transformed by effective immunization; as a result of this, hepatitis B associated with PAN is now an extremely rare disease. Recent figures suggest an incidence of PAN of 0.6–3.6/million adults.[5]

KD is most common in children under the age of 5 years but can occur in older children and young adults, in which case it is more difficult to diagnose because it is not suspected. In a recent Italian study of children under the age of 14 years, the incidence rate was 17.6/100 000 children under the age of 5 years, with a slight increase in reported cases during spring and winter compared with other times of the year. This is a slightly higher incidence rate than previously reported by other studies in Europe with a range of 3.6–15.2/100 000 children under the age of 5 years. Earlier figures from a large-scale study from the United States of over 6000 children admitted to hospital because of KD suggested that the peak age of onset was 1 year, and children under the age of 2 years accounted for over a third of all cases. The under-5-year incidence was reported as 8.1 per 100 000 children in 1988, rising to 18.5 per 100 000 children in 1997, similar to the recent Italian experience. Males were more commonly affected than females (approximately 60% males); there was no obvious seasonal variation. In a recent nationwide hospital survey in Japan, however, the incidence rates for KD during 2011 and 2012 were over 2400 cases per million children under the age of 5 years. The higher incidence of KD in patients of Japanese ethnicity appears to be independent of their geographical location. In fact, during 1996–2006, the average annual incidence of KD in Japanese American children in Hawaii was 210.5/100 000 children, in contrast to the rate for Caucasian children in Hawaii of 13.7/100 000, similar to the rate of 12.0/100 000 among Caucasian children in continental United States.[6]

Leukocytoclastic skin vasculitis is one of the more common forms of small vessel vasculitis occurring with an annual incidence of about 45/million (Table 58.1).[7] Less than a third is found in association with immunoglobulin A (Henoch-Schönlein purpura [HSP], or IgA vasculitis). IgA vasculitis is very common in children and is usually self-limiting; annual incidence is 100–200/million children ≤17 years of age.[8] By contrast, this is a much less common disease in adults (around 13/million/year).

Cryoglobulinemic vasculitis is strongly associated with hepatitis C, and its epidemiology is likely to mirror the prevalence of the hepatitis C virus (HCV). However, there are no published incidence and prevalence figures for cryoglobulinemic vasculitis itself.

PATHOGENESIS OF AAV

The Pathogenic Role of ANCA in GPA and MPA

There is some evidence that ANCA play a significant role in the pathogenesis of GPA, MPA, and EGPA. Based on the immunofluorescence pattern, different forms of ANCA can be distinguished, but only two are of direct clinical relevance: cytoplasmic c-ANCA (corresponding to antibodies directed against PR3) and perinuclear p-ANCA (predominantly corresponding to antibodies directed against myeloperoxidase [MPO]). p-ANCA can also be directed against other antigens, including bactericidal/permeability-increasing (BPI) protein, lactoferrin, human neutrophil elastase (HNE), cathepsin G, and azurocidin, but their clinical significance is not well characterized. Although ANCAs are associated with vasculitis, titers are not reliable for monitoring disease status because there is no clear relationship with remission or relapse.

Transfer of MPO-ANCA in humans (maternal–fetal route) and animal models (necrotizing pauciimmune glomerulonephritis after passive transfer of purified antibody or splenocytes from MPO-deficient mice immunized with purified murine MPO) has resulted in features typical of MPA.[13] By contrast, the pathogenicity of antiPR3 antibodies is less well established. In one animal model of autoimmune-prone nonobese diabetic (NOD) mice, immunization with recombinant mouse PR3 (rmPR3) in complete Freund's adjuvant (CFA) had no clinical

KEY CONCEPTS

Pathogenic Mechanisms in ANCA-Associated Vasculitides

- The recognition of an association between some forms of vasculitis and the presence of antibodies to neutrophil cytoplasm (ANCA) has transformed understanding of the group of diseases considered to be associated with ANCA and in which ANCAs are suspected to have a pathogenic role.
  - Granulomatosis with polyangiitis (GPA)
  - Microscopic polyangiitis (MPA)
  - Eosinophilic granulomatosis with polyangiitis (EGPA)
- A genome-wide association study (GWAS) has demonstrated strong associations with specific alleles.
  - Anti-proteinase 3 ANCA with specific HLA-DP alleles and alleles encoded by genes for α_1-antitrypsin and proteinase 3
  - Anti-myeloperoxidase ANCA with specific HLA-DQ alleles
- Environmental factors
  - Silica exposure
  - Specific strains of *Staphylococcus aureus*
- Inflammatory processes
  - Ineffective T-cell regulation
  - Neutrophil generation of extracellular traps (NETs) containing proteinase 3 and myeloperoxidase
  - Activation of alternative complement pathway by ANCA-activated neutrophils

effect but resulted in high levels of circulating c-ANCA; transfer of splenocytes from these immunized animals into mice with severe combined immunodeficiency (SCID) resulted in vasculitis and severe segmental and necrotizing glomerulonephritis.[14] Transfer of splenocytes from the CFA-alone-immunized mice (controls) resulted in no disease, further suggesting that disease development depends on PR3-specific immune responses. In a second model of PR3ANCA vasculitis, based on animals with a human–mouse chimeric immune system,[15] >70% of mice treated with IgG from patients with antiPR3 AAV (as compared with IgG from patients with nonvasculitic renal disease; or healthy controls) developed mild kidney disease with glomerular hypercellularity and focal pulmonary hemorrhage. Fifteen (83%) mice treated with antiPR3 IgG later showed mild kidney disease with glomerular hypercellularity, and three (17%) had severe glomerular injury. In the lungs, 13 (72%) showed areas of focal pulmonary hemorrhage, whereas lungs of the control group ($n = 8$) appeared normal ($p < 0.01$). There were no granulomatous lesions, but because granulomatous lesions are dependent on a robust T cell–mediated response, the authors argued that a refinement of the model to include greater levels of chimerism and administration of interleukin-7 (IL-7)–Fc protein to augment T-cell development would be required to study this.[15]

Even though these studies strongly support a pathogenic role for ANCA, conventional serological assays fail to detect ANCA in some patients with classic clinical and pathological features of AAV, and titers do not correlate well with disease activity. Roth et al. examined MPO epitopes specificities,[16] reporting 25 different epitopes bound by anti-MPO antibodies; although some epitopes were associated with active disease, others were either not specific to active disease or not associated with disease at all. Igs purified from patients with ANCA-negative vasculitis could bind to a specific MPO epitope. Furthermore, the absence of ANCA in some patients could be explained by competitive binding to a fragment of ceruloplasmin (CP), the natural inhibitor of MPO. This CP fragment decreased anti-$\text{MPO}_{447-459}$ autoantibody reactivity by 30–50%, whereas full-length CP did not have any effect.[16] ANCAs are reported in small numbers of healthy individuals. How the pathogenic transformation of ANCA occurs is still unclear, but it is probably a multifactorial process requiring a complex interaction among genetics, the environment, and the immune system facilitating a break in immune tolerance.

GENETICS

There has been significant progress in the understanding of AAV genetics following the publication of two genome-wide association studies (GWAS).[17] The strongest human leukocyte antigen (HLA) association is with the HLA-DPB1 haplotype, initially described in German cohorts and confirmed in both GWAS, especially for the PR3-ANCA–positive subgroup, regardless of the clinical diagnosis.[14] Further analysis has revealed an association between MPO-ANCA and a single nucleotide polymorphism (SNP) in the HLA-DQ region, which had probably been masked previously as a result of the small number of MPO-ANCA–positive patients included in initial analyses. Other HLA associations are reported, such as HLA-DRB1*09:01 and HLA-DQB1*03:03 in Japanese patients with MPA. Less robust findings, not replicated in other studies, include a protective effect of HLA-DR13(6) and HLA-DR1, but an increased proportion of HLA-DR4 in Dutch patients with GPA compared with controls[18]; HLA-DRB1 in PR3-ANCA-positive (but not MPO-ANCA) patients[17]; HLA-B50, HLA-DR1, HLA-DR9, HLA-DQw7, and HLA-DR3 in GPA.[19-21] In EGPA, the most robust association is with HLA-DRB4. Overall, there is evidence for genetic susceptibility to AAV, related to specific SNPs in the HLA region. Other genetic associations with GPA include *PRTN3, SERPINA 1, PTPN22,* and *CTLA4.*

PR3 is either stored in neutrophil azurophilic granules or exposed on the cell membrane (where it can interact directly with ANCA). Although the proportion of neutrophils displaying membrane PR3 (mPR3^+) is stable over time, surface expression of PR3 may be enhanced. The percentage of mPR3^+ neutrophils is genetically determined. Schreiber et al. showed that among 125 healthy controls, 35 patients with GPA, 15 patients with other inflammatory diseases, and 27 pairs of monozygotic (MZ) and dizygotic (DZ) twins, the percentage of mPR3^+ neutrophils correlated significantly in MZ twins (but not in DZ twins) and the heritability percentage was estimated as 99%. Furthermore, the absolute number of PR3 molecules expressed on the cell membrane was correlated among MZ (but not DZ) twins, with a heritability estimate of 96.7%.[22] Patients with GPA have a higher percentage of mPR3^+ neutrophils compared with healthy controls or patients with other inflammatory diseases (mPR3^+ percentage of 76.8% vs 56.1% vs 59.4%, respectively).[22] Following neutrophil activation and enzyme release, PR3 can mediate direct tissue damage. α_1-antitrypsin, encoded by the gene *SERPINA1* (found on chromosome 14), is the major inhibitor. Two α_1-antitrypsin alleles, Z and S, are associated with low enzymatic activity. A significant correlation with the Z allele (odds ratio [OR] 0.3; p = 1.25 × 10–5), but not the S allele, is reported in PR3-ANCA–positive patients with GPA.[17] *PRTN3* (the gene encoding PR3) is associated with GPA, especially among patients who are PR3-ANCA-positive.[17]

The 620WPTPN22 variant of *PTPN22* (encoding lymphoid tyrosine phosphatase) correlates with abnormal regulatory CD4 T regulatory cell (Treg) function, increased humoral activity, and enhanced neutrophil function in patients with GPA.[23] CTLA-4 (encoding cytotoxic T lymphocyte antigen-4) polymorphisms are associated with GPA,[14] especially the G allele of CT60 (p = 0.001) and +49 (p = 0.03). By contrast, only borderline significance was noted between CT60 SNP and MPA (p = 0.05).[24] CTLA-4 is a negative regulator of T-cell activation, which competes with the costimulatory molecule CD28 for binding of CD80 or CD86 on antigen-presenting cells (APCs). Abatacept, a monoclonal antibody (mAb), containing the binding domain of CTLA-4 reduces CD28–CD80/CD86 interaction and therefore T-cell stimulation, which could explain its potential benefit in a small trial of non–life-threatening GPA.[25] Haplotypes of IL-10 (a pleiotropic cytokine with complex and multiple effects in immune modulation) are associated with several immunological disorders, including systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), and giant cell arteritis. IL-10 production is largely (50–70%) determined by genetic factors, and elevated plasma levels are reported in EGPA, but not in GPA.[26] Wieczorek et al. evaluated the impact of functionally relevant IL-10 polymorphisms in 403 patients with GPA, 103 with EGPA (compared with 507 controls).[26] There was a significant association with the 3575/1082/592 TAC haplotype, part of the extended ancient haplotype of IL-10.2, in ANCA-negative EGPA, but not in GPA.[26]

EPIGENETICS

Genetic factors alone are not enough to explain the range of phenotypic presentations in AAV. Epigenetic dysregulation is increasingly recognized as a contributor to immune-mediated diseases. Epigenetics relates to heritable changes in the function of genes, without altering the DNA sequence. It includes DNA methylation, histone, and microRNAs (miRNAs). Epigenetic modifications can be stable over time or can respond to developmental and environmental triggers, leading to phenotypic aberrances. Central to the pathogenesis of AAV is a dysregulated immune response resulting in ANCA production and aberrant expression of their target autoantigens, MPO and PR3. The expression of MPO and PR3 occurs primarily during early neutrophil development to produce intragranular constituents and is silenced in mature cells. However, in AAV, expression remains active. One epigenetic change that helps explain this is the reduced levels of the H3K27me3 histone modification at both the MPO and PR3 gene loci. H3K27me3 histone is associated with transcriptional silencing in patients with AAV compared with healthy individuals.[27]

ENVIRONMENTAL AND INFECTIOUS TRIGGERS

Genetic and epigenetic modifications may render a patient susceptible to developing disease in the presence of an appropriate trigger. Several triggers have been associated with AAV, including toxins, viral and bacterial infections, and some licit and illicit drugs.

Silica dust exposure has been associated with the development of AAV and other autoimmune diseases, such as SLE, RA, and scleroderma.[28] Silica is an abundant earth material found in sand, grain, grass, and wool. Processing these materials may expose workers to respirable crystalline silica. Silica-induced ANCA-positive disease is often associated with p-ANCA, targeting MPO, and the clinical presentation is usually MPA rather than GPA.[29] Case-control studies show that a high percentage (22–46%) of patients with AAV were previously exposed to silica.[25,29] A systematic review and meta-analysis of 332 cases and 516 controls found that prior silica exposure was associated with development of AAV, with a summary odds ratio (OR) of 2.56 (95% CI 1.51–4.36). Pooled ORs were similar for GPA and MPA, 3.56 (95% CI 1.85–6.82) and 3.95 (95% CI 1.89–8.24), respectively. Other confounders, such as other occupational exposures or tobacco use, were not analyzed, which could have resulted in an overestimation of the risk attributed to silica.[25] The mechanism by which silica exposure triggers the development of AAV is not fully understood. *In vitro,* silica can activate monocytes and macrophages, releasing cytokines, such as IL-1 and tumor necrosis factor-α (TNF-α), as well as releasing oxygen radicals and lysosomal enzymes, including proteinase 3 and myeloperoxidase.[30] Furthermore, silica can inactivate α_1-antitrypsin. Asbestos, another silicon-containing mineral, has been suggested as a trigger for AAV in a small case-control study of 31 patients (22 GPA, 8 MPA, 1 EGPA) and 30 healthy controls; three patients had prior exposure to asbestos versus none of the controls.[31] There are few published studies investigating the potential pathogenic role of asbestos in the development of AAV.

It is estimated that 63% of patients with GPA are chronic nasal carriers of *Staphylococcus aureus,* resulting in an increased risk of relapse. Maintenance treatment with trimethoprim-sulfamethoxazole (cotrimoxazole) has been shown to reduce the incidence of relapse in a double-blind, placebo-controlled study in patients with GPA, where a maintenance dose of 960 mg two times daily of trimethoprim-sulfamethoxazole resulted in a 60% reduction in relapse. However, this has not been replicated in other studies. The mechanism for the pathogenic role of *S. aureus* is still unclear. Potential pathways include stimulation of B and/or T cells by *S. aureus* superantigens; polyclonal activation of B cells by cell wall components of the bacterium, resulting in persistence of ANCA; and neutrophil priming leading to surface expression of PR3.[28]

Although parvovirus B19 has been proposed as a trigger for AAV in a few case reports, a case-control study failed to demonstrate any association because IgG antibodies to parvovirus B19 were detected equally in the sera of patients with AAV and control subjects, and all 13 patients with AAV and 39 controls were negative for IgM antibodies and viral DNA.[32] Hepatitis B virus (HBV) is implicated in the pathogenesis of PAN,[28] but there is no evidence to support a role for HBV or HCV in AAV. The presence of circulating c-ANCA and PR3-ANCA has been reported to be higher in patients with chronic hepatitis B and C compared with controls. In a study of patients with liver disease (11 patients with primary biliary cirrhosis, 216 with chronic hepatitis B, 516 with chronic hepatitis C, and 44 healthy controls), ANCAs were detected in 55.6% of patients with hepatitis C (all had a c-ANCA pattern with PR3 specificity and 4.8% had concurrent MPO specificity).[33] ANCA-positive patients had a higher prevalence of skin involvement, anemia, abnormal liver functions, and elevated α-fetoprotein (FP) levels[33]; however, the findings were not replicated in other studies.[34]

Lysosomal-associated membrane protein 2 (LAMP-2) is a heavily glycosylated type 1 membrane protein, abundant on neutrophil and endothelial cell surfaces, which shuttles between lysosomes and the cell membrane. LAMP-2 cross-reacts with FimH, a gram-negative adhesin, which facilitates bacterial entry to host tissues. Preliminary studies have suggested a role for LAMP-2 in small-vessel vasculitis. The LAMP-2 epitope P41–49 has been reported to have a 100% homology with amino acids 72–80 of mature FimH.[35] Antibodies to human LAMP-2 have been shown to injure human microvascular endothelium *in vitro* and induce focal necrotizing glomerulonephritis (FNGN) in rats; immunization with FimH-induced pauciimmune FNGN associated with antibodies that bound human and rat LAMP-2; furthermore, patients with pauciimmune FNGN were found to have an increased likelihood of infections with FimH-expressing bacteria shortly before presentation of their FNGN.[35] LAMP-2 antibodies were found in patients with active disease or relapse but not in those in remission.[35] Although this a promising new explanation for some cases of small-vessel vasculitis, the lack of replication of these findings makes them hard to substantiate.

CpG-oligodeoxynucleotides (ODN) is a short synthetic DNA containing unmethylated CpG motifs, highly prevalent in bacterial DNA, and recognized by Toll-like receptor 9 (TLR9), which is expressed by a variety of cells in the immune system. TLR9 triggering results in proinflammatory IL production. It has been reported that CpG motifs and IL-2 exposure can induce B lymphocytes to proliferate, increase antigen presentation, produce a range of cytokines, and differentiate into Ig-producing cells, ultimately leading to ANCA production.[36]

DRUG INDUCED AAV

The most commonly implicated drugs that can induce an AAV-like syndrome are propylthiouracil (PTU), hydralazine, levamisole-adulterated cocaine, TNF-α inhibitors, sulfasalazine, D-penicillamine, and minocycline (Fig. 58.1).

Propylthiouracil

The most commonly described drug associated with the presence of ANCA is propylthiouracil (PTU). PTU is used to treat hyperthyroidism and was the first drug described to induce a condition mimicking AAV in the 1990s. Even though its use has declined over time, reports of PTU-induced AAV still emerge. Clinically, PTU-induced AAV may manifest as acute kidney injury caused by pauciimmune necrotizing and crescentic glomerulonephritis in addition to respiratory tract, joint, and skin diseases.

Reports of the proportion of patients who develop ANCA as a result of exposure to antithyroid medications varies widely from 4% to 46%; by contrast, the prevalence of antithyroid drug-induced AAV is much lower (0–1.4%). Although PTU is the most commonly reported antithyroid drug, methimazole and carbimazole have also been implicated. In a study by Noh et al.,[37] the estimated annual incidence of antithyroid drug-induced vasculitis was 0.53–0.79 patients per 10 000 patients with Graves disease, especially for patients receiving propylthiouracil; the ratio of the estimated incidence for methimazole and propylthiouracil was 1 : 39. Most patients with PTU-induced ANCA will not develop clinical features of vasculitis. Patients with PTU-induced AAV (usually MPO-positive) are younger, more commonly female compared with those with primary AAV, and usually have significantly higher anti-MPO ANCA titers compared with patients without vasculitis. Other ANCA subtypes may be found, including HNE-ANCA and lactoferrin (LF)-ANCA; however, when PTU-induced AAV develops, MPO-ANCA is usually present, regardless of the existence of other forms of ANCA. The pathogenesis of AAV related to antithyroid drugs is unclear. PTU is predominantly metabolized in the liver, but a proportion is modified by MPO in neutrophils.[38] Neutrophils are responsible for neutrophil extracellular trap (NET) formation, and PTU can induce abnormal configured NETs *in vitro;* these abnormal NETs cannot easily be released into liquid phase and are not effectively digested by DNase I, therefore remaining in the tissue.[39] Immunization of rats with abnormal NETs results in production of MPO-ANCA.[39]

Hydralazine

Hydralazine is widely used to treat hypertension, acting as a smooth muscle relaxant and causing arterial and arteriolar vasodilation. It has been implicated in the development of drug-induced SLE and AAV. High titers of MPO-ANCA, ANA, anti–double-stranded DNA (dsDNA), and antihistone antibodies are found; hypocomplementemia is also frequent. The underlying mechanism of action for hydralazine-induced AAV is not clear. One potential pathway by which hydralazine acts is through reverse epigenetic silencing of tumor suppressors, but also potentially of MPO and PR3.

Levamisole-Contaminated Cocaine

It is commonplace for illicit drugs, such as cocaine, to be combined with adulterants, such as levamisole, in an effort to increase profits. Levamisole is similar in physical appearance and has possible potentiating effects on levels of dopamine in the central nervous system. It is estimated that >75% of cocaine users in the United States are exposed to levamisole.

Clinical manifestations of AAV induced by levamisole-contaminated cocaine include constitutional features; arthralgia; retiform purpura involving the ears, face, and extremities; and, less commonly, renal and lung diseases. Laboratory abnormalities include leukopenia, neutropenia, and high-titer p-ANCA, directed against MPO-ANCA or against atypical p-ANCA–associated antigens, such as HNE, lactoferrin, and cathepsin G. PR3-ANCA, ANA, and antiphospholipid autoantibodies have also been described in these patients. This multiplicity of antibodies helps distinguish AAV induced by levamisole-contaminated cocaine from primary AAV, which usually targets just one antigen.

Levamisole has an estimated mean half-life of 5.6 hours; therefore serum testing is likely to be negative if the most recent exposure occurred >24 hours prior to sample collection. Urinary detection of levamisole is highly suggestive of drug-induced disease and is useful if exposure occurred <48 hours prior to testing.

The mechanism by which levamisole-contaminated cocaine induces AAV is unclear. Levamisole, like PTU, could serve as a substrate for MPO to form reactive metabolites that might induce autoimmunity. Levamisole can enhance NETosis through engagement of muscarinic (subtype 3) receptors; furthermore, neutrophil extracellular traps (NETs) generated by levamisole can induce endothelial cell death and vascular dysfunction by disrupting normal endothelium-dependent vasorelaxation. Abusing cocaine without levamisole can also trigger a syndrome

FIG 58.1 Proposed pathogenic mechanisms in antineutrophil cytoplasmic antibody (ANCA) associated vasculitis. The interaction between activated neutrophils and ANCA is depicted in the figure, with resting neutrophils becoming activated (A), interacting with ANCA in the intravascular space (B), triggering a series of cascading events leading to vascular invasion (C) by inflammatory cells and the formation of neutrophil extracellular traps (NETs) and eventually chronic inflammation in the extravascular space (D).

mimicking AAV. The clinical presentation can be identical to that of patients with GPA, although cerebral angiitis, urticarial vasculitis, and EGPA-like syndromes have also been described. In GPA-like vasculitis, patients typically present with cutaneous vasculitis, nasal septal destruction, and pauciimmune crescentic glomerulonephritis. The autoantibody profile usually includes c-ANCA with PR3 specificity, although there are reports of cases with negative ANCA or p-ANCA with PR3 specificity. In these cases, the target of p-ANCA may be atypical, such as HNE.

Cocaine-induced midline destructive lesions (CIMDLs) in the upper respiratory tract mimic limited forms of GPA.[40] Patients with CIMDLs may present with or without ANCA, and when ANCA-positive, the pattern often varies. Some patients are positive for c-ANCA with PR3 specificity, but more often, patients with CIMDLs present p-ANCA with specificity for atypical ANCA, such as HNE. Wiesner et al. reported that 76% of the patients with CIMDLs were ANCA-positive (mostly p-ANCA): 57% had PR3-ANCA and 86% had HNE-ANCA; this compares with the absence of HNE-ANCA in GPA and MPA, suggesting that the presence of HNE-ANCAs may be helpful in distinguishing CIMDL from GPA.[41]

Table 58.2 provides a summary of the most significant associations between drugs and ANCA or AAV. The management of all forms of drug-induced AAV is withdrawal of the offending agent, supportive measures, and, in severe cases, immunosuppression, dialysis, and plasma exchange.

LOSS OF B- AND T-CELL TOLERANCE IN ANCA-ASSOCIATED VASCULITIS

The imbalance of effector and Tregs underpins the autoimmune dysregulation seen in AAV with multiple alterations in the circulating T-cell population. Patients with AVV have a reduced number of circulating Tregs,[42] which are functionally impaired, and an expanded population of CD4 effector memory T cells with an increased number of activated T cells.[43] Persistence of CD4 T-cell activation in peripheral blood correlates with disease severity.[44] Aberrant T helper (Th) polarization, with an increase in proinflammatory Th17 responses, further contributes to vascular injury.[43] It has been suggested that these alterations to the peripheral T-cell compartment could be influenced by environmental factors, such as infection.

The discovery of B cells in the inflammatory lesions in AAV together with the success of B-cell depletion therapies suggests that B cells play a significant role in the pathogenesis of AAV; however, the exact mechanism of this involvement is still not known. Regulatory B cells are reduced in AAV, whereas B-lymphocyte stimulator (BLyS) levels are significantly increased, thereby promoting B-cell differentiation, proliferation, and survival.[45] B cells may play a number of roles in AAV: as precursors to antibody-producing plasma cells; as APCs; producing proinflammatory mediators; or in costimulation of T cells.

ROLE OF NEUTROPHILS

In addition to containing the antigens for ANCA, activated neutrophils release many mediators that modulate the inflammatory response and can directly contribute to tissue inflammation, vascular injury, and damage in AAV via phagocytosis, degranulation, and cytokine production. Neutrophils release B cell–activating factors (BAFFs) that enhance B-cell proliferation and retard apoptosis. Neutrophils from patients with AAV are more prone to spontaneous release of NETs.[46] In the normal immune system, NETs consist of chromatin fibers released from dying neutrophils and are designed to trap and kill extracellular pathogens. NETs not only contain proinflammatory proteins that directly cause endothelial cell damage and complement activation but also form a link between innate and adaptive immunity via providing access to MPO and PR3.

ROLE OF COMPLEMENT

Despite the apparent paucity of immune complexes in AAV, complement (and in particular activation of the alternative complement pathway) plays a crucial role in the pathogenesis of AAV. When primed neutrophils are activated by ANCA, they produce C5a, which, in addition to recruitment, primes additional neutrophils for further activation by ANCA.[47] C3a, C5a, and soluble C5b-9 levels are elevated in active disease; plasma levels of complement factor H, a regulator of the alternative complement pathway, are significantly lower in patients with active AAV.[48] Low serum levels of C3 at diagnosis are associated with a worse prognosis.[49] There is also a suggestion that C5a may play a role in the hypercoagulability associated with active AAV.

PATHOGENESIS OF KAWASAKI DISEASE

The incidence of KD is highest in East Asian countries, such as Japan, Korea, and Taiwan. The incidence in Japanese children is 10-fold higher compared with that in the United States. Japanese data show a seasonal variation in incidence, with an increase seen in the winter; furthermore, siblings of patients with KD are at increased risk of disease compared with the general population,[60] and the risk of sibling patients is increased among patients whose parents previously had the disease.[60] KD shows geographical clustering, with shared clinical features between clusters of disease. These findings suggest a role for an infectious environmental trigger, together with genetic susceptibility. Several disease susceptibility genes have been identified, including genes that affect the function of molecules involved in the calcineurin-nuclear factor of activated T cells (NFATs) pathway; transforming growth factor-β (TGF-β) lipopolysaccharide-induced endothelial cell inflammation pathways; and genes encoding Fcγ receptors, such as *ITPKC, FAM167-BLK, CD40, FCGR2A, HLA, CASP3, TGFB2, TGFBR2, SMAD3,* and *PLCB4/PLCB1.*[61] *CD40* and *FCGR2A* have been associated with disease susceptibility in Europeans.

SNPs identified within the *ITPKC* and *PLCB4/PLCB1* genes are associated with the risk of coronary artery aneurysms.[61] *ITPKC* and *CASP3* SNPs are associated with lack of response to intravenous immunoglobulin (IVIG) treatment.[62] ITPKC is a negative regulator of T-cell activation via downregulation of the Ca^{2+}/NFAT signaling pathway. The SNP located in the intron of *ITPKC* regulates splicing, decreasing negative regulation of T cells and leading to increased T-cell activation and IL-2 production.[63]

TNF-α, nuclear factor-κB (NF-κB), IL-17, TGF-β, interferon-γ (IFN-γ), granulocyte–colony-stimulating factor (G-CSF), IL-1β, IL-6, follistatin-like protein 1, and TLR2 are reported to be elevated in patients with KD.[64,65] In the acute phase of disease, circulating IL-17 levels and IL-17–induced cytokinesis are increased, suggesting an imbalance between Th17 and Tregs. Th17 levels are higher in children with coronary lesions.[66] There is evidence for marked activation of cytotoxic and Th lymphocytes and dendritic cells, with upregulation of type I IFN responses, supporting a possible viral etiology of KD, based on a transcriptomic study of patients who died or who were undergoing heart transplantation.[67]

KD has been suspected to be triggered by bacterial or viral infections, but no single causative agent has been identified. It has been suggested that superantigens (SAgs) are implicated. Several microorganisms can produce SAgs, including bacteria (*e.g.,* staphylococci, streptococci, mycobacteria, *Mycoplasma, Yersinia, Lactobacillus)* and viruses (*e.g.,* Epstein-Barr virus). SAg-producing bacteria have been isolated from children with acute KD, including TSST-1 producing *S. aureus* and pyrogenic exotoxin–producing *Streptococcus.*[68] In a mouse model involving injections of intraperitoneal *Lactobacillus casei*, disease could not be induced in recombinase activating gene-1–deficient mice, implicating T cells as critical drivers of the disease process.[69]

PATHOGENESIS OF POLYARTERITIS NODOSA

The pathogenesis of idiopathic PAN is unknown; clinical responses to immunosuppressive therapy strongly support an underlying immunological mechanism. Elevated levels of IL-2, IL-8, IFN-γ, TNF-α, and IL-1β have been reported in PAN, as well as elevated levels of circulating soluble adhesion molecules, such as intercellular adhesion molecule-1, vascular cell adhesion molecule-1, and E-selectin, suggesting that endothelial cell activation could perpetuate and potentiate the inflammatory milieu. IFN-γ and TNF-α increase the expression of class I major histocompatibility complex (MHC) antigens and induce MHC class II expression, resulting in antigen presentation to T cells. In one study of 24 patients with idiopathic PAN, macrophages and CD4 T lymphocytes were the predominant cell types found in lesions. T lymphocytes were more abundant in nerve biopsy specimens compared with muscle biopsy specimens (52% vs 35%; $p < 0.001$), whilst macrophages were predominant in muscle specimens (45% vs 33%; $p = 0.005$). Histologically, T lymphocytes were distributed throughout the vessel wall, whereas macrophages predominated in the periphery.[70]

In HBV-induced PAN, there is direct injury to the vessel wall as a result of viral replication[59] and deposition or *in situ* formation of immune complexes, which activate complement, thereby recruiting and activating neutrophils. The immunological process usually occurs within 6 months of HBV infection. During the active phase of disease, complement levels are low, consistent with complement consumption resulting from immune complex deposition.

Alterations in the *MEFV* gene (encoding pyrin) may represent an important susceptibility factor for PAN. Pyrin is critically important in regulating IL-1β production; mutations of pyrin may be associated with loss of regulation of inflammatory pathways via apoptosis and IL-1β release, resulting in augmented inflammation, similar to patients with familial Mediterranean fever, who can be carriers of *MEFV* mutations.[71]

PATHOGENESIS OF CRYOGLOBULINEMIC VASCULITIS

The pathological hallmark of cryoglobulinemic vasculitis is deposition of cold-precipitating Igs in small vessels, resulting in vascular inflammation and damage. In most patients, chronic HCV infection is the trigger, but cryoglobulinemic vasculitis can also occur in the context of other chronic infections and in some autoimmune rheumatic diseases and lymphoproliferative disorders.

HCV plays several important roles in the pathogenesis of cryoglobulinemic vasculitis. HCV glycoproteins interact directly with B-cell surface receptors, lowering the activation threshold and resulting in polyclonal activation and expansion of B cells.[72] Circulating, clonally expanded B cells produce monoclonal IgM rheumatoid factor (RF). Mixed cryoglobulins contain a monoclonal IgM RF directed against the Fc segment of IgG and polyclonal IgG. When IgM RF is exposed to cold conditions, it undergoes conformational changes resulting in cryoprecipitation. Cold-insoluble immune complexes are formed predominantly by IgM RF linked to IgG (which, in turn, is bound to HCV core protein). Cryoglobulinemic vasculitis should be considered an antigen-driven disease, because HCV persistence ensures sustained lymphoid proliferation and continued cryoglobulin production.

C1q protein levels and C1q binding are significantly increased in cryoglobulinemic vasculitis. C1q is required for binding of immune complexes to endothelial cells. Although mixed cryoglobulins can be detected in up to 60% of patients with chronic hepatitis C, cryoglobulinemic vasculitis occurs only in a minority, suggesting that host factors must be equally important in the pathogenesis of the disease.

PATHOGENESIS OF EGPA

Despite the established role of ANCA in GPA and MPA, the pathogenic role of ANCA in EGPA is less clear. In EGPA, only 30–40% of patients are ANCA positive; the presence or absence of ANCA in EGPA defines distinct clinical phenotypes. The pathological hallmark of EGPA is prominent tissue and peripheral blood eosinophilia, suggesting a central pathogenic role for the eosinophil. EGPA is considered to be Th2 mediated, given the striking early allergic manifestations, together with the marked increase in circulating Th2 cytokines, including IL-5, which plays a crucial role in eosinophil differentiation in bone marrow as well as recruitment and activation of eosinophils at sites of inflammation. IL-5 could delay apoptosis of eosinophils and modulate the function of mast cells and basophils.[73] Elevated levels of IFN-γ (a potent Th1 cytokine involved in granuloma formation) provide evidence for the involvement of other Th responses. Th17 responses are upregulated, and B lymphocytes and humoral responses are likely to be important, given that B-cell depletion can induce remission and reduce circulating IL-5 and eosinophils.

The precise mechanisms of eosinophil-mediated inflammation in EPGA remains unclear. Eosinophils are granulocytic cells capable of releasing multiple proinflammatory cytokines, chemokines, and reactive oxygen species, which have direct effects on the vessel and perivascular tissues, including tissue fibrosis, thrombosis, and allergic inflammation; indirect effects include recruitment and activation of other inflammatory cells to perpetuate the inflammatory response.

CLASSIFICATION

Several sets of classification criteria have been published, the most recent being one by the American College of Rheumatology (ACR) in 1990. These are primarily for the purposes of epidemiological studies or for defining patients for inclusion in clinical studies, rather than being used in clinical practice. However, as is often the case with classification criteria, they are misapplied as diagnostic criteria in daily practice and may fail to provide a clear-cut distinction between vasculitis and other conditions.[74] An international effort is currently underway to develop improved classification criteria as well as diagnostic criteria for patients with vasculitis or suspected vasculitis, and it is likely to lead to a new set of evidence-based criteria to improve diagnosis and classification of vasculitis in the future.[74] There is considerable overlap between different forms of vasculitis. The group of patients with diseases clustered around the presence of ANCA share many features in common, particularly the presence of glomerulonephritis and pulmonary infiltrates. In the case of EGPA, patients also experience rhinitis, nasal polyps, asthma, and rashes and may develop mononeuritis multiplex or sensory peripheral neuropathy. In addition to renal and lung inflammation, patients with GPA typically suffer from upper respiratory problems, such as nasal crusting or discharge; subglottic stenosis; or hearing loss. Patients with MPA do not usually develop significant upper airway disease; their disease tends to be more limited to the kidneys and/or lungs. All of these conditions can also affect any other organs, such as skin. Skin is the most commonly affected site in most forms of vasculitis. This can vary from small infarcts around nail edges to purpura, ulcers, nodules, and even gangrene.

The development of consensus criteria for diagnosis by the Chapel Hill group has provided a more rational approach to define disease entities. They are not true classification or diagnostic criteria because they are not evidence based (they are consensus of opinion from several experts); but they have advantages over the 1990 ACR criteria. They were developed after recognition of ANCAs, which are an important part of the 2013 definitions. One of the major flaws of the ACR criteria is the failure to recognize MPA as an entity separate from PAN.[74] This failure to separate PAN and MPA has probably prevented proper diagnosis, and it is a historical legacy from an assumption that almost all forms of vasculitis are, in fact, variations of PAN.

DIAGNOSIS

Individual Diseases

AAV are a group of three main entities: GPA, MPA, and EGPA. These three conditions overlap with many shared clinical features. Figs. 58.2 and 58.3 describe clinical patterns in patients with MPA and GPA and show that there are many similarities, with a dominance of kidney and lung involvement in both conditions. EGPA is characterized by eosinophilia, late-onset asthma, and neuropathic involvement, but cardiac involvement may develop in a subset of patients with EGPA, particularly in association with hypereosinophilia. Systemic features, such as malaise, fever, weight loss, or myalgia, could be mistaken for a variety of other conditions, and it may delay recognition of disease. Patients with MPA can present just with isolated microscopic hematuria and hypertension, with nonspecific systemic features. In contrast, patients with GPA typically suffer from upper airway problems, with nasal crusting, blood-stained discharge, sinusitis, or hearing loss. In anti–glomerular basement membrane (anti-GBM) antibody disease, clinical features sometimes overlap with those of AAV, but the dominant features are pulmonary hemorrhage leading to hemoptysis and rapid deterioration in renal function. It is not entirely clear whether the anti-GBM disease should be regarded vasculitis or vasculopathy, but it has been included in the current Chapel Hill Consensus definitions of a small-vessel vasculitis. Confusingly, some patients with anti-GBM antibodies also have ANCA.

The clinical course in MPA is typically acute, whereas GPA may remain undiagnosed for several months or even years before the upper airway and or lower airway symptoms are recognized as being related to vasculitis. For almost all forms of acute AAV, the differential diagnosis is infection, cancer, or drug toxicity. One of the drugs recently recognized to mimic AAV is cocaine,[75a] which can cause local tissue necrosis, especially in the palate, leading to palatal and nasal septal perforation. Interestingly cocaine can induce ANCA production and therefore can be a true mimic of AAV. Typically the ANCA is directed against elastase or is nonspecific. Careful history taking, sometimes with sensitive, confidential, repeated questioning, may be required to eventually identify this as a cause of a patient's condition. Contamination of cocaine with levamisole is becoming a growing problem. Presumably, levamisole (a veterinary anthelmintic agent) is a cheap white powder that can be mixed readily with cocaine but can cause an acute necrotizing vasculitis of skin and the extremities. Discontinuation of levamisole and cocaine usually stops further progression of disease, but once palatal or nasal perforation has developed, patients may require local surgical repair.

Cryoglobulinemic vasculitis typically presents with purpuric lesions on the legs, and the lesions may ulcerate. Patients often complain of joint pains and malaise. Neuropathies can occur with either mononeuritis multiplex or sensory neuropathy;

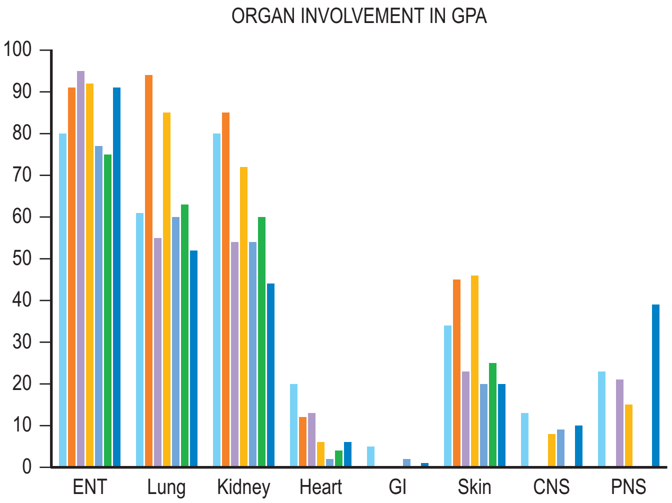

FIG 58.2 Organ involvement in patients with granulomatosis with polyangiitis (GPA). (Data compared across seven cohorts—reviewed by Luqmani R, Ponte C. ANCA associated vasculitides and polyarteritis nodosa. In: Bijlsma JWJ, Hachulla E, eds. *EULAR Textbook on Rheumatic Diseases*. London, UK: BMJ Publishing Group Ltd; 2015. Chapter 27, p.717-753)[75]

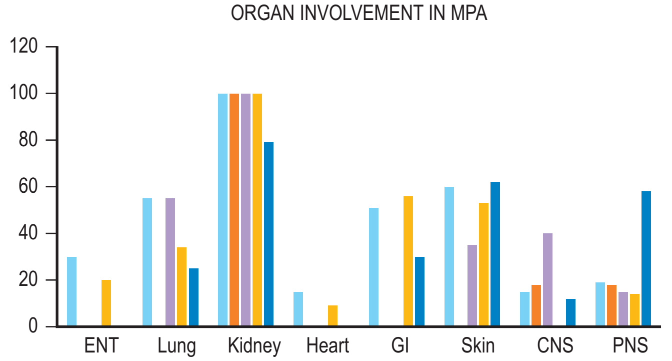

FIG 58.3 Organ involvement in patients with microscopic polyangiitis (MPA). (Data compared across seven cohorts—reviewed by Luqmani R, Ponte C. ANCA Associated Vasculitides and Polyarteritis Nodosa. In: Bijlsma JWJ, Hachulla E, eds. EULAR TEXTBOOK ON RHEUMATIC DISEASES. London, UK: BMJ Publishing Group Ltd; 2015. Chapter 27, p.717-753)[75]

membranous glomerulonephritis is a recognized complication. Most cases appear to be associated with hepatitis C (>90% in some series), and eradication of hepatitis C appears to be effective in reducing the manifestations of disease.

True PAN typically presents with neuropathies, systemic inflammation, and ischemic abdominal pain (difficulty eating because of medium-vessel supply to the gut and nerves). If it is associated with hepatitis B, the patient may or may not have obvious signs of liver disease.

Isolated cutaneous vasculitis typically presents as purpuric lesions, skin ulceration, or broken livedo, and biopsy of the skin will show typical changes of a necrotizing vasculitis.

KD usually presents in childhood as an acute illness, with relapsing high fevers, significant lymphadenopathy, and a systemic inflammatory syndrome. The child typically has mucosal inflammation with strawberry tongue; approximately 10 days after the onset, skin desquamation is a very typical feature. The most worrying feature of KD is the development of coronary artery aneurysms, which occur in around 2–4% of children and can be fatal, if untreated. This can be detected by using echocardiography.

Laboratory Investigations

The investigation of patients with suspected small- or medium-vessel vasculitis should follow a careful history and examination to determine the likely diagnosis and underlying illness. The differential diagnosis is very wide. It is important to be vigilant in looking for positive signs of vasculitis, but it is equally important not to forget to look for more common causes of the clinical presentation. Many of the studies performed can result in nonspecific findings, such as an elevated white blood cell count, platelet count, or the erythrocyte sedimentation rate. The C-reactive protein (CRP) level is typically raised. Patients may be anemic. Liver or, more importantly, renal function may be abnormal. The presence of hypereosinophilia can be suggestive of a diagnosis of EGPA, but there are other causes of hypereosinophilia, particularly drug reactions. It is important to test renal function in patients with suspected vasculitis in case there is nephritis, and it is always important to perform urinalysis for microscopic hematuria or proteinuria. Although these might be explained by the presence of a kidney infection or other causes, they raise a strong suspicion of glomerular inflammation. An abnormal urinary sediment in combination with hypertension should alert the physician to the possibility of kidney involvement by small-vessel vasculitis. Since the 1980s, the discovery of ANCA[12] has transformed the recognition of renal vasculitis, so that these patients can be managed more effectively.

Histology remains a very important diagnostic test, not only to make a positive diagnosis but also to exclude other causes. Although histology from the airways can be nondiagnostic, this may still assist in ensuring that the patient does not have cancer, sarcoidosis, o tuberculosis, or IgG4-related disease, all of which could present in a similar way with inflammation of the upper or lower airway. Renal histology is still the gold standard to diagnose suspected glomerulonephritis and may be useful in predicting the prognosis.[76] Four categories of renal lesion have been proposed: focal, crescentic, mixed, and sclerotic. Follow-up of patients with different patterns has shown outcomes: progressively worse renal outcome from focal (the best) through to sclerotic (the worst) over the subsequent 5 years.

ASSESSMENT

The outcome of small- and medium-vessel vasculitis has been completely transformed by immunosuppressive therapy. With treatment almost all patients with KD recover from their initial illness. In AAV, >70% survive at least 5 years from starting treatment. The majority of patients with PAN respond to initial therapy. However, the risk of recurrence of disease is high in small-vessel vasculitides. Relapse rates are likely to exceed 50% over time.[46] Patients experience comorbidities as a consequence of the disease or its treatment and can suffer from infections or other complications that contribute to their overall poor health. In the long term, small-vessel vasculitides and their treatment can be associated with effects on the cardiovascular system with increased risk of hypertension, coronary heart disease, and stroke.

Immunosuppressants given to patients can significantly improve disease control but may increase the risk of malignancy. The continued use of high doses of glucocorticoid therapy contributes to hypertension, diabetes, heart diseases, osteoporosis, and infection.

It is therefore obvious that careful evaluation of a patient's status is required throughout the course of disease. Constant vigilance is required to detect and manage any flare-up of disease because the consequences of untreated inflammation of vessels to vital organs can be severe. Although for most patients, initial therapy is very successful and improvements in disease status is obvious to the patient, the subsequent disease course can be much more complicated because of comorbidities, the evolution of disease-related damage, and morbidity caused by treatment as well as disease flare-ups. There are no suitable biomarkers that can be universally applied in small- and medium-vessel vasculitides to determine the patient's disease state to provide an evidence-based rationale for adjustment of therapy. ANCA titers fluctuate during the course of disease, and although ANCA remains a very useful diagnostic test, its value in managing variations in disease activity is very limited. Up to 40% of patients have an elevation of ANCA without any new deterioration in clinical state, but a recent study has shown that patients with renal involvement as part of their presentation are likely to have relapses associated with ANCA rises.[77] Among 166 patients with AAV, all were positive for ANCA and 104 had renal involvement (a mixture of PR3-ANCA and MPO-ANCA). The hazard ratio for ANCA rises predicting subsequent relapse was 11.09 (CI 5.01–24.55), suggesting that this test may be of value in detection of future relapse in this subset of patients. However, for the majority of patients with systemic vasculitis, careful clinical evaluation remains a cornerstone of effective disease management as recommended by the EULAR guidelines on management of systemic vasculitis.[78]

In simple terms, at the onset of the condition, disease activity is the dominant problem, and treatment should be directed toward it; but over the course of time, with the development of consequences of vasculitis or its treatment, there is an increasing component of damage or scarring and also side effects of drug therapy. Similarly, different patients function at different levels with the same amount of disease, or damage, and therefore the ability to perform normal tasks is an important component of their overall condition to consider (Table 58.3).

The primary tool used is the Birmingham Vasculitis Activity Score (BVAS) in adults and the Paediatric Vasculitis Activity Score (PVAS) in children (reviewed in Ponte et al., 2014).[79] Training is recommended for assessment in the Birmingham Vasculitis Activity Score (BVAS). BVAS provides a quantitative score based on individual items, providing an effective means to define the patient's status with regards to response to therapy. Many recent studies of different immunosuppressive agents have made use of the BVAS either to define improvement in terms of a fall in BVAS score or to define a cut-off representing active disease, or inactive disease, or flare-up, depending on the number of items present. Although it is subject to observer variability, it provides an effective means by which groups of patients can be compared against each other and allows individual patients to be followed up over the course of their condition. The score is weighted according to the organ system and the individual manifestation, to reflect the severity of the disease. The range of scores for BVAS and PVAS are 0–63. For BVAS GPA, items are divided into major (scoring 3 points) and minor (scoring 1 point each); with 15–19 major items and 19–23 minor items, the range of sores is 0–76. The PVAS was developed as a pediatric version of the BVAS, but validated in children with vasculitis and demonstrated to be effective at discriminating different disease states and is increasingly used as a research tool in pediatric vasculitis.

KEY CONCEPTS

Assessment of Disease Activity in Vasculitis

- For small- and medium-vessel vasculitis in adults, version 3 and a specific version of the BVAS for granulomatosis with polyangiitis (GPA) are used.
- BVAS version 3 is the most generic and applicable across different forms of vasculitis; BVAS for GPA has been specifically designed for use in GPA and contains very specific items related to that condition.
- During sequential monitoring, a time frame of 3 months is recommended so that disease activity is considered to be of most relevance during this time. The time frame is based on pragmatic clinical experience that this is the usual time taken during which immunosuppressive therapy is likely to have a significant effect on active disease manifestations.

Damage Assessment in Vasculitis

The concept of damage in patients with vasculitis is about the permanent consequences of having vasculitis. It is an attempt to measure disease burden regardless of cause. The Vasculitis Damage Index (VDI) is the most widely used and validated measure for assessment of damage in vasculitis (reviewed in Ponte et al., 2014).[79] The VDI captures the long-term consequences of a diagnosis of vasculitis and its treatment and associated comorbidities. Damage is defined as lasting at least 3 months or occurring at least 3 months ago for single time point events (*e.g.,* stroke or myocardial infarction) and should be recorded as a permanent change to the patient's damage status. A VDI of >5 points recorded within 6 months of disease carries a significant increased risk of subsequent mortality compared with a lower damage index at 6 months (reviewed in Ponte et al., 2014).[79] VDI is a useful index of future harm. A further development of the damage index has been the combined damage assessment (CDA). In a comparative study with the VDI, CDA was shown to be inferior to it (reviewed in Ponte et al., 2014).[79]

TREATMENT

Once a diagnosis of small- and medium-vessel vasculitis has been established, treatment should be focused on patients and their problems rather than the specific diagnosis. Treatment for different forms of vasculitis may look very different, but many aspects of different forms of vasculitis require the same therapeutic approach. Without a clear understanding of the underlying pathogenesis of disease, we are inevitably led by the need to suppress inflammation and reduce damage to prevent mortality and improve survival. However, as well as modifying immune dysregulation, it is important to consider other aspects of the patient's condition, such as comorbidities and the prevention of future comorbidities.

TABLE 58.3 Assessing Disease Activity in Vasculitis

System Assessed	BVAS	BVAS WG	PVAS	Comments
General	Myalgia, arthralgia/ arthritis, fever, weight loss	Arthritis, fever	Myalgia, arthralgia/ arthritis, fever, weight loss	These are typical features in many forms of systemic vasculitis.
Skin	Infarct, purpura, skin ulcer, gangrene	Purpura, skin ulcer, gangrene	Polymorphous exanthema, livedo, panniculitis, purpura, skin nodules, infarct, ulcer, gangrene, other skin vasculitis	Skin is a common organ involved in most forms of small and medium vessel vasculitis. Skin manifestations in ANCA-associated vasculitides tend to be less serious compared with manifestations in kidneys, lungs, and upper airways. For skin vasculitis in children the manifestations are more diverse.
Mucous Membrane/ eyes	Mouth ulcers, genital ulcers, adnexal inflammation, proptosis, red eye, (epi)scleritis, conjunctivitis, blepharitis, keratitis, blurred vision, visual loss, uveitis, retinal vasculitis	Mouth ulcer, conjunctivitis/ episcleritis, retro-orbital mass, uveitis, scleritis, retinal exudates	Mouth ulcers, genital ulcers, adnexal inflammation, proptosis, red eye (epi)scleritis, conjunctivitis, blepharitis, keratitis, blurred vision, visual loss, uveitis, retinal vasculitis	Eye involvement is most common in GPA and less often seen in MPA or EGPA.
Ear, nose, and throat	Bloody nasal discharge, paranasal sinus involvement, subglottic stenosis, conductive hearing loss, sensorineural hearing loss	Blood nasal discharge, paranasal sinus involvement, swollen salivary glands, subglottic inflammation, conductive hearing loss, sensorineural hearing loss	Blood nasal discharge, paranasal sinus involvement, subglottic stenosis, conductive hearing loss, sensorineural hearing loss	ENT manifestations are most common in GPA and rarely seen in MPA or EGPA. However, EGPA is often characterized by the presence of nasal polyps, which are inflammatory in nature.
Chest	Wheezing, nodules or cavities, pleural effusion, infiltrates, endobronchial changes, massive hemoptysis, respiratory failure	Nodules or cavities, pleurisy, infiltrates, endobronchial changes, alveolar hemorrhage hemoptysis, respiratory failure	Wheezing, nodules or cavities, pleural effusion, infiltrates, endobronchial changes, massive hemoptysis, respiratory failure	The chest is commonly affected in all three forms of ANCA vasculitis. Wheezing is a common feature of EGPA as are infiltrates. In contrast, infiltrates, nodules, and endobronchial disease dominate in GPA. Massive hemoptysis can occur in patients with GPA or MPA and less frequently in patients with EGPA, but may also be a typical feature with GBM (glomerular basement membrane) disease.
Cardiovascular system	Loss of pulses, ischemic cardiac pain, cardiomyopathy, congestive cardiac failure, valvular heart disease, pericarditis	Pericarditis	Loss of pulses, bruits, blood pressure discrepancy, claudication, ischemic cardiac pain, cardiomyopathy, congestive cardiac failure, valvular heart disease, pericarditis	Cardiovascular manifestations are most widely recognized in KD, which is not particularly well covered by PVAS. Although CVD manifestations do occur in small- and medium-vessel vasculitis, they are more typically seen in large vessel diseases, such as Takayasu arteritis.
Abdominal system	Ischemic abdominal pain, peritonitis, bloody diarrhea	Mesenteric ischemia	Abdominal pain, peritonitis, bloody diarrhea, bowel ischemia	Gut involvement is more typical in medium-vessel vasculitis, especially polyarteritis nodosa, but is well recognized in patients with GPA especially with colitis giving rise to bloody diarrhea.
Renal system	Hypertension, proteinuria, hematuria, impaired renal function, deterioration in renal function	Hematuria, red cell casts, or glomerulonephritis, deterioration in renal function	Hypertension, proteinuria, hematuria, impaired renal function, deterioration in renal function	Renal involvement in small-vessel vasculitis is one of the major manifestations leading to organ failure and death and should be carefully assessed. Renal involvement in medium-vessel vasculitis is much less common and takes the form of infarction of segments of the kidney leading to hematuria and hypertension with consequent impairment of renal function.
Nervous system	Headache, meningitis, organic confusion, seizures, stroke, cord involvement, cranial nerve, lesion, sensory or motor neuropathies	Meningitis, stroke, cord involvement, cranial nerve lesion, sensory or motor neuropathies	Headache, meningitis, organic confusion, seizures, stroke, cord involvement, cranial nerve, lesion, sensory or motor neuropathies	Neurological involvement is a common feature in small- and medium-vessel vasculitis; often it does not lead to immediate loss of life. Strokes are less common, whereas peripheral neuropathies are more common and can cause long-term disability.

No Treatment/Symptom Relief

Small-vessel vasculitis, such as isolated cutaneous vasculitis resulting from infection or use of pharmaceutical agents, may respond to simple withdrawal of the offending agent or resolution of the infection without the need for specific treatment. However, for more recalcitrant disease, symptom relief may be required and occasionally systemic steroids. Symptom relief could be provided in the form of antipruritic agents or topical cream to reduce skin inflammation and/or topical steroids. NSAIDs can be helpful in relieving symptoms of joint pain or swelling. As monotherapy they are unlikely to resolve skin manifestations but could be tried in combination with other therapies. Colchicine has been used for skin vasculitis and occasionally can be effective, although the doses required should remain below 2 mg/day to avoid the predictable side effects of abdominal cramps and diarrhea.

Target-Directed Therapies

In diseases where there is a clearly defined provoking agent, as in hepatitis B–related PAN or hepatitis C–related cryoglobulinemic vasculitis, eradication of the virus is a key part of treatment of the disease. Effective antiviral agents play a vital role in the management of virus, associated with the need for immunosuppression. Hepatitis B–related PAN is treated with a combination of antiviral therapy plus plasma exchange to remove immune-complexes and other inflammatory mediators combined with a course of glucocorticoid therapy. For hepatitis C–related cryoglobulinemic vasculitis, recent reports of virus eradication may also be transforming the outcome of this disease. Unfortunately, the toxicity of these regimens can be considerable, with >40% requiring erythropoietin, red blood cell transfusions, and or G-CSF.

Specific Therapies

In KD, although the etiological factors have not yet been defined, it seems likely that this is related to some kind of infectious agent (see earlier section on pathogenesis). The most effective therapy is use of high doses of IVIG (0.4 g/kg/day for 5 days) combined with high doses of aspirin, which is usually curative. Whether or not this will prevent long-term harm to the cardiovascular system, particularly the coronary arteries, remains to be explored.

Glucocorticoids

Glucocorticoids (Chapter 86) remain a cornerstone in the management of most forms of multisystem vasculitis. They are relatively contraindicated in KD because they may potentially worsen the development of coronary artery aneurysm, but they have been used in combination with IVIG and aspirin with beneficial outcomes. However, they are an integral part of almost all therapeutic regimens for management of vasculitis. In some instances, such as isolated skin vasculitis, they are the only treatment required, but more often they are insufficient on their own without causing significant morbidity from side effects. Typical doses of glucocorticoid therapy are 1 mg/kg/day over a period of 2–4 weeks, reducing to around 10–15 mg/day within 6 months, and then slowly withdrawing steroids in the next 6–12 months. The use of high-dose intravenous methylprednisolone is popular but lacks evidence. The only randomized trial of intravenous methylprednisolone compared it against plasma exchange in patients with severe AAV.[80] This study demonstrated the superiority of plasmapheresis over IV prednisolone, both used as adjunct therapies (in combination with cyclophosphamide and high doses of oral prednisolone) for treatment of severe AAV (mainly MPA plus some cases of GPA) with significant renal impairment (creatinine levels above 500 µmol/ L [5.66 mg/dL]).

The role of glucocorticoid therapy is been increasingly challenged by more recent trials using smaller doses for shorter periods or even eliminating steroid use completely in some instances. Glucocorticoid side effects are well known: weight loss, increased appetite, mood swings, hypertension, risk of diabetes, risk of infection, risk of cataract, and skin striae. The risk of osteoporosis is largely preventable with concurrent use of bisphosphonate therapy (unless there is significant renal dysfunction) with supplementary calcium and vitamin D replacement.

Other Immunosuppressive Therapies

Cyclophosphamide (Chapter 87) has been available since the 1950s but was first used for the management of systemic vasculitis in the 1970s and remains the most effective agent we have for managing multiorgan systemic vasculitis. Initially it was used as a daily oral agent at 2–3 mg/day, and it transformed the outcome of patients with AAV from inevitable mortality to a high likelihood of survival. It is a cytotoxic agent and carries with it the risk associated with chemotherapy, including increased risk of malignancy, especially in the bladder because it is predominantly excreted through the kidneys and accumulates in the bladder. Initial protocols were associated with excessive risks of bladder cancer (approximately 33-fold), but despite this, the daily oral cyclophosphamide dosing regimen was not effective in maintaining control of disease. Therefore over the past 20 years or so, there have been a number of trials comparing reduced doses of cyclophosphamide, high-dose intermittent pulse therapy,[81] or with combination strategies of induction with short courses of cyclophosphamide followed by a switch to another drug for maintenance,[81] or by replacing cyclophosphamide with another agent, such as methotrexate. All these studies[81] have demonstrated the equivalence of using shorter courses of daily oral cyclophosphamide and, more recently, of using of high-dose intermittent pulses of cyclophosphamide to reduce the total dose even further. The total cumulative dose from six cycles of cyclophosphamide over a period of 3 months would be 6 g (based on 15 mg/kg/treatment on six occasions). This compares with 9–12 g of cyclophosphamide given as daily oral therapy over 4–6 months.[81]

Although the relapse rate for patients given high-dose intermittent cyclophosphamide was higher during the subsequent 5 years compared with that for patients who were not given daily oral cyclophosphamide, relapse was always effectively managed with reintroduction of therapy and never led to mortality.[78] The consequences of exposure to cyclophosphamide are likely to be risk of cancer (more recent studies suggest that this risk is relatively modest now that the regimens include much lower total doses), infertility, hair loss, nausea, vomiting, diarrhea, cytopenia, and increased risk of infection. Less common complications of cyclophosphamide include hyponatremia. The introduction of rituximab for AAV has had a significant impact on the use of cyclophosphamide, with increasing numbers of patients being managed with rituximab in place of cyclophosphamide, especially if patients are of child-bearing years, or if there is a potential contraindication to using cyclophosphamide, such as a previous history of bladder cancer.

Because of the nature of AAV, relapse is common. Therefore a single course of therapy rarely achieves long-lasting remission. Repeat cycles of treatment are likely to be required, which accounts for the accumulation of higher doses of cyclophosphamide, especially in the pre-rituximab era. Therefore although each individual course of therapy may only contain 6–9 g, during a patient's life time, they may require treatment for several relapses, which would then start building up the total exposure to cyclophosphamide. Nevertheless, even though it is being slowly replaced, it remains an important aspect in the therapy of vasculitis even in the present time.

Azathioprine is an immunomodulator with cytostatic properties. It inhibits cell division; it has been an effective immunosuppressant agent for decades. It was first used in combination with steroids and found to reduce mortality in systemic vasculitis in an open-label retrospective study of 64 patients.[82] The 5-year survival of patients given no therapy was 12%, and those given steroids alone had a 53% survival rate, whereas those treated with steroids plus another agent (mainly azathioprine but a few had cyclophosphamide) had a survival rate of 80%. It is an oral medication given at 2–2.5 mg/kg/day, and it has largely been superseded as an induction agent by cyclophosphamide. Azathioprine is usually now used as maintenance therapy once the disease has been controlled with another agent. It has been shown to be equivalent to methotrexate and superior to mycophenolate[76] as maintenance therapy. It is a relatively safe immunosuppressant and can be used safely throughout pregnancy.

Methotrexate (MTX) is popular among rheumatologists but less so among renal physicians who regard it with some suspicion because of its potential for nephrotoxicity. The latter is only the case for patients who have well-established renal disease (typically with a creatinine level >300 μmol/L). MTX is an effective immunosuppressant agent used very widely in the management of inflammatory arthritis and has found its place in the management of GPA, where studies have demonstrated its efficacy in comparison to oral cyclophosphamide.[78] However, it needs to be given continuously, rather than as induction regimen over the short period of time. Although MTX is as effective as cyclophosphamide in inducing remission in GPA, stopping the drug inevitably leads to relapse. MTX is recommended for non–life-threating AAV, usually in combination with steroid treatment. MTX is available either as oral, intramuscular, or subcutaneous administration. The dose is 20–25 mg/week in most studies of vasculitis. It is contraindicated in pregnancy.

Cotrimoxazole, an antibiotic containing sulfonamide and trimethoprim, was fortuitously discovered to have beneficial effects in patients with GPA who had been treated coincidentally for infections. There has been a significant advance in our understanding of GPA, partly as a result of this historical experiment and partly based on suggestions that *S. aureus* plays a role in initiating disease by its effect on the nasal mucosa. Eradication of the organism has been suggested as one mechanism by which it works, although the drug is not particularly effective against this organism. It is more likely that the drug has an immunosuppressive effect in itself; it has been demonstrated to be effective in combination with low-dose steroids in a randomized trial of localized forms of GPA.[78] It is also commonly used as a prophylactic agent against *Pneumocystis jiroveci* infection; it is given 3 times per week for patients receiving other more potent immunosuppressant therapy, such as cyclophosphamide or even MTX (despite the potential for drug interactions leading to anemia).

Mycophenolate mofetil is a widely used transplantation drug that has been tested in AAV but is less effective than azathioprine as maintenance agent for patients who have achieved remission. It is currently being tested against cyclophosphamide as an induction agent in AAV. Is typically given as 2–3 g/day as an oral dose, along with reducing courses steroids. It is contraindicated in pregnancy.

Cyclosporine is a well-established immunosuppressive drug that has been used for transplantation for many decades. Cyclosporine has been given to limited numbers of patients with systemic vasculitis, with one small well-conducted trial[82] in 32 patients with GPA. In combination with plasmapheresis, it was as effective as continuous oral cyclophosphamide as a maintenance agent. It is generally limited by its toxicity and is not routinely used.

Leflunomide, an antilymphocyte agent used extensively for the management of inflammatory arthritis, has been tested in patients with AAV in limited trials demonstrating its ability to maintain remission. Indeed, in a recent meta-analysis, it was reported to be superior to azathioprine, MTX, and mycophenolate as a maintenance agent for AAV, but more trial data are needed. It is an oral agent that is characterized by a very long half-life, and it is not suitable for use in pregnancy.

The role of hydroxychloroquine in mild forms of vasculitis is uncertain. There is anecdotal evidence that it is beneficial in patients with skin manifestations with small-vessel vasculitis. Its use probably stems from its known effects in the treatment of connective tissue diseases with skin and joint manifestations, such as SLE. Other similar agents, such as mepacrine and dapsone, have also been used for skin vasculitis with occasional reported positive outcomes. However, the potential toxicity for each of these agents should be considered alongside the relatively limited evidence for benefit.

Specific Immunotherapy

Better understanding of the pathogenesis of vasculitis (see section on pathogenesis) has led to the development of targeted immunotherapy for some of these diseases. Rituximab is an mAb against B cells (Chapter 89) and has been in widespread use for treatment of RA. Its role as an effective agent in AAV is well established with two randomized trials demonstrating efficacy comparable with cyclophosphamide.[78] Rituximab induction therapy is just as effective as cyclophosphamide for moderate and moderate-to-severe AAV. Maintenance therapy with rituximab is a real possibility with the potential to provide long-term control and reduce relapse risk. The long-term consequences of repeat cycles of rituximab, however, are unexplored. The risks are hypogammaglobulinemia, which occurs in most cases, and the potential increase in incidence of infections. The most feared complication is the risk of reactivation of the JC virus leading to the complication of progressive multifocal leukoencephalopathy (PML), which has a very high mortality rate.

Other Therapies

Belimumab is currently undergoing clinical trials as a maintenance agent for AAV. The drug is a BAFF inhibitor and may be an effective means to control the disease over the long term. Mepolizumab is an mAb directed against IL-5, which controls eosinophil production. Mepolizumab has been successfully used in the treatment of hypereosinophilic syndrome and is undergoing a trial in EGPA. IVIG (Chapter 84) has been available as a replacement therapy for patients with hypogammaglobulinemia for several years, and it is the standard of care for KD, but its use in AAV has been limited. An initial study suggested benefit, but the likelihood is relatively short-term control.[82] Plasmapheresis has been available for several decades. It is not entirely clear how it works; there are many theories suggesting the removal of circulating immune mediators is effective in reducing inflammation. It has been successful for rescue therapy in patients with very aggressive AAV or anti-GBM disease. The MEPEX trial demonstrated that it was able to reduce renal dysfunction in patients with severe AAV.[78] However, the long-term follow-up of the MEPEX trial demonstrated that the difference between patients treated with plasma exchange and those given methylprednisolone pulses (both as adjunct treatment alongside cyclophosphamide and steroid) did not last.[83] It has been suggested this is accounted for by the fact that many patients with severe renal disease had already developed irreversible changes to their kidneys and that renal dysfunction would have been secondary to damage rather than active disease. A new study is underway to test the role of plasma exchange in patients with less severe renal disease, but results are not yet available. Plasmapheresis is effective in conjunction with antiviral therapy and steroids in the management of hepatitis B–related PAN.

OUTCOMES

The majority of patients have a successful initial outcome. Either the condition is self-limiting in the case of more isolated forms of skin vasculitis or the initial immunosuppressive therapy is successful. Over 94% of patients with generalized AAV would expect to survive the first 18 months,[78] whereas patients with more severe disease, especially with significant renal impairment, have a mortality of around 25% after 2 years.[82] This contrasts with >80% likelihood of dying without adequate treatment. However, with current therapy, 5-year survival figures suggest around 25–30% mortality among AAV-affected patients.[84]

The bigger problem, however, is morbidity. The quality of survival for most patients with multiorgan disease is complicated by episodes of relapse in 50–70% of cases and low-grade grumbling disease, which never quite goes into full remission in up to a third of cases.[85] This is added to the comorbidity experienced by older patients, usually a combination of vasculitis-related damage, steroid-induced side effects, and the long-term consequences of immunosuppressive agents. In the first year of diagnosis, the most likely cause of mortality is active vasculitis or infection,[62] the latter being a surrogate measure of the severity in immunosuppressant therapy required to control the disease.

Long-term adverse outcomes in vasculitis can be measured using a structured VDI (see Assessment section above). One of the most important outcomes is the development of end-stage renal failure and the requirement for dialysis. It is likely that this is significantly reduced as a result of effective therapy given within the first 4 months of diagnosis. Transplantation is successful in patients with AAV, and these patients should be offered this treatment. Ten-year survival rates (32.5%) are similar to those reported for other patients without diabetes receiving a kidney transplant.[86] The immunosuppressive regimens used for maintaining the transplant (Chapter 81) are often sufficient to keep the vasculitis in remission, but there is a need for ongoing review.

Infection is a significant concern, especially in the early course of disease when potent treatment being commenced, especially high doses of steroids. The risk of serious infection requiring hospitalization is very high in the first year,[62] especially if the steroid doses remain high after 6 months. Interstitial lung disease (nonspecific interstitial pneumonia) is reported in around 20% of Japanese patients, especially those with MPA. This is a higher prevalence than that seen in other populations and may reflect genetic and environmental differences unique to Japan. Chronic neuropathy occurs in 15% of patients with AAV[87] and can be very distressing for patients. Upper airway disease generally continues to cause long-term problems in 65% of patients with GPA because of chronic mucosal damage causing symptoms of chronic nasal congestion, discharge, and discomfort.[88] Symptom relief is only partially successful in alleviating these problems. The risk of cardiovascular disease among patients with small-vessel vasculitis is probably around four times greater in patients with AAV compared with the general population. The risk of cardiovascular events is around 14% within 5 years of diagnosis, especially in older patients who have baseline hypertension and MPO antibodies.[89] Cancer is associated with the presence of small-vessel vasculitis. It may predate as well as occur at the same time as diagnosis or develop subsequently, but it is recognized as a risk among patients treated with immunosuppressive and cytotoxic agents. Cancer of the bladder particularly has been an established risk arising from treatment with cyclophosphamide for many years; the original data from the 1970s suggested up to 33-fold increased risk of bladder cancer among patients treated with cyclophosphamide for vasculitis compared with background controls. However, this risk has been reduced with the use of more limited courses of cyclophosphamide (typically 3–6 months duration) and particularly with use of intermittent cyclophosphamide delivery. In a recent large series from the European Vasculitis Study Group (EUVAS), the only increased risk of cancer was for nonmelanoma skin cancer, and this may also have reflected the use of azathioprine as well as use of cyclophosphamide.[55] Shang et al.[90] showed that in a meta-analysis of over 2500 patients, the standardized incidence rate of late-occurring malignancies, particularly nonmelanoma skin cancer, leukemia, and bladder cancer, was 1.74 (95% CI = 1.37–2.21). We advise all of our patients to wear sun protection.

The ability to work is significantly affected by AAV; among 410 patients interviewed, 26% of those of working age were classified as work disabled.[91] The strongest influences on this outcome were fatigue, depression, high levels of damage (measured using the VDI), and being overweight. Patients' functional outcome can be variably affected by vasculitis and its treatment. Patients report impairment of function as measured by using generic tools, such as EQ-5D or the short form 36.[92] The impairment is similar to that found in other chronic diseases. Physical functions tend to be more affected than mental functions, especially in older patients with evidence of neurological involvement, usually peripheral neuropathy. Functional outcome is not directly correlated to disease activity, although in a Japanese cohort, 18 months after initiation of therapy, many aspects of function had started to improve.[93] One of the problems of determining long-term outcomes in patients with vasculitis is the compounding effect of the very intensive immunosuppressive therapy required to control disease. Over the last 3 decades, we have seen dramatic shift away from long course cyclophosphamide toward short courses of intermittent dose therapy, but we are now witnessing an era when targeted biological therapies are able to take the place of cyclophosphamide. Therefore eliminating the use of cyclophosphamide altogether in some patients may reset potential future outcomes. If this is coupled with a reduced use of glucocorticoid therapies and maintaining better disease control with less frequent relapses, the outcome may well be improved considerably for patients in the future.

ON THE HORIZON

- Improved understanding of the underlying pathogenic mechanisms in different forms of vasculitis is starting to lead to more logical, rational therapies, some of which have become established as standard of care or should be available in the near future.
- Rituximab is available and is being increasingly used in place of cyclophosphamide in the management of ANCA-associated vasculitis (AAV). Rituximab therapy is also effective in patients with cryoglobulinemic vasculitis, even when associated with the presence of hepatitis C. There is a concern that this might lead to reactivation of the virus and increase the risk of hepatoma or induce the development of the B-cell clone. However, better control of hepatitis C with effective antiviral agent is now possible.
- Multiple proinflammatory cytokines are being explored as therapeutic targets, although this will only allow for the suppression of common pathways in the end stage of inflammation.
- Mepolizumab has recently been shown to be effective in the treatment of eosinophilic granulomatous polyangiitis (EGPA) in a large randomised controlled trial.
- Blocking interleukin (IL)-6 may be of benefit for some patients.
- The discovery of the involvement of the complement pathway (C5) in AAV has led to the testing of therapies directed against C5a in humans.
- The ultimate goal remains to identify upstream pathologies leading to vasculitis, which promises to fundamentally change the management of these devastating diseases, as it may permit the induction and maintenance of drug-free remission.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following types of vasculitis are usually associated with the presence of antineutrophil cytoplasmic antibody (ANCA)?
   A. Microscopic polyangiitis
   B. Polyarteritis nodosa
   C. Goodpasture syndrome
   D. Cryoglobulinemic vasculitis
   E. Granulomatosis with polyangiitis

2. Which of the following is the *least* common form of vasculitis in Europe?
   A. Kawasaki disease
   B. Polyarteritis nodosa
   C. Granulomatosis with polyangiitis
   D. Microscopic polyangiitis
   E. Leukocytoclastic cutaneous vasculitis

3. Which of the following treatments are *not* effective for use in patients with newly presenting generalized ANCA-associated vasculitis?
   A. Colchicine
   B. Glucocorticoid therapy alone
   C. Glucocorticoids and methotrexate
   D. Rituximab and glucocorticoid therapy
   E. Plasmapheresis with cyclophosphamide and glucocorticoid therapy

Large-Vessel Vasculitides

Cornelia M. Weyand

Most tissues have compensatory mechanisms that allow them to sustain the damaging effects of acute and chronic inflammation, but medium and large arteries are organs without redundancy and limited regenerative capacity. Life is unsustainable unless the major arteries have uncompromised function. Accordingly, inflammatory damage to such arterial vessels leads to severe clinical consequences, immediately posing a threat for the loss of function of vital organs. When affected by inflammation, the aorta and its branches have two possible response patterns: *(i)* Inflammatory destruction of the vessel wall leads to dilatation, aneurysm formation, and rupture. Alternatively, the wall layers dissect. *(ii)* The inflammation initiates a maladaptive response to injury, resulting in luminal occlusion, disruption of blood supply, and ischemic damage of dependent organ structures.

In contrast to other vasculopathies, especially those related to atherosclerosis, vasculitides of the larger blood vessels are almost always associated with a syndrome of intense systemic inflammation.[1] Recent evidence has challenged the traditional view that systemic inflammation represents a spillover of inflammatory mediators from the vasculitic lesions. Instead, systemic activation of the innate immune system appears to be a pinnacle event that initiates the processes leading to vessel wall inflammation. The coincidence of malaise, fever, wasting, and myalgias, with signs of ischemia caused by vascular failure, remains a critical clue for the physician when diagnosing and treating large-vessel vasculitides (LVVs).

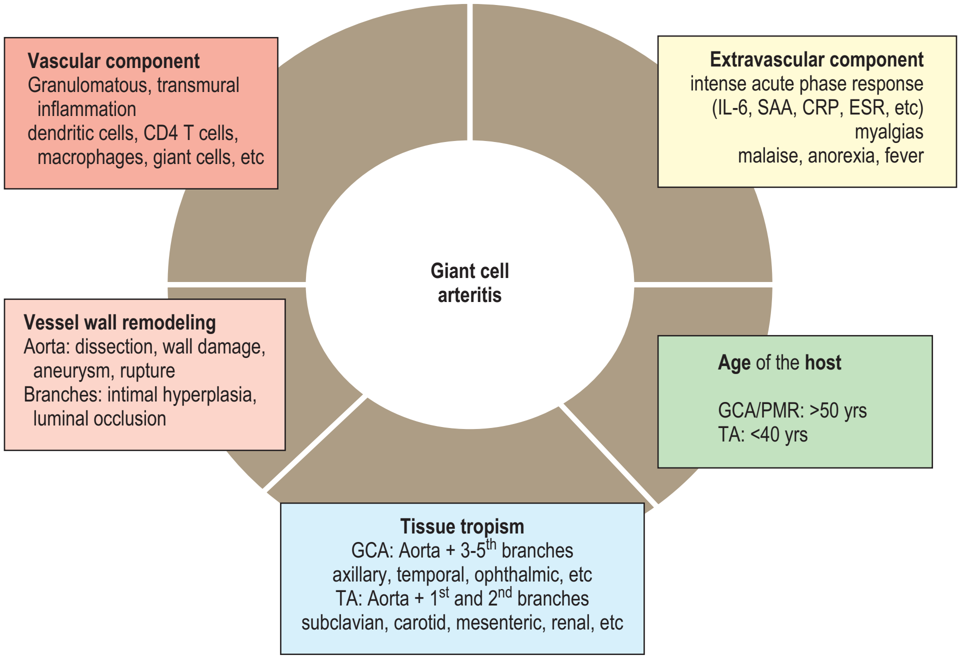
The two major forms of LVVs are giant-cell arteritis (GCA) and Takayasu arteritis (TA). In addition, aortitis can infrequently be seen in other diseases, such as infections, connective tissue diseases, sarcoidosis, and inflammatory bowel disease (IBD), and occasionally is diagnosed as an idiopathic syndrome. Polymyalgia rheumatica (PMR) is a condition closely related to GCA; it occurs in the same patient population and often precedes or follows the clinical diagnosis of GCA.[2] Patients with PMR do not have typical vascular lesions; consequently, PMR is not classified as a vasculitis. However, patients with PMR do have a systemic inflammatory syndrome indistinguishable from GCA, and about 10% of patients with PMR eventually progress to full-blown vasculitis. Similarities in the vascular lesions of GCA and TA have been interpreted as revealing parallels in immunopathogenesis. Whether similarities in histomorphology and tissue targeting reflect similarities in underlying molecular defects remains unclear. Whether the systemic inflammatory reactions accompanying GCA, TA, and PMR have disease-specific elements also remains unanswered, but this has opened the possibility of developing biomarkers that are urgently needed for clinical monitoring. Excellent progress has been made in unraveling the pathogenesis of GCA, and this will inevitably lead to improvements in diagnosis, long-term management, and broadening of the therapeutic armamentarium.

EPIDEMIOLOGY

GCA may be a very old disease, as suggested by historic evidence that more than 1000 years ago removal of the temporal artery was recommended by a physician in Baghdad. In 1932, Horton et al. at the Mayo Clinic in Minnesota recognized that GCA was an inflammatory vasculopathy when they found dense inflammation in the temporal arteries of two patients who were systemically ill and had severe headaches. The first reports of TA, or "pulseless disease," in young women surfaced in Japan in the nineteenth century. The syndrome was named after Dr. Takayasu, an ophthalmologist, who, in 1905, described peculiar optic fundus abnormalities caused by ischemia-driven collateral formation.

The strongest risk factor for GCA, TA, and PMR is age.[3,4] GCA and PMR are essentially absent in individuals <50 years of age, and their incidence climbs continuously during the seventh and eighth decades of life. TA is almost exclusively diagnosed in individuals <40 years of age, with peak incidence during the second and third decades of life. Women are affected more often by all three syndromes compared with men, with a 2 : 1 ratio in PMR and GCA and a 9 : 1 ratio in TA.[3,5]

Marked geographical variations in the incidence and prevalence of GCA, TA, and PMR have given rise to speculations about environmental exposures as key factors in disease pathogenesis. GCA is the most frequent vasculitis in the Western world, with yearly incidence rates reaching 10–20 cases per 100 000 persons >50 years of age.[3] In general, PMR is diagnosed three- to fourfold more frequently, with a prevalence of up to 1 case per 133 individuals >50 of age.[2] Iceland, Norway, Sweden, and Denmark are high-risk areas; higher incidence rates are also seen in Scandinavian immigrant populations in the United States. The risk is significantly lower in Hispanics and African Americans. Although TA can afflict all races, a predilection exists for individuals of Asian and Central and South American origins. Japan, Thailand, India, Turkey, and nations in Central and South Americas are considered high-incidence regions. TA is a rare disease with an annual incidence of 1–2 cases/million. The typical patient is a female in her 20s to 30s. In middle-aged men and women, it can be challenging to differentiate TA from rapidly progressing atherosclerotic disease, especially as both disease processes may coexist.[6]



Vascular component
Granulomatous, transmural inflammation
dendritic cells, CD4 T cells, macrophages, giant cells, etc
Extravascular component
intense acute phase response (IL-6, SAA, CRP, ESR, etc)
myalgias
malaise, anorexia, fever
Giant cell arteritis
Vessel wall remodeling
Aorta: dissection, wall damage, aneurysm, rupture
Branches: intimal hyperplasia, luminal occlusion
Age of the host
GCA/PMR: >50 yrs
TA: <40 yrs
Tissue tropism
GCA: Aorta + 3-5th branches
axillary, temporal, ophthalmic, etc
TA: Aorta + 1st and 2nd branches
subclavian, carotid, mesenteric, renal, etc

FIG 59.1 Key Pathogenic Traits in Giant-Cell Arteritis (GCA). In the emerging pathogenic model, five hallmarks of disease have been identified that represent fundamental pathogenic traits and distinguish GCA from other immune-mediated disorders. Vascular GCA (granulomatous vasculitis) is now separated from extravascular GCA (systemic inflammation and intense hepatic acute phase response). Age remains the strongest risk factor with evidence for a signature immunosenescence program in patients with GCA. The stringent tissue tropism for selected vascular beds is suspected to reflect heterogeneity of vascular cells. Clinical complications are related to the patterning of vascular damage, spanning from wall destruction to luminal occlusion.

ETIOLOGY AND PATHOGENESIS

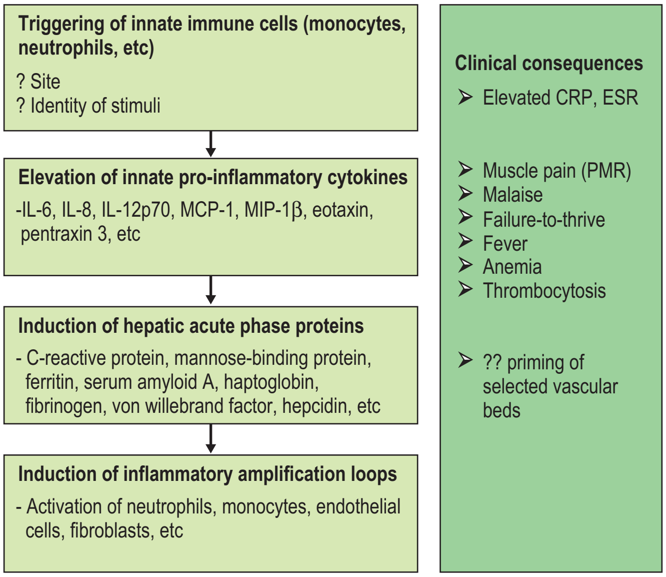
Abnormal innate and adaptive immune responses are essential pathogenic elements in medium-vessel vasculitides and LVVs. The end result is a disease process that separates GCA, PMR, and TA from other vasculitides and from other autoinflammatory and autoimmune syndromes. Progress has been made in identifying and characterizing the cellular and molecular elements that define LVVs. Recent work has delineated disease-specific signatures, with the goal to mark the pinnacle abnormality triggering the disease and to discover intersection points that lend themselves for diagnostic and therapeutic purposes.

Pathogenic studies and careful clinical observation have prompted a substantial shift in the pathogenic model (Fig. 59.1): LVVs are now understood to be chronic conditions that target restricted vascular beds and have two major disease components: *(i)* granulomatous, intramural inflammation inducing vascular wall remodeling; and *(ii)* extravascular inflammation manifesting with an intense acute phase response, myalgias, and constitutional symptoms. Emerging data suggest at least partial autonomy in the pathogenic cascades of both disease components, predicting separate biomarkers, separate pathogenic mechanisms, and separate responses to immunosuppression. Similarities in tissue tropisms and histological lesions of GCA and TA suggest overlapping disease pathways, and many aspects of immune pathogenesis may be transferrable from one syndrome to the other. The etiopathogenesis of PMR is less well understood, but experimental evidence suggests that it represents a *forme fruste* of GCA, in which inflammatory attack to the vessel wall remains below a threshold, and standard histology describes noninflamed arteries.

Distinctive features—hallmarks of disease—provide clues to the fundamental pathogenic mechanisms (see Fig. 59.1), including a stringent age cutoff, a stringent tissue tropism for selected vascular territories (aorta and major branches), an extravascular disease module defined by an abrupt and intense acute phase response, a granulomatous transmural vasculitis, and two opposing patterns of vessel wall remodeling causing aortic wall destruction versus luminal occlusion in the branch vessels.

INNATE IMMUNE SYSTEM DEFECTS

Innate immune cells make critical contributions to the pathogenesis of LVVs, but where circulating monocytes and neutrophils encounter their activating stimuli remains unknown (Fig. 59.2). Circulating monocytes and macrophages are highly activated[7] and contribute to the array of proinflammatory cytokines measurably elevated in the serum of affected patients.[8] Altered neutrophil functionality has also been described.[9] Early in the disease process, circulating neutrophils resemble those induced by a lipopolysaccharide stimulus, displaying T-cell suppressive functions. Interleukin-8 (IL-8) and IL-6 are associated with neutrophil activation. IL-6, first described in the early 1990s, is highly elevated in GCA and PMR[10] and is explicitly steroid sensitive.[11] IL-6 acts as an inducer of the acute phase response in the liver, triggering production of C-reactive protein (CRP),



Triggering of innate immune cells (monocytes, neutrophils, etc)
? Site
? Identity of stimuli
Elevation of innate pro-inflammatory cytokines
-IL-6, IL-8, IL-12p70, MCP-1, MIP-1β, eotaxin, pentraxin 3, etc
Induction of hepatic acute phase proteins
- C-reactive protein, mannose-binding protein, ferritin, serum amyloid A, haptoglobin, fibrinogen, von willebrand factor, hepcidin, etc
Induction of inflammatory amplification loops
- Activation of neutrophils, monocytes, endothelial cells, fibroblasts, etc
Clinical consequences
➢ Elevated CRP, ESR
➢ Muscle pain (PMR)
➢ Malaise
➢ Failure-to-thrive
➢ Fever
➢ Anemia
➢ Thrombocytosis
➢ ?? priming of selected vascular beds

FIG 59.2 **Extravascular Giant-Cell Arteritis (GCA).** Circulating innate cells (monocytes, neutrophils, etc.) are highly activated and elicit a hepatic acute-phase response. Several of the acute phase proteins serve as biomarkers (C-reactive protein [CRP], erythrocyte sedimentation rate [ESR]) of disease. Extravascular GCA is explicitly sensitive to corticosteroid therapy and to cytokine blockade. Whether the extravascular competent has a direct or indirect involvement in driving/sustaining granulomatous vasculitis remains unknown. Polymyalgia rheumatic (PMR) may represent an isolated form of extravascular GCA.

FIG 59.3 **Vascular Giant-Cell Arteritis (GCA).** Adaptive immune responses in vascular GCA are supported by transmural granulomatous infiltrates. Dendritic cells (DCs), present in healthy arteries at the adventitia–media border, serve as antigen-presenting cells (APCs) and provide costimulatory signals but are deficient in the coinhibitory ligand programmed death ligand 1 (PD-L1). Wall-infiltrating T cells are multifunctional, producing a broad spectrum of effector cytokines, including interferon (IFN)-γ, interleukin (IL)-17, IL-9, and IL-21. Macrophages, some of which transform into multinucleated giant cells, supply a multitude of cytokines, metalloproteinases, reactive oxygen species (ROS), growth factors, angiogenesis factors and inducible nitric oxide synthase (iNOS). Their functional commitment depends on their geographical location in the vessel wall.

serum amyloid A (SAA), and several other acute-phase proteins. Accordingly, treatment with an IL-6 receptor–blocking antibody, effectively reduces the laboratory abnormalities measured in patients with GCA.[12] Whether IL-6 has additional functions in the disease process, particularly in the inflamed vessel wall, is uncertain. Some acute-phase proteins (*e.g.,* SAA) have proinflammatory functions by themselves, functioning as proinflammatory amplifiers.[13] Although abnormal innate immunity dominates the extravascular component of LVVs, underlying mechanisms (*e.g.,* what the original triggers are, where the activation occurs, how the systemic inflammation interfaces with vascular inflammation) are essentially unexplored.

Defects in innate immunity contributing to the early and late events in the vasculitic lesions are much better understood[14] (Fig. 59.3). A population of vessel wall–residing dendritic cells (vasDCs) have been identified in normal human arteries,[15] localized at the adventitial–medial junction, close to the adventitial microvascular network. Given their strategic positioning, they are believed to guard the artery's "backdoor." vasDCs serve a gatekeeper function in vasculitis, and stimulation of such vasDCs is a prerequisite to break the natural immunotolerance (immune privilege) of the arterial wall. Their activation presages vasculitis, as indicated by their transition from the resting state to the activated state in PMR arteries, where no vessel wall infiltrates are as yet detectable.[16] In frank vasculitis, vasDCs undergo expansion, penetrate deep into the wall, produce chemokines and cytokines, and express costimulatory ligands.[17] They have been implicated in presenting local antigen to induce T-cell clonal expansion and, through their chemokine production, shape the composition of the intramural granulomatous infiltrates. Considering that vital arteries (*e.g.,* the aorta) are protected by immune privilege, malfunction of endogenous vasDCs may, indeed, be the pinnacle defect–initiating vasculitis.

Other innate immune cells captured in the vasculitic lesions, specifically macrophages, are particularly important as inflammatory effector cells.[18] Multiple functional domains of macrophages have pathogenic relevance. Intriguingly, the functional commitment of lesional macrophages is closely linked to their geographical location in the tissue site.[19] Intima-positioned macrophages produce inducible nitric oxide synthase, participating in regulating vascular tone. Adventitial macrophages secrete cytokines (IL-1β, IL-6, transforming growth factor-β [TGF-β]), conditioning the local inflammatory environment. Granuloma formation and giant cells dominate in the media and at the media–intima border. Functional profiling of media-residing macrophages has connected them to tissue damage; they produce metalloproteinases and reactive oxygen species (ROS), provide antioxidant regulation, and supply growth factors for myofibroblasts and newly formed microvessels. Essentially they drive the hyperplasia of the intimal layer that leads to luminal obstruction

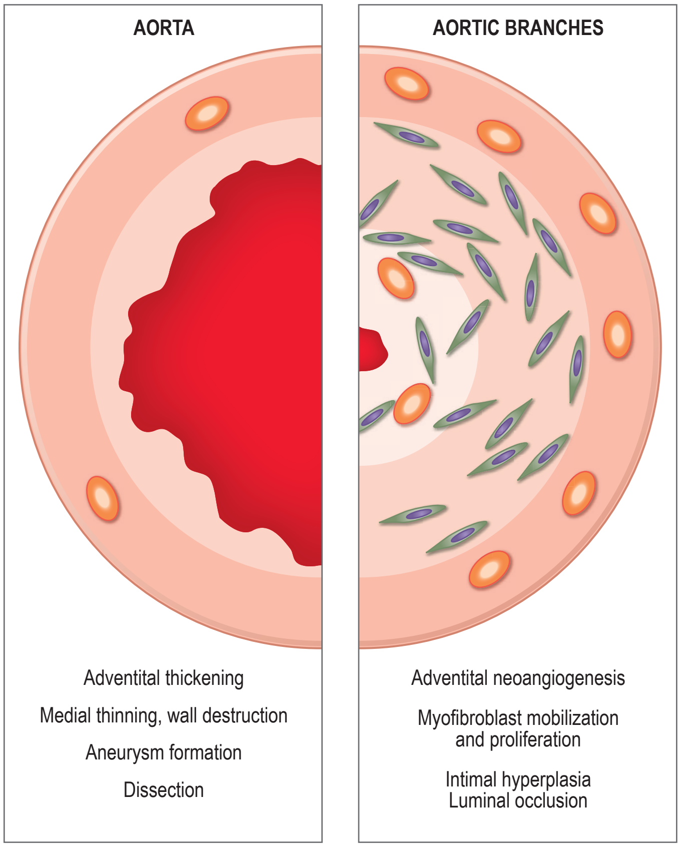

FIG 59.4 Patterns of Vessel Wall Damage in Giant-Cell Arteritis (GCA). Transmural granulomatous vasculitis results in two distinct damage patterns. In the aorta, the inflammatory infiltrates destroy the wall, inducing dissection and aneurysm formation. As a result of neoangiogenesis and fibrosis, the adventitia expands. In the aortic branches, transmural granulomatous infiltrates predominantly elicit a maladaptive healing response, characterized by the mobilization, migration, and proliferation of myofibroblasts forming hyperplastic and lumen-obstructive neointima. Formation of neotissue is associated with microvascular neoangiogenesis in the intima, media, and adventitia. New research indicates that intimal hyperplasia and neoangiogenesis are ultimately regulated through the intensity of the T-cell response in the vasculitic lesions.

and tissue ischemia. Whether macrophage effector functions are fundamentally different in aortitis, compared with branch vasculitis, requires further exploration. Differences of tissue damage patterns (wall destruction versus luminal occlusion) suggest at least substantial variances (Fig. 59.4).

ADAPTIVE IMMUNE SYSTEM DEFECTS

The hallmark lesions in the vessel wall are granulomatous infiltrates, in essence a mixture of highly activated macrophages, giant cells, and surrounding lymphocytes (see Fig. 59.3). The overwhelming majority of these lymphocytes are memory CD4 T cells. CD8 T cells are infrequent, and B cells are rare. Multinucleated giant cells are present in about 50% of patients, often localized close to the intima–media border adjacent to the lamina elastica interna. Fragmentation of that elastic membrane is a hallmark of GCA.

Analysis of clonal CD4 populations has yielded identical T-cell receptors (TCRs) in independent temporal artery biopsies from the same patient, strongly supportive for antigen driving T-cell behavior in the tissue microenvironment.[20] Wall-embedded vasDCs serve as antigen-presenting cells (APCs); the nature of the antigen remains unknown. Reports about infectious agents isolated from temporal arteries have notoriously not been confirmed in independent studies. The older adult host is expected to accumulate viral and bacterial microorganisms, and locally deposited pathogens may not indicate causal involvement but, rather, represent the vascular microbiota. Carefully designed experiments need to probe for a specific role of pathogens isolated from temporal artery tissue.

T helper 1 (Th1) cells are a key pathogenic element in GCA. Interferon-γ (IFN-γ), the Th1 marker cytokine, has multiple disease-relevant functions: activating endothelial cells and macrophages, regulating wall remodeling, inducing microvascular neoangiogenesis, and driving intimal-layer expansion.[14] IFN-γ production is predominantly produced in the adventitia, where T cells are instructed by vasDCs. Th1 cells are present in lesions from untreated patients and persist despite prolonged corticosteroid therapy,[21] suggesting independence of vasculitogenic Th1 cells from the steroid-sensitive acute-phase response and emphasizing their role as stabilizers of chronic-persistent lesions. During early vasculitis, Th1 cells are accompanied by Th17 cells. However, Th17 cells are highly sensitive to steroid therapy and chronic lesions are Th17 depleted.[21] Comparative analysis of sequential temporal artery biopsy tissues harvested from patients before and after treatment has demonstrated that adaptive immune responses evolve over the course of the disease and that different subpopulations of lesion-residing T cells are differentially responsive to immunosuppression.

Recent data have emphasized that the T-cell infiltrate in GCA-affected arteries is typically multifunctional and composed of a broad spectrum of functional lineages.[22] Besides Th1 and Th17 cells, Th9, and IL-21–producing T follicular helper (Tfh) cells are part of the infiltrate. Little is known about precise effector functions of these T cells. However, overall the T-cell population recruited to and retained in the vessel wall is functionally highly diverse, raising the possibility that a mixed set of antigens with vasculitogenic potential. Alternatively, the defect leading to granulomatous wall inflammation is the sequel of antigen-nonspecific defects.[22]

T cells have now been placed at the top of the artery's maladaptive response to injury, but precise effector pathways are not understood (see Fig. 59.4). Chronic aortitis leads to wall destruction and aneurysm formation. Dissection is increasingly recognized as a sequel of aortic wall inflammation. In rare cases, LVV results in the fatal complication of aortic rupture. In TA, direct cytotoxic function of CD8 T cells, natural killer (NK) cells, and γδ T cells has been implicated in local tissue injury.[23] Conversely, in the aortic branches, LVV typically causes luminal stenosis/occlusion as a result of formation of lumen-obstructive neotissue. Proliferating myofibroblasts lay down matrix and build hyperplastic intima. Newly formed microvessels appear in the adventitia and intima to supply oxygen and nutrients to the thickening wall. How T cells instruct vascular cells to this maladaptive wound healing response and whether heterogeneity of such vascular cell populations imposes the disease's tissue tropism are the subjects of ongoing research. So far, the few wall-infiltrating B cells have not been assigned to a specific pathogenic mechanism.

KEY CONCEPTS

Large Vessel Vasculitis

- Medium and large arteries in humans have multiple wall layers and a wall structure substantial enough to be the target of transmural inflammation.
- Vasculitis causes the rapid and concentric growth of hyperplastic intima, leading to luminal occlusion and ischemia of dependent tissues. Intramural inflammation of the aorta can result in wall damage followed by aneurysm formation and rupture.
- Because of the vital function and nonregenerative nature of large human arteries, the threshold for the induction and persistence of innate and adaptive immune responses in the wall structures of such arteries must be explicitly high.
- Inflammatory infiltrates typical for granulomatous vasculitis enter the vessel from the "back door," the adventitia, and not from the lumen.
- Besides their critical role in securing blood flow, medium and large blood vessels also possess immunoregulatory functions mediated by dendritic cells (DCs) indigenous to the vascular wall. DCs in each vascular territory express a distinctive pattern of Toll-like receptors (TLRs), giving each vessel its own immunological identity.

Defective T Regulatory Cells and Insufficient Immune Checkpoints in Giant Cell Arteritis

Recent data have brought to the forefront that antigen-nonspecific immunoregulatory pathways may have disease relevance in LVVs, specifically in enabling unopposed and lasting adaptive immune responses to induce and sustain vessel wall inflammation.

Like in many chronic inflammatory lesions, GCA's arterial wall infiltrates lack sufficient antiinflammatory T regulatory cells (Tregs). This may be a consequence of the proinflammatory milieu, but recent studies have identified a novel mechanism of Treg-dependent immunosuppression that is nonfunctional in GCA. In healthy individuals, secondary lymphoid tissue are occupied by a population of CD8 Tregs that effectively control clonal expansion of CD4 T cells, and thus the overall size of the CD4 T-cell compartment.[24] Such CD8 Tregs suppress activation and expansion of neighboring CD4 T cells by the directed transfer of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase 2 (Nox2)–containing membrane particles. The population of Nox2$^+$ CD8$^+$ Tregs is distinctly low in patients with GCA and remains low with antiinflammatory therapy, suggesting a preexisting abnormality in the patients' immune system. Implicating Nox2 expressed on CD8 T cells in the threshold setting of CD4 T-cell immunity opens an entirely new perspective in vasculitis research and redirects the focus away from antigenic triggers that induce protracted macrophage activity.

A second immunoregulatory defect weakening proper control of CD4 T-cell immunity has been localized to the programmed death 1 (PD-1) immunoinhibitory checkpoint.[25] Inhibitory checkpoints are designed to protect tissue from excessive immune reactivity. PD-1 is expressed on activated T cells, the ligand PD-L1 is expressed on APCs. Triggering of PD-1 sends negative signals into T cells and stops their proliferation and polarization. DCs in patients with GCA, both lesional vasDCs and circulating DCs, are PD-L1^{low}. GCA T cells thus lack negative signaling and fail to undergo clonal contraction. Indeed, in inflamed temporal arteries PD-1$^+$ T cells are strongly enriched. In human artery–chimeric mice, blocking PD-1 with antibody treatment exacerbates vasculitis, and wall-infiltrating PD-1$^+$ T cells produce a spectrum of effector cytokines (IFN-γ, IL-17, IL-9, IL-21, etc.). Most importantly, PD-1–PD-L1 interactions in the artery have direct impact on the density of newly formed microvessels and the thickness of the hyperplastic intimal layer.[25] Hyperactive checkpoints are now targeted therapeutically to unleash T-cell immunity in patients with cancer. A role for PD-1–derived negative signaling in vasculitis predicts that such patients are at risk to develop drug-induced vasculitis.

CLINICAL FEATURES IN GIANT CELL ARTERITIS

CLINICAL PEARLS

Clinical and Epidemiological Clues in Giant-Cell Arteritis

- Patient older than 50 years of age
- Female
- Northern European heritage
- Laboratory findings of a highly activated acute-phase response
- Insidious onset of nonspecific symptoms (weight loss, night sweats, malaise, fever)
- Ischemia of ocular structures, cranial muscles, scalp, or upper extremities

Clinical manifestations of GCA reflect the combination of a systemic inflammatory syndrome with vascular insufficiency (Table 59.1).[2,26] Increased sensitivity of vascular imaging methods and longer survival of affected individuals have made it clear that in most patients medium and large arteries are involved. In some patients, the disease preferentially targets more peripheral branches of the aorta (*e.g.*, cranial arteries, such as the temporal artery). In others, the aorta and its proximal branches (*e.g.*, subclavian, axillary arteries) are involved to a major extent. In a subpopulation of patients, the clinical consequences of arterial inflammation are minimal, and these consequences come to clinical attention because of failure to thrive.

In cranial GCA, symptoms result from vascular stenosis of the neck and head arteries, most prominently in the branches of the external carotid artery. Arteritis of the scalp arteries leads to the typical presentations of headaches and scalp tenderness. Patients report difficulties with wearing glasses or combing their hair. The headaches are often intense and unresponsive to standard analgesics. Headaches are a nonspecific clinical symptom, yet in an older individual with other findings of an inflammatory syndrome, physicians need to rule out GCA. Insufficient blood flow to the masseter muscles and the tongue causes jaw or tongue claudication, elicited by prolonged chewing and talking. Although this type of claudication is present in <30% of patients, it is clinically helpful because it rarely occurs outside of GCA. Similarly, painful dysphagia can be a useful clinical clue.

The orbits and the optic nerve are strictly dependent on blood supply from the external carotid system, particularly the ophthalmic artery. GCA in branches of the ophthalmic artery, specifically the posterior ciliary arteries, leads to anterior ischemic optic neuropathy, presenting as sudden and painless vision loss. Typically, patients lose vision in the early-morning hours or wake up blind. Involvement of one eye may be followed by visual loss in the partner eye if the disease is not diagnosed and treated promptly. Besides anterior optic neuropathy, GCA can cause a number of ischemic complications in the orbits and along the visual axis, which may present as diplopia or partial vision loss.[18] If recognized and treated immediately, vasculitis-associated sight

loss is preventable, which indicates that GCA should be considered an ophthalmological emergency.

Chronic nonproductive cough can be related to arteritis in bronchial artery branches. If the vertebral and basilar arteries develop vasculitic stenosis, ischemia of the central nervous system manifests with transient ischemic attacks or frank stroke.

In patients with large-vessel GCA, cranial symptoms may be minimal, and temporal artery biopsy can be negative.[27] Instead, vascular insufficiency is focused on the upper-extremity vessels and the aorta. In rare cases, lower extremities are affected. Typically, patients have asymmetrical blood pressure readings or experience total loss of upper-extremity blood pressure and pulse. The underlying lesions are occlusions in the distal subclavian arteries, often extending into the axillary sections (Fig. 59.5). Patients with subclavian GCA are on average about 10 years younger at disease onset compared with those with dominant cranial manifestations. Diagnosis of large-vessel GCA can be delayed as symptoms are nonspecific and the systemic inflammatory component is less pronounced. Ischemic pain in the hands when using the arms is often combined with coolness and bluish discoloration. Gangrene of the fingertips is rare. Disability can be significant, as patients have difficulties with activities of daily living. With stenotic lesions of the subclavian arteries, blood pressure readings can be unreliable or not possible, requiring alternative strategies for blood pressure monitoring. Although carotid involvement is considered infrequent, it can be challenging to distinguish atherosclerotic disease and vasculitic disease. Patients with carotid GCA are at high risk for cerebral ischemic events. Aortic involvement preferentially targets the thoracic aorta and infrequently the abdominal aorta (Fig. 59.6). Dilation of the aortic root can lead to aortic insufficiency. Aortic aneurysms are often clinically silent. The diagnosis may first be made from tissue obtained surgically during aortic aneurysm repair. In extreme cases, the aortic wall ruptures.

The response pattern of arteries to inflammation may not include intimal hyperplasia, thus eluding luminal compromise and vascular failure. In such patients, the systemic inflammatory component dominates the clinical presentation. Fever, fatigue, malaise, weight loss, and depression are often intense enough to prompt a workup for a malignancy. GCA needs to be a differential diagnosis in all cases of fever of unknown origin, particularly in older individuals. Patients with cranial GCA have abnormally thick and tender temporal arteries exhibiting nodularity and loss of pulses, whereas clinical findings in nonstenosing GCA can be unremarkable. Temporal artery biopsy should be pursued even if clinical examination does not suggest the diagnosis.

CLINICAL FEATURES IN POLYMYALGIA RHEUMATICA

PMR is diagnosed in patients presenting with pronounced stiffness and pain in the shoulder and pelvic girdle muscles (see Table 59.1).[2] Laboratory testing reveals a systemic inflammatory syndrome; arterial biopsy is negative for arteritis. It is estimated that about 10% of patients with PMR without any signs of vascular inflammation will eventually develop full-blown vasculitis. Notably, PMR often occurs in patients with GCA and is present in about 40% of patients with GCA at disease onset. Tapering of immunosuppressive therapy in GCA is frequently associated with new or remittent PMR symptoms.[26] Complaints are focused on muscle pain and stiffness, classically affecting the neck, shoulders, and pelvic girdle. The muscles of the torso may be involved. Peripheral areas of the arms and legs are spared. Muscle pain is most intense in the early morning and improves during the day. Inability to get out of bed, stand up from a chair, or get off the toilet seat should alert the physician to consider PMR. Some patients with PMR have synovitis or bursitis in their shoulder and hip joints,[2,28] making it difficult to distinguish these patients from those with seronegative polyarthritis. No diagnostic procedure that allows for the diagnosis of PMR is available; the syndrome remains an exclusion diagnosis in cases of myalgia combined with laboratory signs of systemic inflammation. On clinical examination, passive motion of shoulder and hip joints is seen to be maintained, but active motion is restricted because of pain. Muscle strength is often normal. Careful evaluation of the temporal arteries is warranted to avoid missing fully developed GCA.

CLINICAL FEATURES IN TAKAYASU ARTERITIS

The clinical manifestations of TA are diverse and depend on the affected vascular territory (see Table 59.1; Table 59.2).[29] Initial

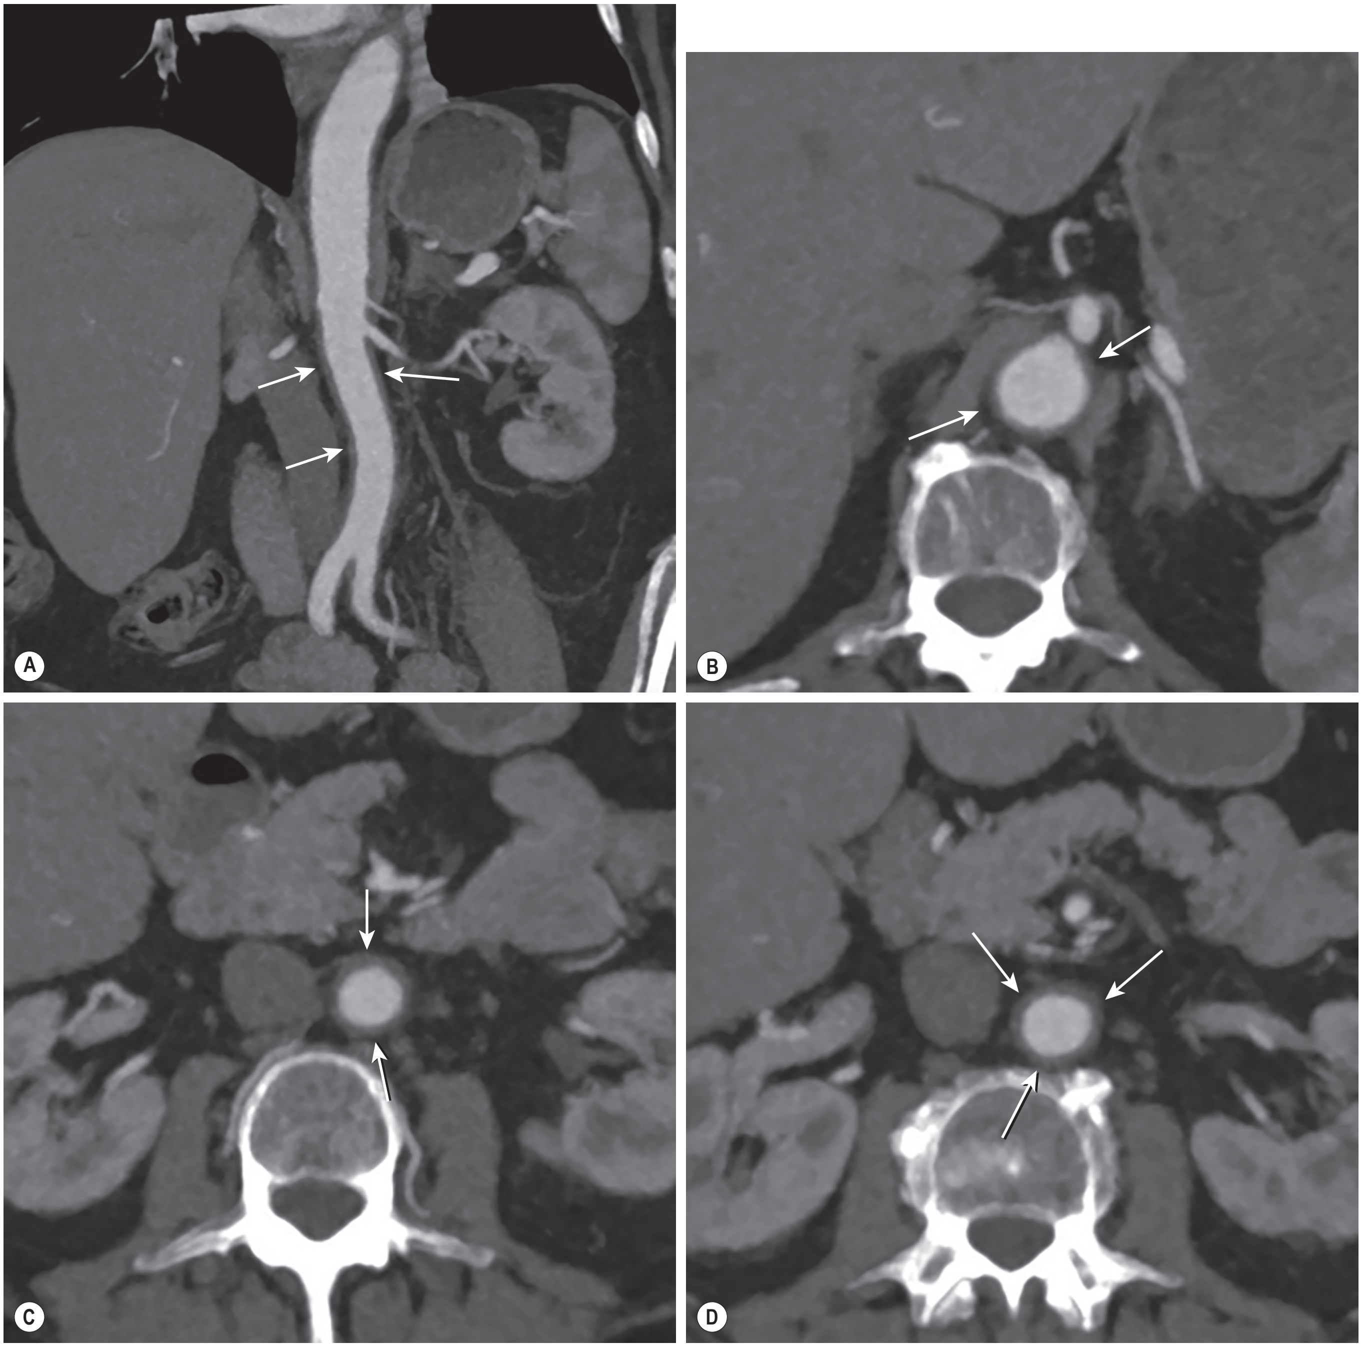

FIG 59.5 **Diagnostic Imaging in Giant-Cell Arteritis (GCA): Computed Tomographic Angiography (CTA).** Contrast-enhanced CTA in a 74-year-old female with a temporal artery biopsy positive for GCA. CTA imaging shows diffuse, circumferential mural thickening along the entire descending aorta and the abdominal aorta (A). Arrows mark the thickened aortic wall. Axial images (B, C, and D) reveal the circumferential distribution *(arrows)* of the wall thickening from the distal arch to the intrarenal portion of the aorta. Thickness measurements can be used to monitor disease burden over time. The aortic diameter is within normal limits, indicating that the aortitis has not yet resulted in aneurysm formation. [Images were generated by Dr. D. Fleischmann, Department of Radiology, Stanford University.]

symptoms are usually nonspecific and include fever, cough, malaise, weight loss, night sweats, myalgias, and arthralgias. Signs of vascular deficiency develop later in the disease course and generally are ischemic in nature. Geographical variations in disease pattern have been reported, likely reflecting the interplay between host risk genes and dysfunctional immunity. In North American, Japanese, and Korean patients, the aortic arch and its primary cervical and upper extremity branches are preferentially targeted, giving rise to aortic insufficiency, cerebral ischemia, face and neck pain, ocular ischemia, and the typical presentation

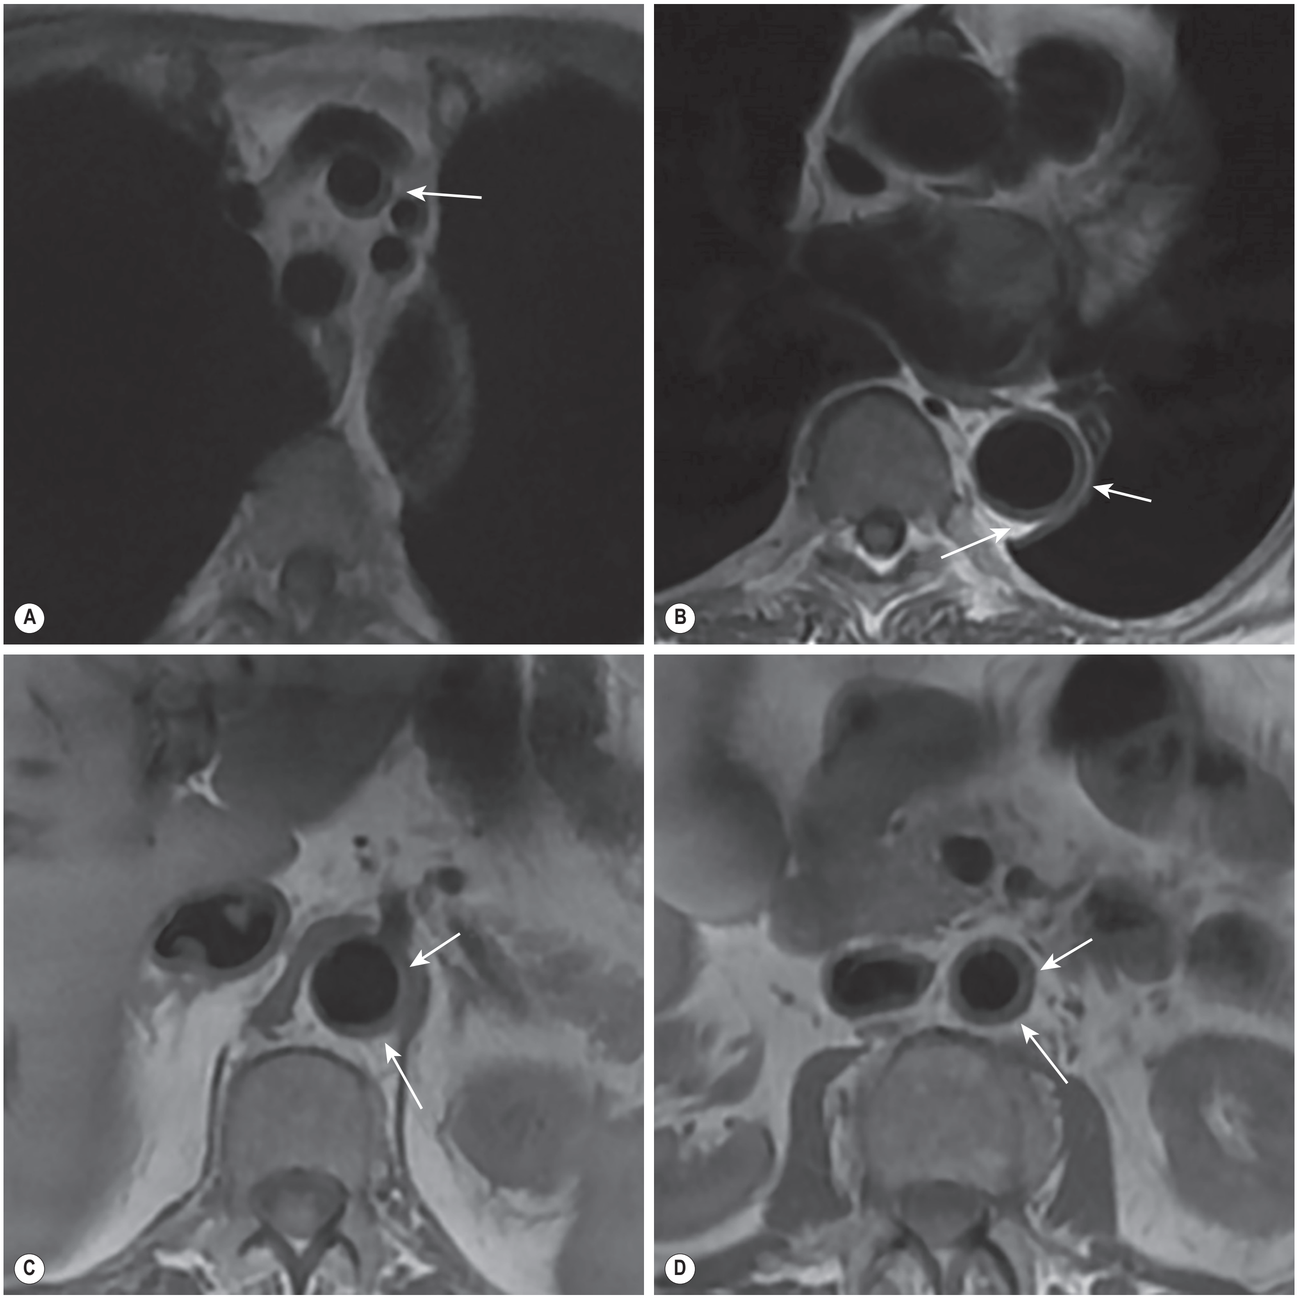

FIG 59.6 **Diagnostic Imaging in Giant-Cell Arteritis (GCA): Magnetic Resonance Angiography (MRA).** Contrast-enhanced MRA of the chest and abdomen in the patient whose computed tomographic angiography (CTA) images are presented in Fig. 59.5. Double-inversion recovery magnetic resonance imaging (MRI) scans in the axial plane demonstrate diffuse, contiguous mural thickening of the great vessels (A, brachiocephalic trunk) and the aorta (B–D). Arrows are placed to mark the circumferential distribution of the mural thickening and compare luminal diameter and wall thickness at different levels of the vessels. [Images courtesy of Dr. D. Fleischmann, Department of Radiology, Stanford University.]

of "pulseless disease" (Fig. 59.7). In patients in India, the abdominal aorta and renal arteries are more commonly affected, causing renovascular hypertension and the long-term risk of cardiac failure (Fig. 59.8).[30]

Nonspecific complaints of headaches, syncope, and face and neck pain are often misinterpreted as stress-related problems, particularly in young women. Consequently, the diagnosis can be missed for months. Only a few patients come to clinical attention because of catastrophic neurological symptoms related to brain ischemia. Helpful clues are differences in blood pressure, loss of pulses, and vascular bruits heard on clinical examination. Retinal neoangiogenesis, induced by hypoperfusion of the eye,

TABLE 59.2 Takayasu Arteritis: Relationship Between Clinical Symptoms and Affected Vascular Territories

Vascular Bed Involvement	Approximate Frequency (%)	Predominant Clinical Symptoms
Subclavian	90	Arm claudication, pulselessness
Common carotid	60	Visual defects, stroke, transient ischemic attack, syncope
Abdominal aorta	45	Claudication, hypertension, abdominal angina
Renal	35	Hypertension
Aortic arch/root	35	Aortic insufficiency, congestive heart failure
Vertebral	35	Dizziness, visual impairment
Celiac axis	20	Abdominal angina
Superior mesenteric	20	Abdominal angina
Iliac	20	Claudication
Pulmonary	10	Dyspnea, chest pain
Coronary	10	Myocardial infarction, angina

is now relatively rare, but fleeting visual abnormalities may indicate transient ischemic attacks. Signs of aortic insufficiency are unlikely to be encountered in early disease, but continuous monitoring for aortic dilation is an essential part of follow-up care. Coronary artery stenosis in a young patient must prompt the physician to rule out TA. In a subset of patients, the origins of mesenteric arteries are involved by stenosing vasculitis. Clinical consequences include weight loss, nausea, vomiting, diarrhea, and abdominal claudication, typically elicited by the increased intestinal blood demand following a meal.

Renal artery stenosis may be clinically silent and is often noticed in routine screening. Correct measurement of blood pressure can represent a pressing clinical problem if the upper-extremity arteries are affected. Involvement of the infrarenal aorta can lead to lower-extremity claudication. Musculoskeletal examinations are usually unrevealing, although joint and muscle pains are common complaints.

DIAGNOSIS

Classification criteria have been developed for GCA and TA to differentiate patients with LVV from those with other vasculitic entities (Tables 59.3 through 59.5).[31-33] Age at disease onset and the pattern of arteritis are clearly important for establishing the diagnosis and distinguishing between these two related vasculopathies. Diagnostic criteria for PMR remain a challenge (see Table 59.3) as they rely on nonspecific symptoms, such as muscle pain and stiffness and elevated erythrocyte sedimentation rate (ESR), all of which can occur in many other diseases.[2] No specific laboratory test is currently available to diagnose PMR. Therapeutic responsiveness of patients with PMR to low-dose corticosteroids is clinically helpful but stresses the need for objective diagnostic criteria.

Laboratory Tests

In all three conditions—GCA, PMR, and TA—the laboratory findings indicate an intense acute-phase response in a vast majority of patients.[2,26,34] Generally this is captured by measuring ESR or CRP. It is important to note, however, that a subset of patients with GCA has normal ESR readings, even before initiation of immunosuppressive therapy. A normal ESR or CRP reading is not sufficient to exclude the diagnosis, and further diagnostic workup is required if clinical presentation is suspicious for vasculitis. Other acute-phase proteins, such as fibrinogen and SAA, have been reported to be elevated as well. IL-6 is a potent inducer of acute-phase proteins in the liver and has been found to be a sensitive marker of continuous systemic inflammation.[10,11]. Other laboratory abnormalities, such as elevation of alkaline phosphatase, thrombocytosis, and anemia, are in line with a robust acute-phase response.

Autoantibody measurements are not helpful beyond excluding differential diagnoses, such as rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), or antineutrophil cytoplasmic antibody (ANCA)–related vasculitides. No disease-specific autoantibodies for GCA and TA have been discovered, emphasizing that B-cell immunity may not contribute to vascular inflammation.

Tissue Biopsy

In patients with TA, tissue biopsies are rarely available unless the patient had to undergo vascular reconstructive surgery. In most patients, the diagnosis is made on the basis of imaging procedures revealing luminal and wall abnormalities in affected blood vessels.

In contrast, arterial biopsy remains a critical diagnostic approach in managing patients with GCA. Temporal arteries are easily accessible, and a segment of these arteries can be removed in an outpatient setting. Recommendations include harvesting 2–3 cm of the temporal artery, starting at the most symptomatic side. Frozen tissue sections can lead to a quick diagnosis of granulomatous vasculitis. Whether the second side should be biopsied during the same surgical procedure remains a matter of debate. In cohorts that included several hundred patients, vasculitis was detected in 2–3% of tissue samples from the second side if the first side was negative. If the clinical suspicion is strong, biopsy confirmation can be sought from a second-side biopsy immediately after the first biopsy or after careful monitoring of the patient for several weeks. Negative findings on temporal artery biopsy do not exclude the diagnosis of GCA. In a retrospective cohort study, about half of all patients with subclavian GCA had no evidence of vasculitis in the temporal arteries, emphasizing that the disease may display clear preference for certain vascular territories.[35] There has been a recent trend toward considering negative biopsies as "false negative" and classifying patients with a negative biopsy as having GCA. This may lead to unnecessary immunosuppressive therapy, and the patient may not thus obtain a proper diagnosis. Findings that prompt biopsies (headaches, elevated acute-phase reactants) are notoriously nonspecific, and both physicians and patients are anxious to avoid treatable blindness, biasing toward overtreatment. The temporal artery biopsy remains a powerful diagnostic tool and the major tool that allows unequivocal classification of the disease process. A technically proper temporal artery biopsy will detect vasculitis in the vast majority of patients.

Corticosteroid therapy does not eradicate pathological findings of vascular wall infiltrates, and biopsy can still be valuable in making the diagnosis in patients on steroids.[21] Nevertheless it is possible that treatment with steroids leads to a false-negative biopsy result in some patients.

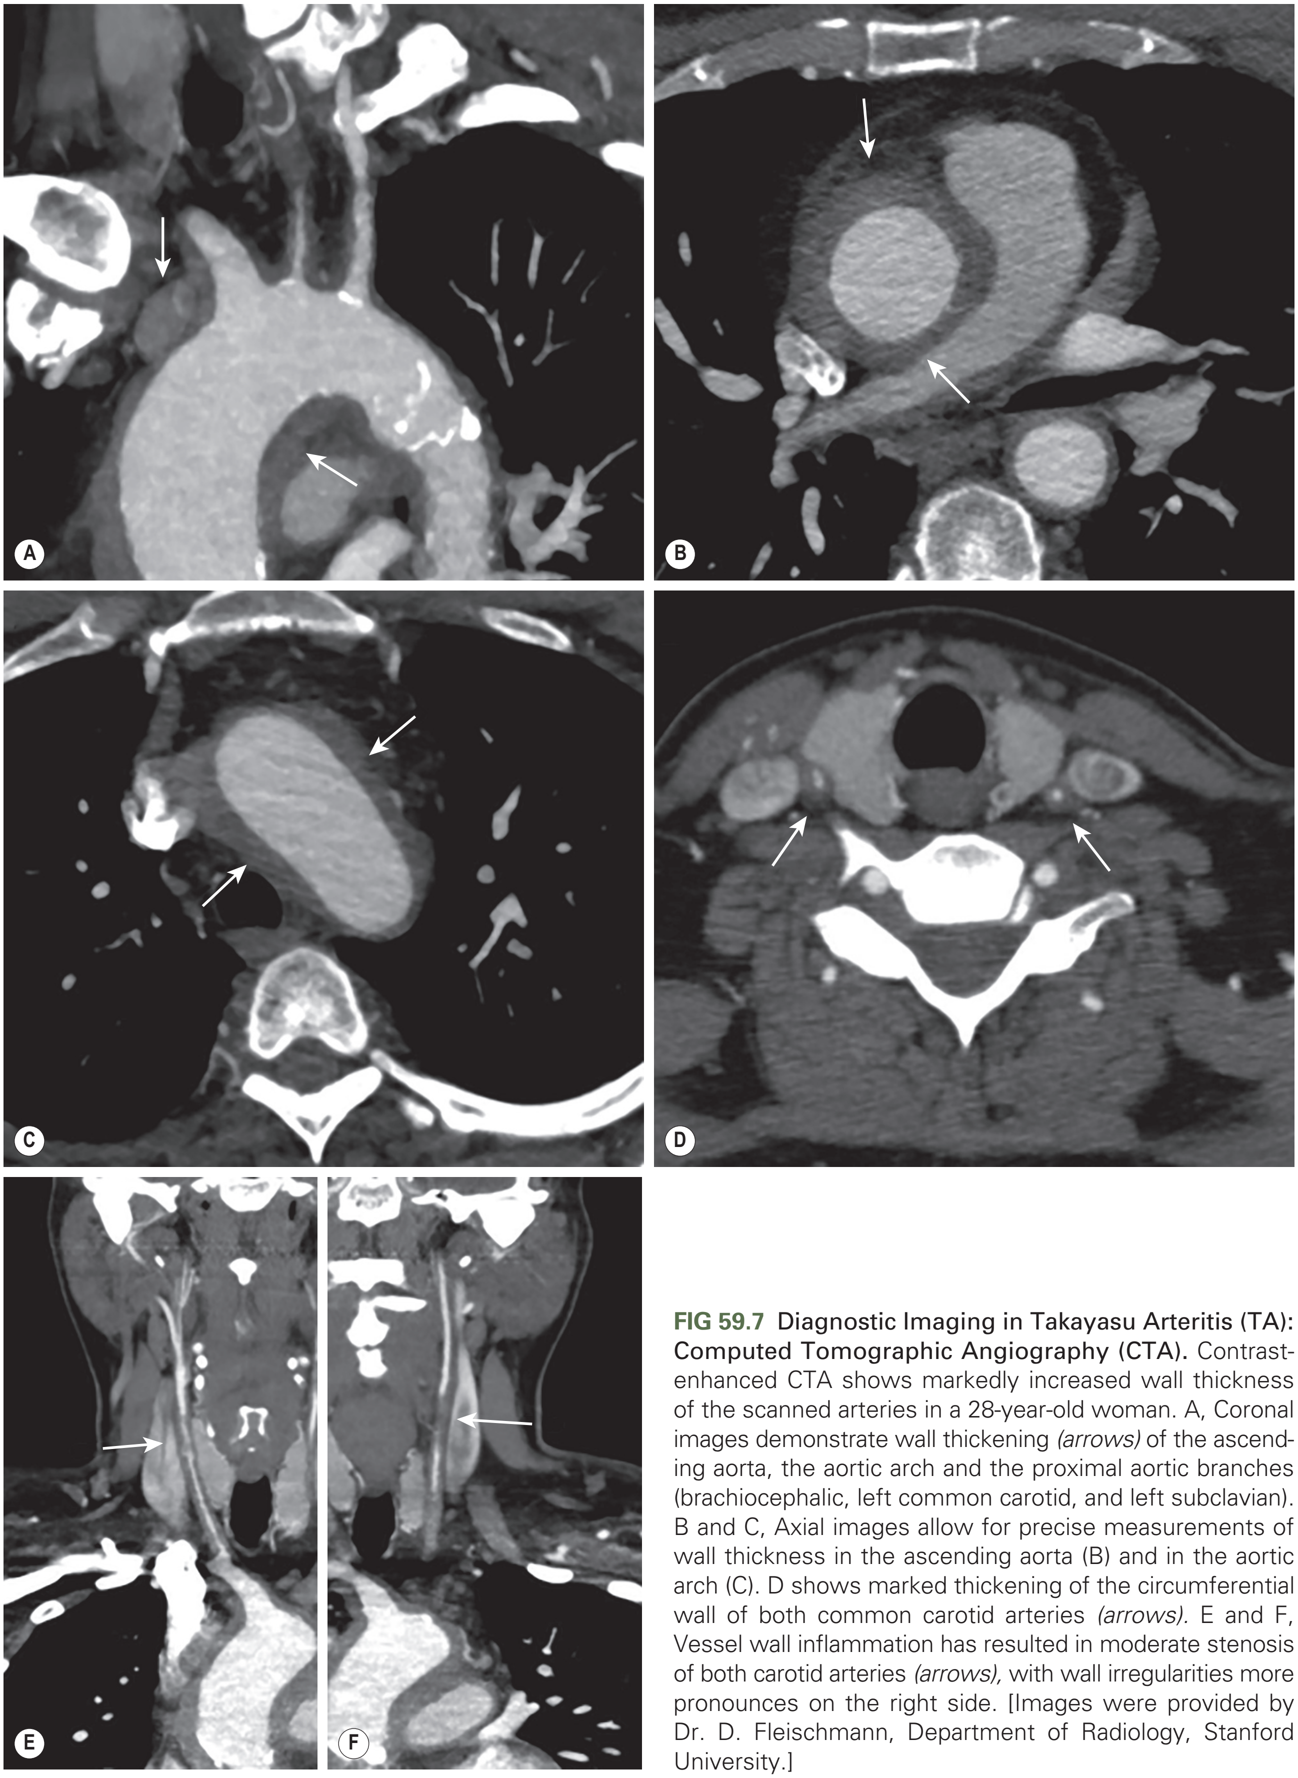

FIG 59.7 **Diagnostic Imaging in Takayasu Arteritis (TA): Computed Tomographic Angiography (CTA).** Contrast-enhanced CTA shows markedly increased wall thickness of the scanned arteries in a 28-year-old woman. A, Coronal images demonstrate wall thickening *(arrows)* of the ascending aorta, the aortic arch and the proximal aortic branches (brachiocephalic, left common carotid, and left subclavian). B and C, Axial images allow for precise measurements of wall thickness in the ascending aorta (B) and in the aortic arch (C). D shows marked thickening of the circumferential wall of both common carotid arteries *(arrows).* E and F, Vessel wall inflammation has resulted in moderate stenosis of both carotid arteries *(arrows),* with wall irregularities more pronounces on the right side. [Images were provided by Dr. D. Fleischmann, Department of Radiology, Stanford University.]

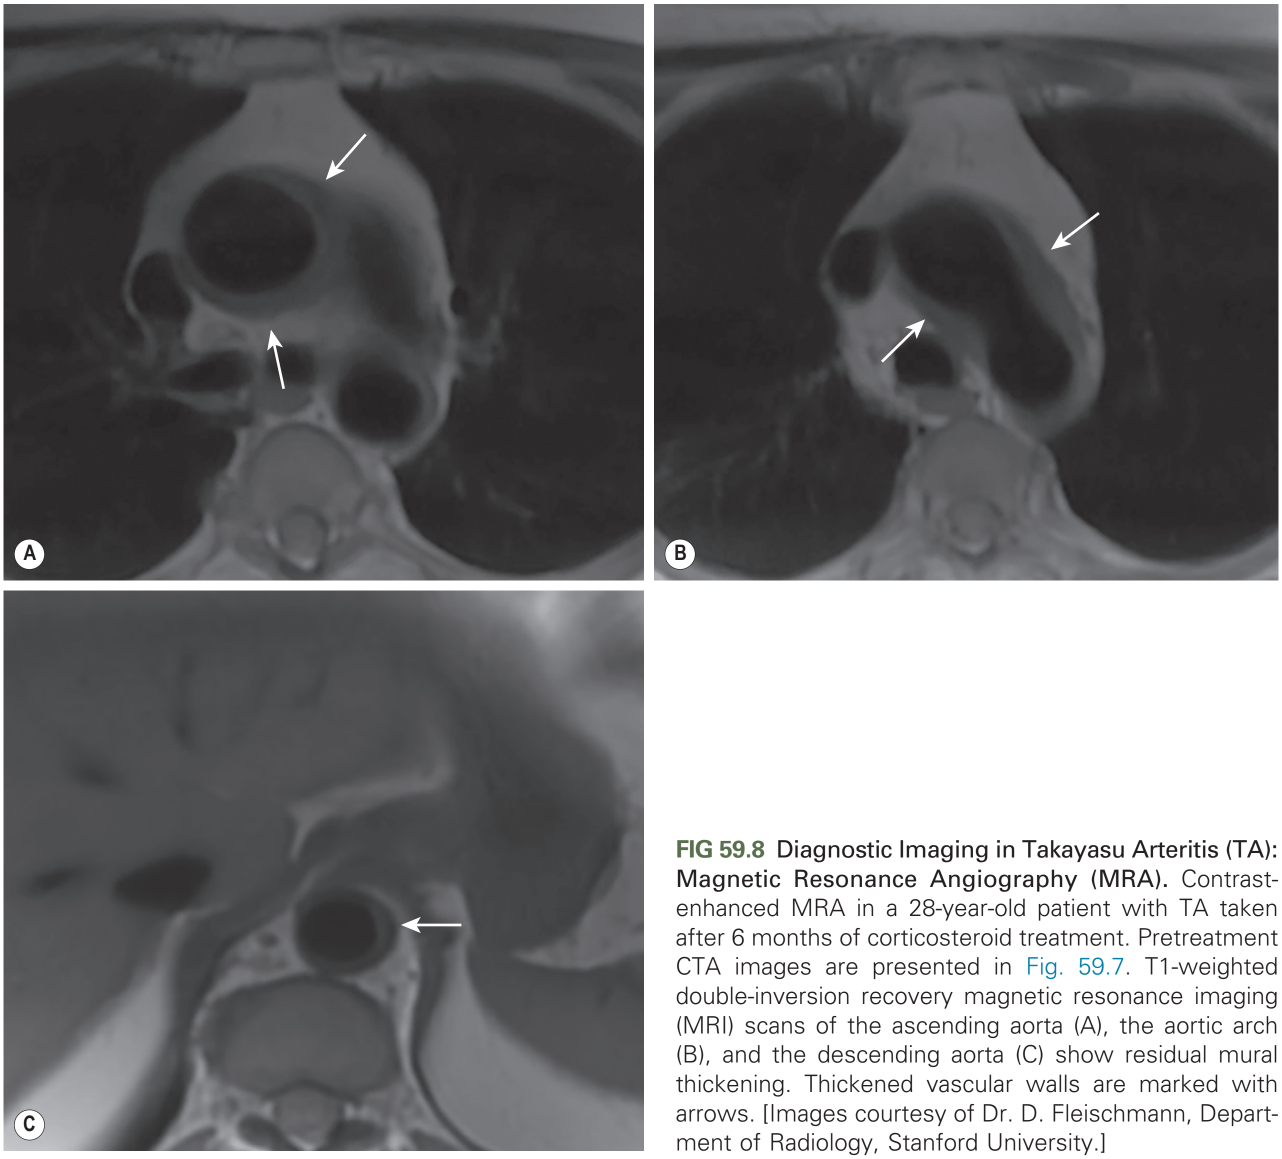

FIG 59.8 Diagnostic Imaging in Takayasu Arteritis (TA): Magnetic Resonance Angiography (MRA). Contrast-enhanced MRA in a 28-year-old patient with TA taken after 6 months of corticosteroid treatment. Pretreatment CTA images are presented in Fig. 59.7. T1-weighted double-inversion recovery magnetic resonance imaging (MRI) scans of the ascending aorta (A), the aortic arch (B), and the descending aorta (C) show residual mural thickening. Thickened vascular walls are marked with arrows. [Images courtesy of Dr. D. Fleischmann, Department of Radiology, Stanford University.]

TABLE 59.3 American College of Rheumatology 1990 Classification Criteria for Giant-Cell Arteritis[a] and Polymyalgia Rheumatica

Age at disease onset ≥50 years
New-onset or new type of headache
Temporal artery tenderness or decreased artery pulse
Elevated erythrocyte sedimentation rate (≥50 mm/hr)
Histological incidence of arteritis (characterized by a predominance of mononuclear cell infiltrates or a granulomatous process with multinucleated giant cells)

[a] A patient is classified as having giant-cell arteritis if at least three of the five criteria are present.

Reprinted from Hunder GG, Bloch DA, Michel BA, et al. The American College of Rheumatology 1990 criteria for the classification of giant cell arteritis. Arthritis Rheum 1990; 33: 1122–1128, with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. ©1990.

TABLE 59.4 Provisional Classification Criteria for Polymyalgia Rheumatica

Age ≥50 years	required
Bilateral shoulder ache	required
Abnormal C-reactive protein (CRP) and/or erythrocyte sedimentation rate (ESR)	required
Morning stiffness >45 minutes	2
Hip pain or limited range of motion	1
Absence of rheumatoid factor (RF) or anti-citrullinated protein antibody (ACPA)	2
Absence of other joint involvement	1
A score of ≥4 is categorized as polymyalgia rheumatica.	

Reprinted from Dasgupta B, et al. Provisional classification criteria for polymyalgia rheumatica: A European League Against Rheumatism/American College of Rheumatology collaborative initiative. Arthritis Rheum 2012; 64: 943–954.

Histomorphological reports describe mononuclear cell infiltrates penetrating through all layers of the vessel wall (Fig. 59.9).[1] Recent discussions have focused on the diagnostic relevance of isolated inflammatory cell clusters in the adventitia or perivascular lymphocytes limited to small blood vessels.[36] These findings may not be sufficient to indicate arteritis. Multinucleated giant cells may or may not be found. They tend to lie along the internal elastic lamina, at the junction between the media and the intima. Media destruction is not unusual, but findings of fibrinoid necrosis should prompt a search for a different vasculitic entity. The vessel lumen is more or less compromised by hyperplastic intima formed from proliferating fibroblasts, smooth-muscle cells, and deposition of acid mucopolysaccharides.

The histology of TA is similar to that of GCA, making it difficult to dissect both syndromes in tissue samples derived from the aorta or its primary branches. Lymphocytes and plasma cells accumulate around vasa vasorum and form transmural infiltrates. Marked wall thickening with inflammatory tissue extending into perivascular structures is typical for TA (Fig. 59.10). Destruction of elastic membranes is often extensive and combined with patchy areas of media necrosis. Weakening of the vessel wall can lead to aneurysm formation. Inflammatory lesions may be arranged in a "skipped" pattern, with normal vessel wall segments alternating with stretches of intense destructive inflammation.

TABLE 59.5 American College of Rheumatology 1990 Criteria[a] for the Classification of Takayasu Arteritis

- Disease onset at ≤40 years
- Claudication of an extremity
- Decreased brachial artery pulse
- >10 mm Hg difference in systolic blood pressure between arms
- Bruit over the subclavian arteries or the aorta
- Arteriographic evidence of narrowing or occlusion of the entire aorta, its primary branches, or large arteries in the proximal upper or lower extremities

[a]For purposes of classification, a patient is classified as having Takayasu arteritis if more than three of the six criteria are fulfilled.

Reprinted from Arend WP, Michel BA, Bloch DA, et al. The American College of Rheumatology 1990 criteria for the classification of Takayasu arteritis. Arthritis Rheum 1990; 33: 1129–1134, with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. ©1990.

Physicians may encounter morphological findings of granulomatous aortitis in patients undergoing aortic aneurysm repair without any prior diagnosis of vasculitis. Detailed workup of these patients is necessary to identify those with undiagnosed PMR, GCA, or TA. Rare causes of aortitis, including inflammatory bowel disease, sarcoidosis, syphilis, relapsing polychondritis, and connective tissue disease, should be ruled out. Isolated granulomatous aortitis is diagnosed as idiopathic aortitis. The pathogenesis and prognosis of this condition are essentially unknown.

Diagnostic Imaging

Modern imaging modalities have fundamentally changed the diagnostic approach to LVV.[26] Indeed, diagnosing TA mostly depends on identifying vascular lesions in typical distribution by imaging.[37]

Conventional angiography still has its place in preoperative planning and can be combined with intravascular interventions. It provides ideal visualization of the vascular lumen not only for large but also for medium-sized arteries, such as the axillary and brachial arteries (see Fig. 59.5). Ultrasound (US)–based methods are extremely useful for screening carotid arteries, but they have also emerged as the method of choice for initial assessment of the distal subclavian arteries, vertebral arteries, renal arteries, and femoral arteries. US examination is also the optimal method for long-term monitoring of vessel bypasses in patients who have undergone revascularization surgical procedures. Magnetic resonance imaging (MRI), magnetic resonance angiography (MRA),

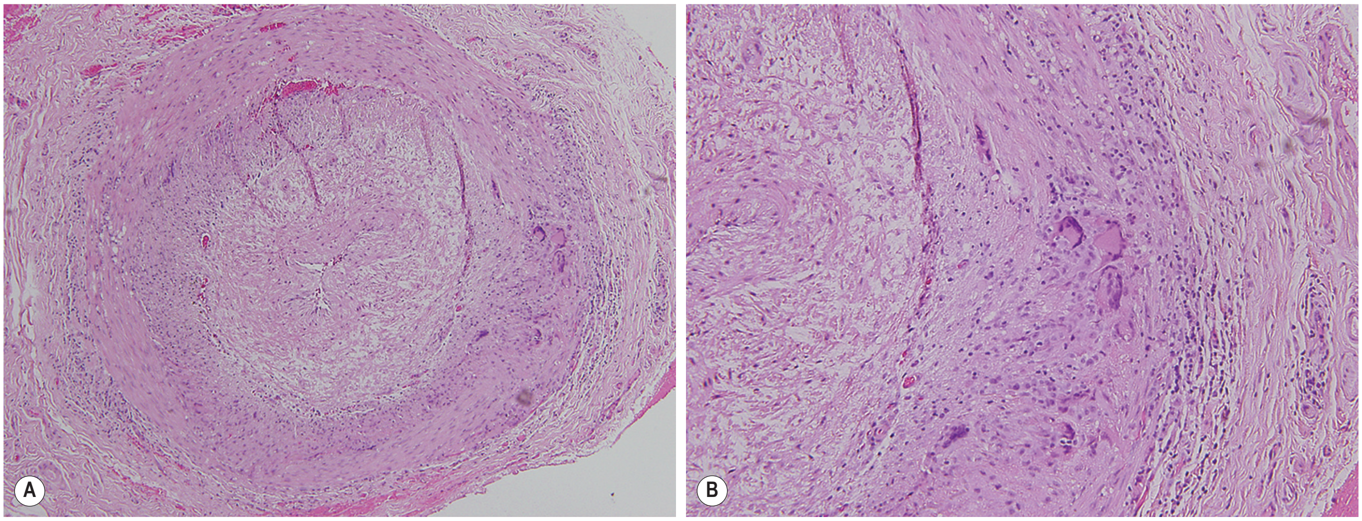

FIG 59.9 Histomorphology of Giant-Cell Arteritis (GCA). (A) Temporal artery cross-section with mononuclear infiltrates throughout all wall layers. The adventitia is infiltrated by round cells with cuffing of vasa vasorum by lymphocytes. The vessel lumen is occluded by intimal hyperplasia. (B) Higher magnification showing intense granulomatous inflammation with multinucleated giant cells in the proximal media and at the media–intima junction.

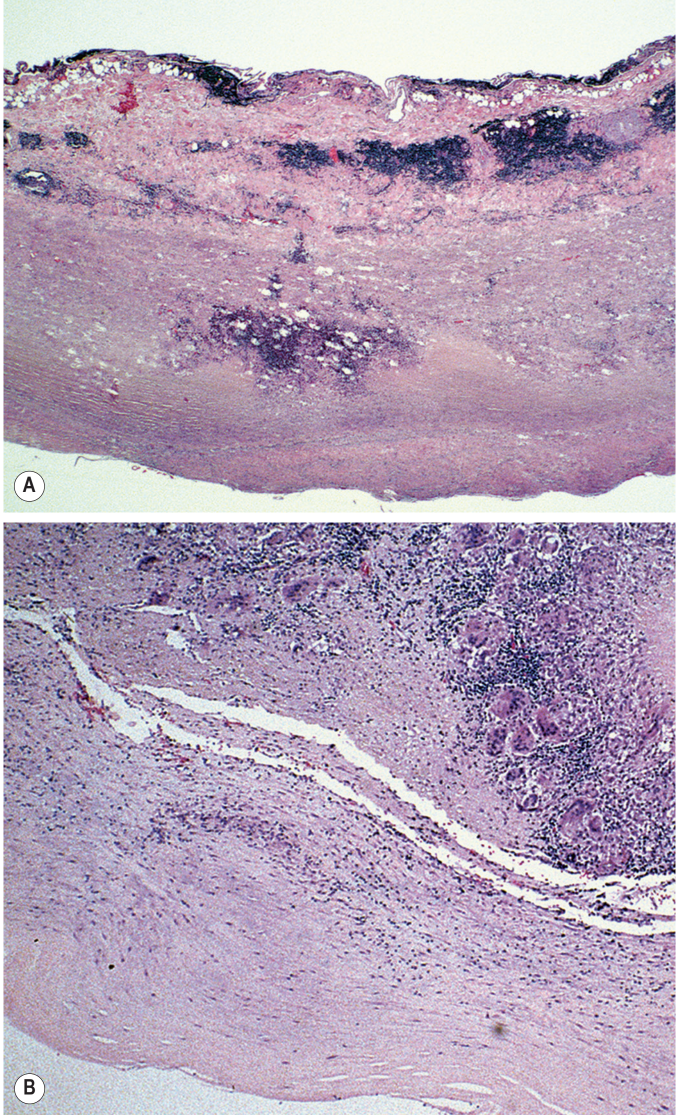

FIG 59.10 **Histopathology of Takayasu Arteritis (TA).** (A) Full-thickness section of the aortic wall shows dense mononuclear infiltrates in the adventitia and media. The intima is thickened and wavy; hematoxylin and eosin (H&E). (B) Florid granulomatous inflammation along the media–intima junction with numerous giant cells; H&E.

and computed tomography (CT) are now widely used for evaluating the vascular tree. These methods provide excellent information on abnormalities of the vascular lumen and wall, with increasing resolution, now capturing abnormalities in the more peripheral arterial branches. CT imaging is fast, well tolerated by patients with claustrophobia, and allows excellent assessment of the aorta and its wall (see Fig. 59.7). However, it has the disadvantages of contrast loading and radiation exposure. With its inherent multiplanar imaging capabilities, magnetic resonance is used to examine neck vessels, the aorta, and its primary branches (see Figs. 59.6 and 59.8). Great hope was placed on its potential to measure wall edema and intramural vascularity, which would make MR useful for estimating disease burden and responses to therapy. However, a carefully conducted study comparing imaging results with laboratory parameters of inflammation to results from surgically harvested vessel biopsy specimens has been disappointing, cautioning one that edema-weighted MR should not be used as a sole means of measuring disease activity and therapeutic responsiveness.[38] Both, CT angiography and MRA are now used routinely to monitor progression or regression of vascular involvement and have an important place in managing the chronic phase of GCA and TA.

THERAPEUTIC MANAGEMENT

THERAPEUTIC PRINCIPLES

Treatment of Large Vessel Vasculitides

- To prevent vision loss, patients with giant-cell arteritis (GCA) require immediate treatment. Similarly, with the threat of catastrophic cerebral ischemia in Takayasu arteritis (TA), prompt initiation of therapy is imperative.
- Corticosteroids are the immunosuppressive drug of choice for large-vessel vasculitides (LVVs). Often, the drugs must be given over a period of several years but may be clinically effective at very low doses.
- Clinical trials have failed to show convincing steroid-sparing effects for either methotrexate or tumor necrosis factor (TNF)-α blockade in GCA.
- A phase 3 clinical trial has demonstrated steroid-sparing effect of treatment with tocilizumab.
- Molecular studies of the inflammatory infiltrate in GCA have shown that early and untreated disease is characterized by two functional T-cell lineages; T helper (Th)1 and Th17 cells. Th17 cells are rapidly responsive to corticosteroids, whereas Th1 cells persist and promote chronic, smoldering vasculitis.
- It is not known whether the smoldering activity persisting beyond the acute phase of the disease requires immunosuppressive therapy or whether the benefits of chronic immunosuppressive therapy outweigh the potential risks.
- Clinical experience (not evidence-based therapeutic trials) suggests that a combination of methotrexate, mycophenolate mofetil, or TNF-α–blocking agents with corticosteroids may be beneficial in controlling disease in some patients with TA.
- Close monitoring for diabetes, hypertension, and hyperlipidemia combined with bone-saving therapy should be part of the treatment regime in patients with LVVs on long-term corticosteroids.

With increasing knowledge of the disease process and refinement of diagnosis and long-term treatment, the prognosis for patients with LVVs has significantly improved. Life expectancy of patients with GCA is preserved. Follow-up studies of Japanese patients with TA have suggested good control of disease activity in about 75% of patients, with only 25% experiencing serious complications and cardiac manifestations dominating long-term outcome. Whether vasculitis predisposes patients to accelerated atherosclerotic disease, given the combination of chronic inflammation and injury to vessel wall structures, is still being discussed. It is not known whether progression of atherosclerosis and its complications require a different management approach or whether standard vasoprotective measures (treating hypertension and hyperlipidemia, smoking cessation, etc.) are sufficient.[6]

Pathogenic studies have pointed out that the traditional view of GCA as a self-limiting disease is incorrect.[11] To the contrary, granulomatous vasculitis has shown surprising resistance to immunosuppression, with vessel wall infiltrates persisting for >12 months in almost 50% of patients despite appropriate immunosuppressive therapy. Based on examination of serial temporal artery biopsy specimens from patients before and after treatment, it is now clear that arteritis persists, albeit sustained

ON THE HORIZON

- Medium and large arteries in humans sense danger signals through wall-embedded cells; changing the understanding of how the immune system interacts with the vascular system.
- The multilineage nature of vasculitic T cells, which display differential therapeutic responsiveness, almost certainly will require more complex therapies, adapted to disease stage and immune status of the host.
- The immune system changes profoundly with age. Age-appropriate management of each patient and avoidance of overtreatment of older adults are important.
- Current therapies in large-vessel vasculitis induce partial remission. Appropriately designed studies are required to explore whether partial remission is sufficient and whether the risk/benefit ratio is maintained if complete remission is attempted.

by an immune network distinct from that in untreated patients.[21] It is currently not known whether this persistent smoldering process needs to be treated and what the risk/benefit ratio is for the older patient population affected by GCA. Unchanged life expectancy in GCA suggests adequacy of current management. Whether intensification of immunosuppressive therapy or chronic maintenance therapy can prevent long-term complications, such as aortic aneurysm/dissection from GCA aortitis, and improve the overall prognosis is unknown. The ultimate decision depends on the cost/benefit analysis comparing the risk from smoldering disease with the risks imposed by long-standing immunosuppression. In that context, it is important to remember the profound impact of the immune aging process, which leaves the patient with an impaired immune system and amplifies the risk of immunosuppression.[39]

Induction Therapy

In newly diagnosed patients with GCA, TA, and PMR, the immunosuppressants of choice are corticosteroids. Patients with GCA are started on a daily prednisone dose of 40–60 mg (about 1 mg/kg body weight). In patients with PMR, a daily dose of 20 mg prednisone is sufficient in almost all patients. The response is usually dramatic, with improvements within 24–48 hours. The promptness of clinical improvement is so exceptional that it has been suggested as a diagnostic criterion for PMR. However, the promptness of response may be limited to extravascular LVVs. Myalgias, fever, malaise, and headaches improve swiftly, in parallel with a fast reduction of acute-phase reactants (CRP, IL-6, ESR). Emerging data suggest that the vascular component is much more resistant to immunosuppression and may require entirely new therapeutic strategies.

Once the condition is stabilized, steroid tapering is guided by close monitoring of the clinical presentation as well as laboratory markers of inflammation. In general, steroids should be reduced by 10–20% every 2 weeks. Monthly monitoring of ESR and CRP is mandatory to adjust therapy. Patients frequently return with signs or symptoms of recurrent disease as immunosuppression is lowered. Fortunately, disease exacerbations causing vision loss are infrequent. Disease flare-ups typically present with PMR symptoms or nonspecific manifestations of malaise and failure to thrive. In most patients, a transient small increase in the steroid dose reinstates disease control.

Much effort has been invested in identifying steroid-sparing agents. In a small study, treatment with pulse corticosteroids appeared to have long-term beneficial effects, reducing the overall steroid requirement and the rate of disease flare-ups.[40] After pulses of 1000 mg methylprednisolone were administered for 3 consecutive days, therapy was continued with oral prednisone, and daily doses were swiftly tapered. Compared with the control arm, patients who received three initial steroid pulses had lower likelihoods of disease flare-ups. Particularly, once they reached prednisone doses close to 10 mg/day, these patients could tolerate steroid withdrawal significantly better, and most were taking 5 mg/day prednisone at 36 weeks.[40] The benefit from initial pulse therapy continued over subsequent months, suggesting the potential benefit of intense immunosuppression during early disease.

Several biological agents have been explored or are currently undergoing testing in clinical trials.[41] Tumor necrosis factor-α (TNF-α) inhibitors may have a role in TA but had no steroid-sparing effect in GCA.[42] Preliminary study results suggest that targeting T-cell costimulation with abatacept may prevent disease relapses in GCA. Ustekinumab, a monoclonal antibody (mAb) targeting IL-12 and IL-23, was reported to have potential efficiency in refractory GCA in a small open-label study. The IL-6 receptor blocker tocilizumab has been explicitly effective in reducing acute phase reactants (CRP, ESR) and is being explored in GCA and TA and a phase 3 double-blind trial of tocilizumab given weekly or every other week demonstrated substantial steroid-sparing effect over a one-year period.[12]

Maintenance Therapy

With a major shift in the pathogenic concept about LVVs, especially the realization that the disease process has two, partly independent components (extravascular, vascular) and that vessel wall infiltrates persist chronically, the therapeutic needs for maintenance therapy have become the dominant issue for the treating physician. Patients with PMR are often managed successfully with low-dose corticosteroids (prednisone 5 mg daily) and typically are highly responsive to transient and very small dose increases (1–2 mg prednisone/day). Long-term management of patients with GCA and TA relies on low-dose corticosteroids as well unless there is objective evidence for progressive vascular wall inflammation. Unfortunately no reliable biomarkers can separate the extravascular and vascular disease components, and no evidence that suppressing acute phase response in the periphery will ultimately restrict transmural vasculitis has been presented.

Methotrexate is considered to have mild-to-moderate steroid-sparing potential in GCA and PMR[43] but is more frequently used in TA.[44] When given to human artery–severe combined immunodeficiency (SCID) chimeras, acetylsalicylic acid (aspirin) has marked antiinflammatory activities, with suppression of IFN-γ in vascular lesions. Clinical trials are needed to test whether this immunosuppressive action can translate into corticosteroid sparing. Because arteries are the primary targets of LVVs, the use of aspirin as an antiplatelet agent should be routinely recommended.

There is no evidence that immunosuppressants, such as azathioprine and cyclophosphamide, lower steroid needs, prevent vascular complications, or shorten the duration of steroid use. Whether any of the biological agents described above has a place to effectively suppress vessel wall inflammation and change the course of chronic disease is currently unknown.

An integral part of chronic immunosuppression with prednisone is regular monitoring for diabetes and hypertension. Patients should be encouraged to increase physical activity, as steroid-induced myopathy occurs frequently. A major issue of chronic steroid treatment, particularly in older individuals, is the risk of excessive bone loss, possibly resulting from increased bone resorption and impaired bone formation. Several effective and safe therapies for osteopenia/osteoporosis are available.

Calcium and vitamin D supplementation should be part of the therapeutic regimen.

In many, but not all, patients, immunosuppressive treatment can be discontinued 18–24 months after diagnosis. Markers of systemic inflammation may remain elevated, and continuous monitoring for aortic involvement and recurrence of cranial arteritis is recommended.

Most patients with PMR are sufficiently treated with an initial dose of 20 mg of prednisone per day. In some patients, 10 mg of prednisone can induce and sustain a clinical response. Steroids should be titrated to minimally needed doses to avoid side effects; tapering usually needs to be slow, over many months. In TA, long-term management should be tailored to individual patient conditions.[44] It has been argued that patients should be maintained on a low dose of corticosteroids, such as 5–7 mg prednisone daily, even after successful control of active disease.

Given the age at disease onset in TA, preventive measures to counteract accelerated atherosclerosis and optimize blood pressure control are important aspects of management.

It has been suggested that up to 50% of patients with TA may require a second immunosuppressive agent.[44] Steroid-sparing effects of methotrexate have been reported for some patients. Similarly, mycophenolate mofetil may have clinical efficiency, although only published data on a small patient cohort are available. Empirically, azathioprine may have a place in maintenance therapy of patients with TA. Finally, there may be a place for agents blocking TNF-α in patients with persistent disease activity. Results from well-designed placebo-controlled treatment trials testing the efficiency of such immunosuppressive drugs are awaited.

Detecting and treating hypertension is an essential component of caring for patients with TA. Untreated hypertension leads to acceleration of atherosclerosis and cardiac insufficiency. In patients with upper-extremity involvement, obtaining accurate blood pressure measurements is a challenge and requires education of the patient and caregivers.

Revascularization Procedures

Besides pharmacological therapy, revascularization procedures—including both surgical and endovascular interventions—have vastly broadened therapeutic options in patients with TA and large-vessel GCA.[45] To minimize the risk of complications, such as rapid reocclusion, an effort should be made to suppress vascular wall inflammation, ideally before subjecting the patients to revascularization treatment. Conventional bypass grafts are still considered the method of choice. Percutaneous transluminal angioplasty can be useful in managing renal artery stenosis or other short-segment lesions. Bypass surgery is needed in patients with cerebrovascular ischemia in whom catastrophic strokes may be prevented by bypassing critical stenosis of cervical vessels with grafts originating from the aortic arch. Reestablishing flow in the upper- and lower-extremity arteries can be complicated by multiple and long-segment stenosis, and arterial reconstructions with prosthetic graft materials or veins may be the only alternative to obtain long-term patency. Placing of conventional stents can be complicated by eliciting rapid restenosis, and it is not known whether outcomes can be improved by drug-eluting stents. Occlusive disease of the coronary arteries usually represents a challenging clinical scenario, and most physicians opt for conventional bypass surgery. Depending on symptoms, patients with aortic regurgitation may require repair of the weakened aortic wall.

MULTIPLE CHOICE QUESTIONS

1. A 27-year old female presents with a 6-weeks history of intermittent fever, arthralgias and weight loss. She was admitted after she fainted in the emergency room. On physical examination she has no palpable peripheral pulse in her left upper extremity, and Takayasu arteritis (TA) is added as a differential diagnosis.
   Which of the following statements is true:
   A. She should be scheduled for temporal artery biopsy, to rule out giant cell arteritis.
   B. Laboratory tests, e.g. sedimentation rate will be of no use, as they can be non-specifically abnormal.
   C. A pregnancy test should be performed.
   D. A detailed physical examination will not be helpful.
   E. If a diagnosis of TA is made, it will be a self-limited disease.

2. Giant cell arteritis and Takayasu arteritis have a stringent tissue tropism. Which of the following vascular beds can be involved? Identify all correct answers:
   A. Aortic arch
   B. Carotid artery
   C. Subclavian artery
   D. Renal capillaries
   E. Arteries in the skin

3. Extravascular GCA may result in the following laboratory abnormalities. Identify the incorrect answer:
   A. Elevated C-reactive protein
   B. Autoantibodies to nuclear antigens
   C. Thrombocytosis
   D. Elevated serum amyloid A
   E. Elevated alkaline phosphatase

Systemic Autoinflammatory Syndromes

Catharina M. Mulders-Manders, Jeroen C.H. van der Hilst,
Jos W.M. van der Meer, Anna Simon

Autoinflammatory diseases, which are also known as *periodic fever syndromes,* encompass a group of rare disorders characterized by recurrent or persistent inflammation. *Autoinflammation* is a term that has been used since the late 1990s to illustrate the difference between autoimmune disorders and diseases characterized by exuberant inflammation. Typically, autoinflammatory diseases do not show features of excess adaptive immune system activation, and autoantigens or auto-antigen specific T-cells are not present in these diseases. It is now recognized that autoinflammation and autoimmunity form two ends of a spectrum of inappropriate immune system activation and share several common features.

Located at the autoinflammatory end of this spectrum are the classic monogenic autoinflammatory diseases: familial Mediterranean fever (FMF), cryopyrin-associated periodic syndrome (CAPS), mevalonate kinase deficiency (MKD; also known as *hyperimmunoglobulin D and periodic fever syndrome* [HIDS]), and tumor necrosis factor (TNF) receptor–associated periodic syndrome (TRAPS). The number of autoinflammatory diseases is increasing rapidly. New monogenic autoinflammatory diseases have been identified in the last decades. For many of the recently described autoinflammatory diseases, no genetic cause has been found yet.

It has also become clear that autoinflammation is at least partially involved in the pathogenesis of other, more common diseases, such as gout, Crohn disease, and ulcerative colitis.

As it is impossible to discuss all autoinflammatory diseases in detail here, the classic monogenic diseases FMF, CAPS, TRAPS, and MKD have been selected as the main focus of this chapter. Their pathophysiological mechanisms are understood to a much higher degree than in many newer autoinflammatory diseases, and their clinical presentations have been described precisely.

In addition, two other autoinflammatory diseases are discussed, one with relatively high prevalence and the other because of its interesting pathophysiological mechanism: *(i)* periodic fever, aphthous stomatitis, pharyngitis, and adenitis (PFAPA) syndrome and *(ii)* Schnitzler syndrome.

The cornerstone of diagnosing an autoinflammatory disease is the clinical assessment of the patient. This includes a detailed medical and family history and direct observation of an inflammatory episode. The first step in the diagnostic process is to exclude other more common causes of recurrent inflammation, including infections, malignancy and paraneoplastic phenomena, and autoimmune disease.[1] A first differential diagnosis can be made on the basis of age of onset, associated signs and symptoms, duration of inflammation, family history, and ethnic background, (Table 60.1), and this can guide targeted diagnostic testing.

KEY CONCEPTS

Autoinflammation Versus Autoimmunity

- Common features:
  - Inflammation due to excessive immune activation
  - Phenotypes characterized by exacerbations and remissions
- Distinctive features:
  - Autoinflammation: dysregulation of innate immunity, no high-titer autoantibodies or autoantigen-specific T cells
  - Autoimmunity: dysregulation of adaptive immunity, defect in lymphocyte function, autoantibodies may be present.
- Autoinflammation and autoimmunity form two ends of a continuous spectrum of excessive immune system activation.
- Many diseases show overlapping features between autoinflammation and autoimmunity.

EPIDEMIOLOGY

It is important to realize that the incidence of specific diseases varies widely among ethnic groups. With more than 100 000 patients worldwide, FMF is the most prevalent monogenic autoinflammatory disease. It is most common in individuals originating from around the Mediterranean basin, such as Turks, Jews (primarily non-Ashkenazi), Arabs, and in Armenians. In these selected populations, the carrier frequency of mutations in the *MEFV* gene can be as high as one in three individuals.[1] This may indicate a survival benefit for carriers of heterozygous mutations, possibly through protection against certain unknown infectious agents.

The first patients with MKD were described in 1984 in The Netherlands[2] (then referred to as HIDS). Over 200 patients have now been identified, most of Western European and Caucasian ancestry. This could be partly explained by increased awareness for this disease among physicians in that part of the world. An alternative explanation is a common founder effect with clustering of carriers, illustrated by a carrier rate of 1:153 for the most common mutation in the mevalonate kinase gene (*MVK*) (V377I) in Dutch newborns.[3,4]

TRAPS is seen in patients from around the world, although most patients originate from northwestern Europe. A few dozen families and over 200 sporadic cases have been reported.

The exact prevalence of the CAPS is unknown, but over 130 cases have been recognized. Disease awareness and recognition among clinicians have improved because of the availability of effective treatment for this disease.

PFAPA syndrome was first reported at the end of the 1980s.[5] It is difficult to estimate the incidence of PFAPA, as the level of

TABLE 60.1 Hereditary Autoinflammatory Syndromes

	FMF	CAPS	TRAPS	MKD
Mode of inheritance	Autosomal recessive	Autosomal dominant	Autosomal dominant	Autosomal recessive
Age of onset (years)	<20	Generally <1, in MWS/FCAS <20 possible	Variable, most <10	<1
Main ethnic distribution	Turks, Arabs, Jews, Armenians	Europeans	All	Northwestern Europeans (Dutch, French)
Gene involved	*MEFV*	*NLRP3*	*TNFRSF1A*	*MVK*
Protein involved	Pyrin	NLRP3	TNF receptor type 1	Mevalonate kinase
Duration of typical attack	2–3 days	Variable; hours–days or continuous inflammation	Days–weeks	HIDS: 4–6 days; MA: continuous, flares possible
Distinguishing symptoms	Peritonitis, pleuritis, erysipelas-like skin lesions	Aseptic meningitis; sensorineural deafness; bone lesions, dysmorphic features May be cold-induced	Severe myalgia, periorbital edema	HIDS: lymphadenopathy, attacks induced by vaccination MA: joint contractions, growth and developmental delay
Risk of amyloidosis[a]	Up to 75%	Up to 33%	25%	<5%
Treatment	Colchicine, combination with IL-1 inhibition when resistant	IL-1 inhibition	Mild disease: NSAIDs; Severe disease: IL-1 inhibition	IL-1 inhibition

[a] In patients with long-term uncontrolled inflammation.

CAPS, cryopyrin-associated periodic syndrome; FMF, familial Mediterranean fever; HIDS, hyperimmunoglobulin D and periodic fever syndrome; IL, interleukin; MA, mevalonic aciduria; MKD, mevalonate kinase deficiency; TRAPS, tumor necrosis factor (TNF) receptor–associated periodic syndrome.

awareness of this disease seems to vary among clinicians. A single pediatric center in the United States reported 122 patients fulfilling the criteria for PFAPA in 10 years,[6] making it more common than any of the monogenic autoinflammatory diseases (with the exception of FMF in certain populations). In most patients with PFAPA, symptoms cease before or during adolescence. The cause of this spontaneous resolution is unknown. The characteristic combination of symptoms of PFAPA has been described in adults, but it remains a matter of debate whether these patients suffer from true PFAPA syndrome.

Schnitzler syndrome, first described by the French dermatologist Schnitzler in 1972,[7] is an acquired autoinflammatory disorder with a median age of onset of 51 years. Over 160 cases have been reported worldwide.

SIGNS AND SYMPTOMS

Familial Mediterranean Fever

FMF is an autosomal recessive disease. Over 90% of patients become symptomatic within the first two decades of life. Typically, attacks are characterized by abrupt onset of high fever, peaking soon after onset and lasting for 12 hours to 3 days. Subsequently, the fever subsides rapidly. Painful serositis accompanies the fever. Serositis can also be present without fever. Over 95% of patients experience abdominal pain, which lasts up to 3 days. The pain, which is caused by sterile peritonitis, may initially be focal and progress to more diffuse pain. Before being diagnosed with FMF, a significant proportion of patients will have undergone exploratory abdominal surgery under suspicion of appendicitis. At surgery, intraabdominal adhesions, a result of recurrent peritonitis, may be found. Pelvic adhesions can reduce fertility in female patients. Pleuritis, presenting as thoracic pain, is experienced by approximately 40% of patients. Synovitis with monoarthritis of knee, ankle, or wrist occurs in one-half to three-quarters of patients. An arthritic attack may have a more protracted course compared with nonarthritic FMF, with fever lasting up to a week. Joint pain may persist when fever has already subsided. Synovitis usually resolves completely without joint destruction. The skin can be affected. Erysipelas-like skin lesions overlying the shins are very characteristic of FMF, but are only seen in 30% of patients. Less frequent symptoms of FMF include vasculitis, orchitis, aseptic meningitis, and myalgia. Pericarditis is rare in FMF.

There are no consistent triggers for FMF attacks. Emotional stress or menstruation may increase the frequency of attacks; some patients are able to report specific triggers for their attacks. Attack frequency varies greatly among patients and during an individual patient's life. Attacks may be as frequent as 2–3 times each month and as rare as less than once a year.

The literature on FMF is replete with genotype–phenotype studies. The most consistent finding is that carriers of the M694V/M694V genotype have more severe disease, with earlier onset and higher frequency of arthritis and long-term complications.

Life expectancy of patients with FMF depends on timely initiation of appropriate treatment to prevent amyloidosis. Without amyloidosis, FMF patients have normal life expectancy.

Cryopyrin-Associated Periodic Syndrome

CAPS is autosomal dominantly inherited. Originally, three separate clinical syndromes, all with their own clinical features, were distinguished: familial cold autoinflammatory syndrome (FCAS), Muckle Wells syndrome (MWS), and neonatal onset multisystem inflammatory disease (NOMID), which is also known as chronic infantile neurological, cutaneous and articular (CINCA) syndrome. With the discovery of *NLRP3* mutations in all three diseases, it has become clear that the clinical phenotype of CAPS is a continuous spectrum of severity, instead of distinct diseases. There is no genotype–phenotype association, suggesting a role for other yet undiscovered disease modifying factors.

CAPS often manifests clinically soon after birth or in early childhood. It is characterized by recurrent urticaria-like rash, arthralgia, myalgia, headache, and fever. Ocular symptoms, including conjunctivitis and uveitis, are common. Some patients develop sensorineural hearing loss during adolescence or adulthood. At the severe end of the clinical spectrum, central nervous system (CNS) symptoms, including chronic aseptic meningitis that is characterized by chronic headache, increased intracranial pressure, hydrocephalus, mental retardation, and seizures, are common. Papilledema with optic nerve atrophy can lead to loss of vision. In severely affected patients, arthropathy, with distinct radiographic findings of premature patellar and epiphyseal long bone ossification and osseous overgrowth, develops early in life. If left untreated, this leads to growth retardation, severe joint contractures, and persisting disability.

The duration of attacks is variable and ranges from hours to days. At the severe end of the spectrum, patients have continuous inflammation. Attacks may be triggered by exposure to cold, minor trauma, or emotional stress.

In the past, patients with severe CAPS often died in childhood. This changed after the introduction of anti–interleukin-1 (IL-1) therapy, which is very effective in treating CAPS. Overall, patients without neurological involvement are now believed to have a normal life expectancy.

Tumor Necrosis Factor Receptor–Associated Periodic Syndrome

TRAPS is inherited in an autosomal dominant fashion. Age of onset varies widely. Many patients become symptomatic within the first years of life, with a median age of onset of 3 years, but adult onset is also possible. The usual duration of fever in TRAPS is considerably longer than in the other classic autoinflammatory syndromes: attacks persist for a minimum of 3 days but can last for several weeks. The interval between attacks in a single patient can vary substantially.

Localized myalgia, a deep cramping, and often severely disabling pain in a single limb resulting from monocytic fasciitis and associated with fever is found in virtually all patients. The affected limb may show local erythema, which may migrate to the distal part of the extremity (Fig. 60.1). Almost all patients have abdominal pain, often accompanied by vomiting, constipation, and bowel obstruction. Arthralgia and monoarthritis involving hips, knees, or ankles are present in 25% of patients at some point. Chest pain is frequent and can be caused by pleuritis or may be musculoskeletal in origin. Ocular symptoms range from conjunctivitis and periorbital pain to severe uveitis and iritis. Periorbital edema with conjunctival injection is a distinctive, but infrequent, feature of TRAPS. Other less frequently observed symptoms are pericarditis and lymphadenopathy.

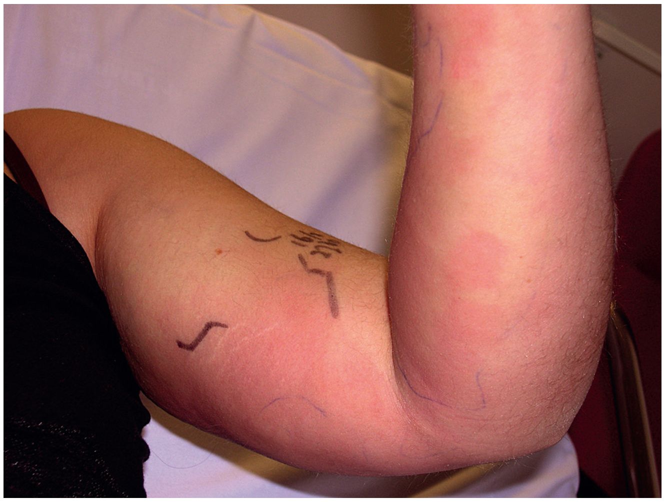

FIG 60.1 Migratory erythematous macular rash during an inflammatory attack in a patient with tumor necrosis factor receptor–associated periodic syndrome (TRAPS).

Mevalonate Kinase Deficiency

Before the discovery of the underlying genetic defect in the mevalonate kinase gene, two distinct autosomal recessive diseases were distinguished, which are now known to form two ends of a continuous spectrum: HIDS at the less severe end and mevalonic aciduria (MA) at the most severe end.

HIDS is characterized by recurrent fever attacks that last for 4–6 days, starting in early childhood. The inflammatory attacks occur on average every 4–6 weeks. Attack frequency varies in a single patient and among patients and tends to decrease later in life. Attacks often start with chills, followed by a rapid rise in temperature. Factors that can provoke an attack are infections, trauma, vaccination, and both physical and emotional stress, although a clear trigger is often absent. Characteristic for HIDS is the first attack being triggered by childhood vaccination.

Fever is accompanied by cervical lymphadenopathy and abdominal pain with vomiting and diarrhea. The skin may show erythema, papules, urticarial rash, or exanthema. The majority of patients suffer from large-joint arthralgia or arthritis. Oral or genital aphthous ulcers may be present during attacks. Hepatosplenomegaly has been reported. Patients with HIDS appear to have normal life expectancy and experience no complications.

MA is located at the severe end of the MKD spectrum. This severe disease is present from birth and is characterized by psychomotor retardation, ataxia, failure to thrive, cataracts, and facial dysmorphia. Episodic fever or inflammation are present in MA. Many patients die in early childhood.

In recent years, it has become clear that the spectrum of MKD comprises more than only these two diseases. Mutations in *MVK* have been found in the absence of typical MKD features in patients with retinitis pigmentosa and early-onset ulcerative colitis. Mutations in *MVK* have also been found in patients with the skin diseases disseminated superficial actinic porokeratosis and porokeratosis of Mibelli, cyclic neutropenia, and macrophage activation syndrome, but there is no evidence of decreased mevalonate kinase activity in these patients.[8] Mutations in these diseases may overlap with mutations that may cause MA and HIDS.

Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Adenitis Syndrome

PFAPA is primarily a childhood disease with a usual onset before the age of 5 years. Patients suffer from recurring episodes of fever that generally last for 3–6 days and recur with great regularity. Additional symptoms include pharyngitis, cervical adenitis, and aphthous stomatitis. Other symptoms may include headache, vomiting and mild abdominal pain, arthralgia, and myalgia. Between fever episodes, patients are symptom-free. In most patients, attacks cease after several years, often before or during adolescence.

Schnitzler Syndrome

A typical feature of Schnitzler syndrome is its late onset, at a median age of 51 years. Patients typically present with chronic recurrent and mostly nonpruritic urticarial rash. This can be accompanied by fever, arthralgia or arthritis, and bone pain (Table 60.2). Symptoms progress over years. The presence of monoclonal paraproteinemia, typically of immunoglobulin M (IgM), is characteristic for Schnitzler syndrome. Presence of monoclonal IgG is less common and is sometimes referred to as *variant Schnitzler syndrome.* Onset of symptoms can precede paraproteinemia for

TABLE 60.2 **Diagnostic Criteria for Schnitzler Syndrome**[a]

Major Criteria (≥1 present)
(Chronic) urticarial rash
Monoclonal immunoglobulin M (IgM; or IgG: variant type)
Minor Criteria (≥2 present)
Intermittent fever
Arthralgia or arthritis
Bone pain
Lymphadenopathy
Hepatomegaly and/or splenomegaly
Elevated erythrocyte sedimentation rate (ESR) and/or leukocytosis
Bone abnormalities (on radiological or histological examination)

[a] Schnizler syndrome can be diagnosed only after exclusion of other causes.
From: de Koning et al. Diagnostic criteria for Schnitzler syndrome. Semin Arthritis Rheum 2007:37:137–148.

years, but only little is known about this. Symptom severity is unrelated to the level and type of paraproteinemia.

An important long-term complication of Schnitzler syndrome is Waldenström macroglobulinemia, which, in a single study, had an incidence of 15% 10 years after diagnosis. Patients with Schnitzler syndrome have a normal life expectancy.

PATHOGENESIS

The common pathophysiological feature of most autoinflammatory diseases is overproduction of the proinflammatory cytokine IL-1β. This protein is produced as an inactive proform (pro–IL-1β), which must be cleaved to become activated. The most common pathway of cleavage is by caspase-1. Like IL-1β, caspase-1 is transcribed as an inactive proform (procaspase-1), and it, too, must be cleaved by a multiprotein complex called the *inflammasome.* Several inflammasomes have been identified, of which the nucleotide-binding oligomerization domain (NOD)–like receptor P3 (NLRP3) inflammasome has been studied in greatest detail.

The NLRP3 inflammasome consists of the central protein NLRP3, the adapter protein ASC, and the effector protein procaspase-1. Upon activation of the inflammasome, procaspase-1 is converted into mature caspase-1, which is then able to cleave inactive pro–IL-1β to its active form (Fig. 60.2).

Familial Mediterranean Fever

FMF is caused by mutations in the Mediterranean fever gene (*MEFV*), which encodes the protein pyrin, primarily expressed in peripheral blood leukocytes, especially neutrophils and monocytes. Pyrin is a member of the pyrin-domain (PYD)–containing proteins, which are able to bind to the PYD domain of other proteins, including apoptosis-associated speck-like protein containing a C-terminal caspase recruitment domain (ASC). Binding of pyrin to ASC leads to activation of ASC, with consequent recruitment and activation of procaspase-1. Pyrin can also bind to the PYD domains of other proteins that are able to initiate apoptosis or activate nuclear factor (NF)-κB, including caspase-8 (Fig. 60.3). These complexes are called *pyrin inflammasomes.*

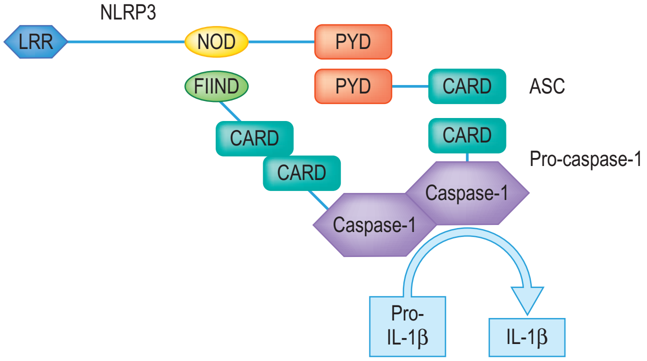

FIG 60.2 The Nucleotide-Binding Oligomerization Domain (NOD)–Like Receptor P3 (NLRP3) Inflammasome. NLRP3 is the central component of this inflammasome. NLRP3 contains three domains: a pyrin domain (PYD), NOD, and a domain of leucine-rich repeats (LRR). Cryopyrin binds apoptosis-associated speck-like protein containing a C-terminal caspase recruitment domain (ASC) through its PYD domain and through the NOD domain. The association of these proteins ultimately leads to the release of active caspase-1, which, in turn, activates interleukin-1β (IL-1β) through the cleavage of pro–IL-1β.

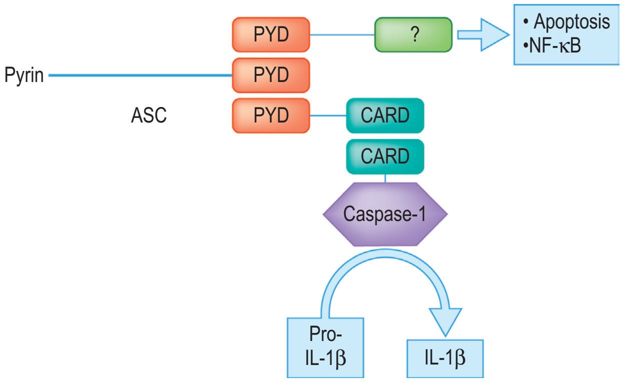

FIG 60.3 Mechanism of Action of Pyrin. Pyrin contains a pyrin domain (PYD) that is able to bind to apoptosis-associated speck-like protein containing a C-terminal caspase recruitment domain (ASC). ASC can recruit caspase-1 via its CARD domain leading to production of mature interleukin-1β (IL-1β). Pyrin is also able to bind to the PYD domain of other proteins involved in inflammation and apoptosis.

So far, over 300 sequence variants in the *MEFV* gene have been reported in the central online Infevers registry (http://fmf.igh.cnrs.fr/ISSAID/infevers/), most of which are clustered in exon 10 of the gene. The six most prevalent mutations (M694V, V726A, M680I, M694I, V694I, E148Q) cause approximately 80% of cases. Recently, autosomal dominant mutations in *MEFV* were described in four families with a colchicine-responsive FMF-like phenotype.[9]

Cryopyrin-Associated Periodic Syndrome

CAPS is caused by mutations in the gene encoding NLRP3. Previous to its discovery at the beginning of this century, the protein was unknown. It was named *cryopyrin,* in analogy with pyrin in FMF and to illustrate the influence of cold exposure in some patients with CAPS. Literature on this gene can be confusing, as the gene previously has also been referred to as *NALP3, PYPAF1,* and *CIAS1.* Mutations associated with CAPS are gain-of-function (GOF) mutations, leading to increased NLRP3 activity.

Tumor Necrosis Factor Receptor–Associated Periodic Syndrome

Mutations in the gene *TNFRSF1A* are responsible for TRAPS. This gene encodes the TNF-receptor superfamily 1A (TNFRSF1A), the main cell surface receptor for TNF. This receptor consists of three domains: an extracellular ligand-binding domain, a transmembrane domain, and an intracellular effector domain. So far, over 100 TNFRSF1A sequence variants have been described, and all TRAPS-associated mutations are located within the extracellular domain of the protein. Upon ligand binding by the extracellular receptor domain, the TNFR forms trimers, triggering the recruitment of intracellular adaptor proteins, which initiate a downstream signaling cascade, leading to NF-κB and mitogen-activated protein kinase (MAPK) activation and caspase-induced apoptosis. When the receptor is activated, the extracellular domain of the TNFR is shed from the membrane. These shed receptors form an extracellular pool of soluble TNFRs, retain their affinity for binding TNF, and are therefore able to mitigate the immune response. Initially, it was hypothesized that TRAPS-associated mutations would lead to defective shedding of TNFR1 receptors, but this hypothesis was discarded as the major pathogenetic mechanism for TRAPS after *in vitro* experiments showed misfolding and intracellular accumulation of mutated proteins. These aggregated receptors retain their normal signaling function and can induce ligand-independent MAPK signalling and production of reactive oxygen species (ROS), resulting in inflammation. (Fig. 60.4)

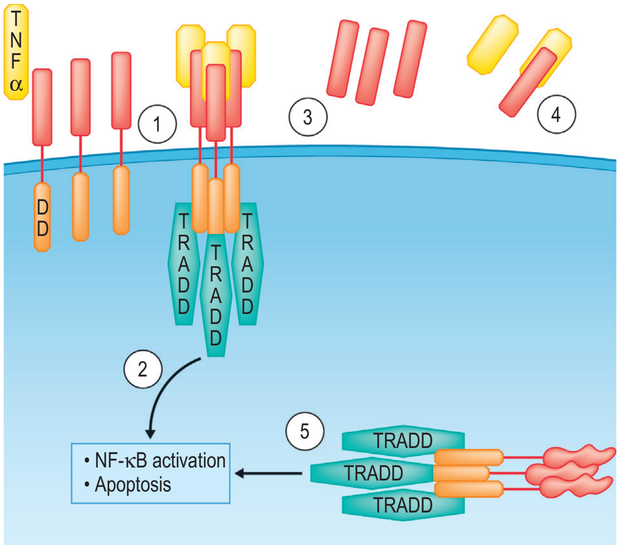

FIG 60.4 **Pathophysiology of Tumor Necrosis Factor Receptor–Associated Periodic Syndrome (TRAPS).** (1) Tumor necrosis factor (TNF) binds to the TNF receptor on the surface of inflammatory cells (2). After receptor triggering, TNF receptor type 1–associated DEATH domain (TRADD) is recruited, inducing a signaling cascade leading to apoptosis and production of proinflammatory cytokines (3). Receptors are shed from the surface, leading to a pool of receptors that dampen immune responses (4). Mutated TNF receptors form aggregates and are retained intracellularly. These aggregated receptors are capable of binding TRADD (5) and stimulate ligand-independent cytokine production.

There are two exceptional *TNFRSF1A* mutations: R92Q and P46L. These mutations do not lead to receptor misfolding and are present in low frequency in the general population. They may, however, cause a mild inflammatory phenotype.

Mevalonate Kinase Deficiency

The genetic defect in MKD is located in *MVK*. Mevalonate kinase is a key enzyme in the isoprenoid pathway and is located directly downstream from 3-hydroxy-3methylglutaryl-coenzyme A reductase (HMG-coA-reductase). The end products of the mevalonate kinase pathway are cholesterol and a number of nonsterol isoprenoids, which are essential compounds in various cellular functions. Mutations in *MVK* lead to reduced mevalonate kinase enzyme activity. In patients with mild disease, residual mevalonate kinase activity is generally 5–15% of healthy controls and is even lower in patients with the severe phenotypes.

The mechanistic link between reduced mevalonate kinase activity and autoinflammation is thought to be defective protein prenylation. Prenylation is a posttranscriptional modification, in which nonsterol isoprenoids are coupled to proteins, influencing protein–protein and protein–membrane interactions.

In a human cellular model of MKD, deficiency of certain isoprenoids were shown to lead to defective prenylation of RhoA, with consequent activation of Rac1 and PKB, which are able to induce IL-1β secretion.[10-12] Defective prenylation with inactivation of RhoA also impairs mitochondrial function. Mitochondria from patients with MKD are elongated and unstable.[12–14] Normally, these abnormal mitochondria would be cleared from the cytosol by autophagy, but in MKD, they accumulate in the cytosol. Abnormal mitochondria release excessive amounts of ROS, and mitochondrial DNA may directly activate NLRP3.[13,14]

Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Adenitis Syndrome

Little is known about the pathophysiology of PFAPA. No genetic defect for PFAPA has been discovered as yet, and this is in agreement with the absence of a clear hereditary pattern. It may be linked to a complex genetic trait. A positive family history has been described, although not all of the patients with a family history were screened for other autoinflammatory diseases.[15,16]

During PFAPA flare-ups, upregulation of complement genes and genes in the IFN–IL-1 pathway are seen. Isolated peripheral blood mononuclear cells (PBMCs) and monocytes of patients with PFAPA show increased IL-1β production without induction of transcription of IL-1β RNA or caspase-1 induction upon lipopolysaccharide (LPS) stimulation. This increased inflammatory response can be abolished by a pan-caspase inhibitor, indicating the important role of the inflammasome in this disease.[17] Spontaneous apoptosis of polymorphous mononuclear cells is significantly lower in patients with PFAPA compared with healthy controls, and during fever episodes, increased production of ROS has been observed *in vitro* in patients with PFAPA.[18]

Schnitzler Syndrome

The etiology of Schnitzler syndrome remains unknown. Involvement of autoreactive antibodies has been suggested, but this finding could not be reproduced.[19] A central role for IL-1β is illustrated by the high efficacy of anti–IL-1β therapy in patients with Schnitzler syndrome.[19,20]

No causative genetic defect for Schnitzler syndrome has been found, but somatic mosaicism of two different *NLRP3* mutations restricted to myeloid cells has been described recently in two patients with Schnitzler syndrome.[21] Strikingly, these patients had the most severe phenotype in this cohort. Somatic mosaicism may be an explanation for the late onset of Schnitzler syndrome, and low-grade mosaicism may not be picked up by routine gene sequencing. Other genetic defects have also been described in very small numbers of patients, but their role in the pathogenesis of Schnitzler syndrome remains unclear.

Schnitzler syndrome is regarded as a paraneoplastic syndrome by some because of its association with Waldenström macroglobulinemia.

LABORATORY TESTS

In classic monogenetic autoinflammatory diseases, an explicit acute-phase response, with elevated inflammatory markers (cross-reactive protein [CRP], erythrocyte sedimentation rate [ESR], serum amyloid A [SAA]) and leukocytosis, is invariably present during symptomatic periods. In other autoinflammatory diseases, this may be less evident.

During clinical disease remission, persistent subclinical inflammation can be found. Cold agglutinins, antinuclear autoantibodies (ANAs), or cryoglobulins are usually not present but may be found in low titers. Proteinuria (over 0.5 g of protein per 24 hours) is highly suggestive for secondary AA amyloidosis.

Elevated serum IgD can be present in MKD. It is discussed in detail in the respective section on the diagnosis of this disease. Similarly, the paraproteins encountered in Schnitzler syndrome are discussed in the section on the symptoms of Schnitzler syndrome.

DIAGNOSIS

Familial Mediterranean Fever

FMF is a clinical diagnosis. A validated set of clinical criteria for the diagnosis of FMF has been defined (The Tel Hashomer criteria, Table 60.3). These criteria have high positive predictive value and negative predictive value in populations with high pretest probability, but their diagnostic accuracy is lower in other populations.

TABLE 60.3 Tel Hashomer Criteria for the Diagnosis of Familial Mediterranean Fever

Major Criteria (≥1 present)
Typical attack[a] with abdominal symptoms
Typical attack[a] with pleural symptoms
Typical attack[a] with monoarthritis
Typical attack[a] with only fever
Incomplete attack[b] with abdominal symptoms
Minor Criteria (≥2 present)
Favorable response to colchicine
Incomplete attack with monoarthritis
Exertional leg pain

[a] Typical attacks are defined as at least three attacks with fever >38°C.

[b] Incomplete attacks are painful and recurrent attacks not meeting the criteria for typical.

The sensitivity and specificity of these criteria for the diagnosis of FMF are >95% and >97%, respectively.

From: Livneh et al. Criteria for the diagnosis of familial Mediterranean fever. Arthritis Rheum 1997;40:1879–85

For experienced physicians, it is not difficult to diagnose FMF in patients who have a medical history compatible with FMF and who come from an ethnic group with high prevalence of FMF. In countries with a low incidence of FMF, several years of diagnostic delay are not unusual, as typical attacks remain unrecognized.

When FMF is suspected on clinical grounds, treatment with colchicine should be initiated immediately. A positive effect of colchicine is confirmatory for the diagnosis FMF.

In populations with a low prevalence of FMF and in atypical cases, sequencing of the *MEFV* gene can be helpful in the diagnostic workup.

Cryopyrin-Associated Periodic Syndrome

CAPS is diagnosed on the basis of typical clinical features, sometimes supported by a positive family history reflecting autosomal dominant inheritance. Detection of mutations in the *NLRP3* gene will confirm the diagnosis in most cases, but cases with “mutation-negative” CAPS have been described. Some of these patients may have somatic mosaicism. Reaction to treatment is the same for these patients as for patients with proven *NLRP3* mutation.

Tumor Necrosis Factor Receptor–Associated Periodic Syndrome

A set of clinical criteria for TRAPS has been proposed (Table 60.4) but has not been validated. The cornerstone of the diagnosis of TRAPS is detection of mutations in the *TNFRSF1A* gene.

Mevalonate Kinase Deficiency

MKD can be suspected when characteristic clinical findings are present in combination with persistent elevated serum levels of IgD >100 international unit per milliliter (IU/mL). Elevation of serum IgD is not pathognomonic for MKD, as it may also occur in other inflammatory conditions, including FMF and PFAPA. Furthermore, in the very young, IgD may be normal, and in some of the affected individuals, IgD is never elevated. Elevated IgD is accompanied by elevated IgA in 80% of patients. The serum level of IgD does not correlate with disease severity, and elevated concentrations are present during asymptomatic periods.

Clinical suspicion of MKD can be confirmed by sequencing of the *MVK* gene. During attacks, traces of mevalonic acid may be found both in urine and serum and can be measured with special techniques, which are, however, not commonly available. Measurement of mevalonate kinase enzyme activity is usually only done in the research setting and requires cell cultures.

TABLE 60.4 Diagnostic Criteria for Tumor Necrosis Factor Receptor–Associated Periodic Syndrome (TRAPS)

- Recurrent episodes of inflammatory symptoms spanning a period of more than 6 months’ duration. Inflammatory symptoms include fever, abdominal pain, myalgia, rash, conjunctivitis/periorbital edema, chest pain, and arthralgia or monoarticular synovitis
- Episodes lasting ≥5 days
- Responsiveness to glucocorticosteroids, but not colchicine
- Affected family members (not always present)
- Any ethnicity may be affected

From: Hull et al. The TNF receptor-associated periodic syndrome (TRAPS): emerging concepts of an autoinflammatory disorder. Medicine (Baltimore) 2002;81:349–68

TABLE 60.5 Diagnostic Criteria for Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Adenitis (PFAPA) Syndrome

I Regularly recurring fevers with an early age of onset (<5 years of age)
II Constitutional symptoms in the absence of upper respiratory infection, which include at least one of the following:
  a) Aphthous stomatitis
  b) Cervical lymphadenitis
  c) Pharyngitis
III Exclusion of cyclic neutropenia
IV Completely asymptomatic interval between episodes
V Normal growth and development

From: Thomas et al. Diagnostic criteria used for PFAPA Periodic fever syndrome in children. J Pediatr 1999;135:15–21

Periodic Fever, Aphthous Stomatitis, Pharyngitis, and Adenitis Syndrome

There is currently no diagnostic test to prove PFAPA. It is diagnosed based on clinical signs and symptoms. The modified criteria by Thomas et al. are used (Table 60.5) and may be supplemented by numeric limits, such as minimum number of attacks and duration of fever. Exclusion of other causes, including other autoinflammatory syndromes, is important.

Schnitzler Syndrome

Schnitzler syndrome is diagnosed on the basis of clinical criteria (see Table 60.2). Exclusion of other causes, particularly monoclonal gammopathy of undetermined significance (MGUS) and chronic idiopathic urticaria, is of paramount importance.

Autoinflammation of Unknown Origin

Regardless of the increasing number of autoinflammatory diseases recognized and the increasing insights in the mechanisms of autoinflammation, an increasing number of patients presenting with an autoinflammatory phenotype cannot be assigned to one of the known autoinflammatory diseases. These patients are considered to suffer from *autoinflammation of unknown origin*. It is likely that further research and newly developed diagnostic techniques will identify new proteins, genetic defects, and pathways in these patients, leading to recognition of new diseases. In patients with autoinflammation of unknown origin, anti–IL-1 therapy can be tried both diagnostically and therapeutically.[21a]

TREATMENT

Colchicine

Colchicine is the treatment of first choice for FMF. Although it has been used since the 1970s, the mechanism of action of colchicine in FMF is still unknown. It is highly effective in preventing attacks. Response to colchicine has been used as a diagnostic criterion for FMF.

The average dose used is 1.0–1.5 mg/day. If tolerated, the dose can be increased up to 3 mg/day in patients with insufficient response. There are few patients with FMF that are unresponsive to colchicine. Others may not be able to tolerate an effective dose of colchicine because of side effects. These patients may benefit from IL-1 inhibition.[22]

As colchicine is the only drug with proven protection against the development of amyloidosis, all patients with FMF should be prescribed colchicine, regardless of disease severity and attack frequency. When anti–IL-1 treatment is started, expert opinion recommends continuation of colchicine in the highest tolerable dose for the prevention of amyloidosis.

The most common side effects of colchicine are diarrhea and abdominal pain. These are dose dependent. In patients with persistent diarrhea, dose reduction can be tried to reduce severity. Myopathy, neuropathy, and leukopenia are very rare, but severe side effects occur primarily in patients with abnormal kidney or liver function or because of interaction with other drugs.

High-dose colchicine has been shown to be teratogenic in animals. However, multiple cohort studies have shown that colchicine can be used safely during pregnancy and breastfeeding. In therapeutic doses, colchicine does not have a negative effect on sperm number and quality, and it has no negative effect on male or female fertility.

As a general rule, there is no place for colchicine in the treatment of autoinflammatory syndromes other than FMF. As an exception to this rule, patients with autoinflammation of unknown origin may experience a favorable effect, especially if their disease shares characteristics with FMF. A small trial has demonstrated decreased attack frequency during colchicine treatment for PFAPA.[23]

Inhibition of Interleukin-1

KEY CONCEPTS

Interleukin-1β (IL-1β)

- IL-1β is a very potent proinflammatory cytokine, tightly regulated at multiple levels.
- The majority of autoinflammatory diseases is caused by dysregulation of IL-1β.
- Measurement of IL-1 β serum levels has no value in the diagnosis of autoinflammation or in assessing disease severity.
- IL-1 inhibition is the treatment of first choice for many autoinflammatory diseases, and it has greatly improved quality of life in patients.

The detection of *NLRP3* mutations in CAPS has illustrated the importance of IL-1β in the pathogenesis of autoinflammation.

The first inhibitor of IL-1 developed was the recombinant human IL-1 receptor antagonist anakinra, which is still the most commonly available IL-1 inhibitor. It competitively binds to the IL-1 receptor, completely inhibiting the actions of both IL-1α and IL-1β. Anakinra has a short half-life and needs to be given as a once-daily subcutaneous injection.

The selective anti-IL-1β monoclonal antibody canakinumab has a longer half-life and is also injected subcutaneously. Standard injection frequency is once per 8 weeks, but shorter intervals may often be necessary in severe disease.

Rilonacept is a construct of two extracellular chains of the IL-1 receptor complex fused to the Fc-portion of IgG. It is given as a weekly subcutaneous injection.

Currently, there is evidence for the effectiveness of anti–IL-1 therapy in many autoinflammatory diseases, including FMF, CAPS, TRAPS, MKD, PFAPA, and Schnitzler syndrome. Typically, anti–IL-1 treatment leads to instant abortion of inflammation with clinical response within the first hours to days after the first injection. This vivid response to treatment is so characteristic that IL-1 inhibition can serve as a diagnostic tool in the diagnosis of these autoinflammatory disorders. Anakinra and canakinumab have both been approved for the treatment of CAPS by the US American Food and Drug Association (FDA) and the European Medical Association (EMA). These agents were given "orphan" status for the treatment of TRAPS by the EMA. In 2016, the FDA and EMA approved the use of canakinumab in patients with HIDS, TRAPS and colchicine-resistant FMF. Rilonacept is approved for the treatment of CAPS by the FDA but is not commonly used in Europe.[24]

In patients with mild MKD and periodic symptoms with long symptom-free intervals, anakinra can be used on demand. In these cases it can be started at the first signs of an attack and only be continued for a few days.[25]

Side effects of IL-1 inhibition include painful injection-site reactions, which are most commonly seen with anakinra, and increased frequency of infections, mostly mild upper respiratory tract infections. More severe infections are rarely seen.

Inhibition of Interleukin-6

Tocilizumab, a monoclonal antibody (mAb) against the IL-6 receptor, has been registered for the treatment of rheumatoid arthritis and systemic-onset juvenile idiopathic arthritis (SoJIA) and is used with increasing frequency in autoinflammatory diseases. It is available as an intravenous infusion or subcutaneous injection. The most common dose is 8 mg/kg in children and adults, or 10 to 12 mg/kg in children with body weight under 30 kg, with an interval of 2–4 weeks. Side effects of tocilizumab are increased susceptibility to infections, most commonly upper respiratory tract infections, elevated liver enzymes, and hematological abnormalities. Bowel perforations have been reported. As IL-6 induces the production of CRP in the liver, anti–IL-6 therapy always normalizes CRP, making it impossible to use it as a marker for disease activity. Tocilizumab has been shown to be effective in patients with anakinra-resistant Schnitzler syndrome, MKD, and TRAPS.

Inhibition of Tumor Necrosis Factor

Three widely used inhibitors of TNF are the mAbs infliximab and adalimumab and the recombinant soluble TNF receptor etanercept. The most common side effect of TNF inhibition is increased risk of serious infections.

Originally, TNF inhibition was regarded the treatment of first choice in patients with TRAPS unresponsive to nonsteroidal antiinflammatory drugs (NSAIDs). However, TNF inhibition induces complete response only in a minority of patients with TRAPS and is therefore far less effective than anti–IL-1 treatment.[26]

Anti-TNF treatment may also be effective in MKD, but responses are mostly partial. It may be tried in patients who show unsatisfactory response to anti–IL-1 treatment.[24,26]

Corticosteroids

Corticosteroids are very effective in PFAPA. Prednisone 1 mg/kg is most commonly used during attacks, although lower doses may also be effective. Use of corticosteroids may increase attack frequency in PFAPA.[26] Mild TRAPS can be treated with a short course of steroids (30 mg daily for 7 days), and patients experiencing more severe attacks may respond to higher doses. The beneficial effect of corticosteroids may decrease over time, necessitating dose escalation.[24,26] Short-term corticosteroids may also be effective in patients with mild MKD.[24,26]

Simvastatin

The finding of dysregulation of the mevalonate kinase pathway, with cholesterol as its major end product, has led to the hypothesis that blockage of this pathway by HMG-CoA reductase inhibitors (statins) would possible be beneficial in patients with MKD. Small trials and case reports showed a statistically significant, but clinically negligible, effect in some patients. Statins have, therefore, been abandoned as treatment for MKD in clinical practice.

Other Immunosuppressive Drugs

In the past, numerous immunosuppressive drugs were tried in a trial-and-error approach to find an effective treatment for the disabling symptoms of autoinflammation. The results have been mostly disappointing, and there is no strong evidence to support the use of other immunosuppressants in autoinflammation. When other treatments are ineffective, some patients may, however, benefit from immunosuppressive drugs.

Other Treatments

It remains a matter of debate whether adenotonsillectomy effectively resolves symptoms in PFAPA. Few meta-analyses have focused on this subject; one of them found two small randomized controlled trials of unclear risk–benefit ratio.[27] A case cohort study on the use of the histamine type 2 receptor antagonist cimetidine (150 mg twice daily) in PFAPA showed that this drug is able to resolve fever episodes in 25% of patients.[6] There are no clinical trials supporting this observation.

Several case reports on the positive effects of hematopoietic stem cell transplantation (HSCT) in patients with severe MKD have been published.[28-30] Because of the severe side effects, HSCT should be considered the last resort.

AMYLOIDOSIS

Secondary or type AA amyloidosis is a serious complication of all autoinflammatory syndromes. It is caused by tissue deposition of insoluble degradation products of the inflammatory protein SAA. Kidneys are most commonly affected. Since SAA is an acute-phase reactant, there is a close relationship between the duration and level of inflammation and the development of amyloidosis. The incidence of AA amyloidosis varies among autoinflammatory diseases. Patients with FMF are at highest risk, with an incidence of up to 75% before the introduction of colchicine treatment for this disease. There is a strong correlation between ethnicity and risk of amyloidosis in FMF, with increased risk among Sephardi Jews.

Up to 25% of patients with TRAPS will develop amyloidosis if left untreated. There seems to be a strong familial predilection. In CAPS, approximately one-third of patients develop amyloidosis in the absence of treatment. Patients with MKD and Schnitzler syndrome have a relatively small risk of amyloidosis, with only a few patients with these diseases and amyloidosis known worldwide.[19] It is unclear why some patients with the same level of inflammation may develop or never develop amyloidosis. This may be related to single nucleotide polymorphisms (SNPs) in the *SAA* gene or certain genotypes.

As proteinuria is often the first sign of AA amyloidosis, patients with autoinflammation should be screened for it with regular urine sampling. Amyloidosis can be confirmed by Congo red staining of the biopsy specimen of affected tissue. This will show

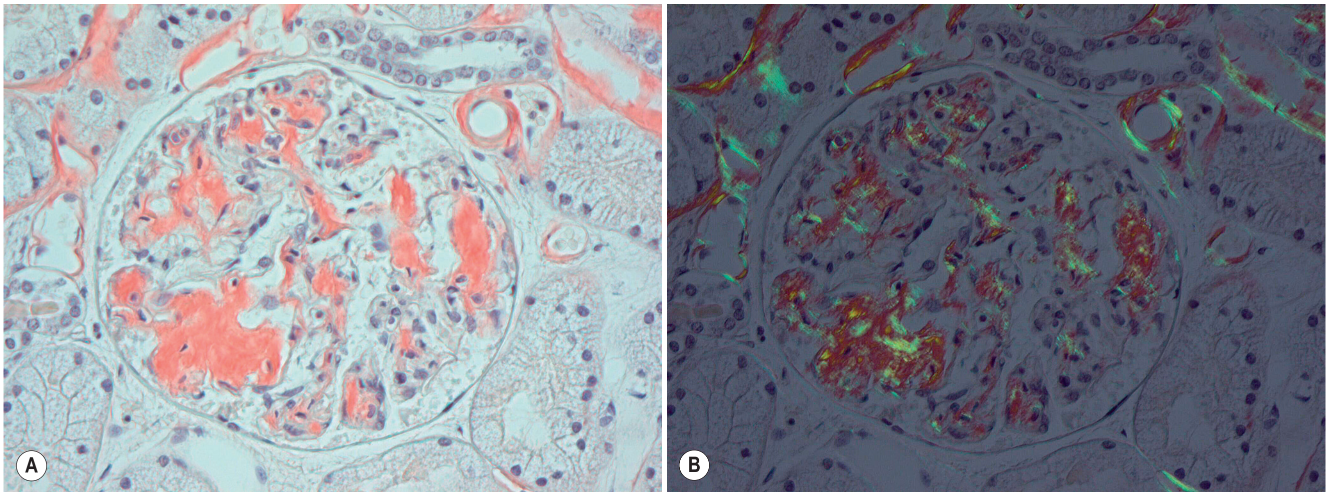

FIG 60.5 Renal Biopsy From a Patient With Amyloid a (AA) Amyloidosis. Amyloid deposits are visualized by staining with Congo red (A). Under polarized light microscopy amyloid deposits show typical apple-green birefringence (B).

an apple-green birefringence under polarized light microscopy (Fig. 60.5). Progression of amyloidosis is strongly dependent on the ability to control the underlying inflammation. If the SAA concentration can be kept under 10 mg/L, progression of amyloidosis can be halted in many cases. Some patients even show regression of amyloidosis during treatment.[31-34] A cohort mainly consisting of patients diagnosed with amyloidosis before the availability of targeted therapy showed a median survival of 19 years after the diagnosis of amyloidosis.[33]

CLINICAL PEARLS

A typical case of autoinflammation

- An 18-year-old Western European woman was seen because of recurrent episodes of fever and skin rash. These attacks started 2 hours after birth when a systemic maculopapular skin rash appeared. The rash remained present on a daily basis but was not triggered or exacerbated by cold exposure.
- At the age of 2 years, the patient developed episodes of fever, approximately 3 days each week. Typically, she had a single daily fever spike up to 39°C, which usually occurred in the evening. There was no hearing loss, and arthralgia/arthritis, dysmorphia, meningitis, myalgias, abdominal pain, and lymphadenopathy were also absent. The family history was negative for autoinflammatory diseases.
- On the basis of the clinical presentation, cryopyrin-associated periodic syndrome (CAPS) was suspected as a cause, and targeted gene analysis was performed. This showed an R260W mutation of the *NLRP3* gene. Thus this patient was diagnosed with CAPS.
- After the diagnosis was made, the patient was successfully treated with anakinra, 100 mg once daily. When canakinumab, the long-acting interleukin-1 (IL-1) inhibitor, became available, she was switched to 150 mg canakinumab once every 2 months; she remains symptom-free.

CONCLUSIONS

ON THE HORIZON

- Identification of new (hereditary) autoinflammatory syndromes in patients with episodic inflammation of unknown origin
- Wider availability and application of interleukin-1 (IL-1) inhibitors and development of new IL-1 inhibitors to improve treatment.

Since the introduction of the term *autoinflammation* at the end of the twentieth century, the clinical characteristics of the classic monogenic autoinflammatory diseases FMF, CAPS, MKD, and TRAPS have been described in more detail. Many new diseases have been identified. Research focused on their pathophysiological mechanism has revealed new genes and pathways and provided further insight into the mechanism of inflammation in general. The development of IL-1–targeting drugs has led to better quality of life for patients and to increased life expectancy in some of these diseases by prevention of complications, such as secondary amyloidosis. Nevertheless, many patients with autoinflammation remain undiagnosed.

For the near future, further study of the mechanisms of inflammation in patients with autoinflammatory diseases will likely provide a deeper insight into the workings of innate immunity and will lead to the identification of even more diseases in the autoinflammatory spectrum. The search for new therapies, preferably oral drugs, for the treatment of autoinflammation will continue.

MULTIPLE-CHOICE QUESTIONS

1. Autoinflammatory diseases are characterized by:
   - **A.** Mutations in the NLRP3 inflammasome
   - **B.** Spontaneous recurrent or persistent inflammation
   - **C.** The presence of autoantibodies

2. What is the MOST common monogenic autoinflammatory disease worldwide?
   - **A.** Cryopyrin-associated periodic syndrome (CAPS)
   - **B.** Familial Mediterranean fever (FMF)
   - **C.** Mevalonate kinase deficiency (MKD)
   - **D.** Periodic fever, aphthous stomatitis, pharyngitis, and adenitis syndrome (PFAPA)
   - **E.** Schnitzler syndrome
   - **F.** Tumor necrosis factor receptor–associated periodic syndrome (TRAPS)

3. What is the treatment of first choice for FMF?
   - **A.** Acetaminophen
   - **B.** Colchicine
   - **C.** Interleukin (IL)-1 inhibition
   - **D.** Tonsillectomy

4. What is the MOST common long-term complication of the monogenic autoinflammatory diseases?
   - **A.** Amyloid A (AA) amyloidosis
   - **B.** Chronic meningitis
   - **C.** Joint contractures
   - **D.** Malignancy

Antiphospholipid Syndrome

Thomas L. Ortel, Doruk Erkan, Michael D. Lockshin

Diagnosis of the antiphospholipid syndrome (APS) requires that a patient has *both* a clinical event (thrombosis and/or pregnancy loss) *and* persistent antiphospholipid antibody (aPL), documented by a solid phase serum assay (anticardiolipin [aCL] or anti β_2-glycoprotein-I [β_2GPI] enzyme-linked immunosorbent assay) or an inhibitor of phospholipid-dependent clotting (lupus anticoagulant [LA] test) or both (Table 61.1).[1] Antiphospholipid syndrome occurs as an isolated diagnosis, referred to as primary APS, or is associated with other systemic rheumatic diseases such as systemic lupus erythematosus (SLE).

The primary antigen to which aPL binds is β_2GPI (apolipoprotein H), a phospholipid-binding plasma protein. β_2GPI is normally present at a concentration of 200 µg/mL and is a member of the complement control protein family. An octapeptide in the fifth domain of the protein and critical cysteine bonds are necessary for both phospholipid binding and antigenicity; a first domain site is implicated in pathogenicity. *In vivo,* β_2GPI binds, primarily as a dimer, to phosphatidylserine on activated or apoptotic cell membranes, including those of trophoblast, platelets, and endothelial cells, undergoing conformational change and becoming antigenic. This binding may initiate cell activation, clearance of apoptotic cells by macrophages, and/or coagulation.[2]

KEY CONCEPTS

- Antiphospholipid antibodies (aPL) exist as a family of autoantibodies directed against phospholipid-binding plasma proteins, most commonly β_2-glycoprotein-I.
- The origin of aPL is unknown but is hypothesized to be an incidental exposure to environmental agents inducing aPL in susceptible individuals.
- In humans, although cross-sectional and prospective cohort studies demonstrate that aPL can predict future thrombosis, the pathogenic mechanism is unknown; more than one mechanism may be involved.
- Concomitant prothrombotic risk factors may promote clotting in an additive manner in aPL-positive patients.

Autoimmune aPL binds β_2GPI (β_2GPI-dependent aPL), which in turn binds negatively charged phospholipids. Drugs (such as chlorpromazine, procainamide, quinidine, and phenytoin), malignancies (such as lymphoproliferative disorders), and infectious agents (such as syphilitic and nonsyphilitic *Treponema, Borrelia burgdorferi,* human immunodeficiency virus, *Leptospira,* or parasites) induce β_2GPI-independent transient aPL. β_2GPI-independent aPLs are usually made up of low-titer aCLs, which may bind directly to phospholipids and are rarely associated with thrombosis.

EPIDEMIOLOGY

Low-titer aCLs occur in <10% of normal blood donors, and moderate- to high-titer aCLs and/or a positive LA test occurs in <1%. The prevalence of positive aPL tests increases with age; because the differential diagnosis of vascular occlusion is broader than it is in young adults, particular care is necessary in diagnosing APS in older patients. Thirty to 40% of SLE patients and approximately one-fifth of rheumatoid arthritis patients have positive tests for aPL.

The strength of association between aPL and clinical events varies among studies. A study of healthy male physicians followed prospectively for 3 years showed that those with moderate to high titers of IgG aCL have a risk for venous thrombosis or pulmonary embolus that is eight times higher than that for men with negative tests. Although a number of studies have tried to estimate the annual thrombosis risk in asymptomatic aPL-positive patients, most of these studies have included predominantly patients with SLE. Despite the lack of well-controlled studies, in aPL-positive individuals with no other systemic autoimmune diseases or risk factors for thrombosis, the annual risk of first thrombosis is probably very low (<1%/year). However, aPL-positive patients with other systemic autoimmune diseases such as SLE are at increased annual risk for first thrombosis (<4%/year).

Approximately 10% of first-stroke victims have aPL,[3] especially those who are young, as do up to 21% of women who have suffered three or more consecutive fetal losses.[4]

ETIOPATHOGENESIS

Antiphospholipid antibodies exist as a family of autoantibodies directed against phospholipid-binding plasma proteins, most commonly β_2GPI. Such proteins bind negatively charged phospholipids (cardiolipin, phosphatidylglycerol, phosphatidylserine, phosphatidylinositol) but not zwitterionic or neutral phospholipids (phosphatidylethanolamine, phosphatidylcholine). Other phospholipid-binding plasma proteins are prothrombin, thrombomodulin, protein C, protein S, and annexins I and V. *In vivo,* the likely relevant phospholipid to which these proteins bind is phosphatidylserine, which is normally sequestered on the inner cell membrane but is exteriorized during cell activation and apoptosis. Annexins bind to exposed phosphatidylserine and create a “remove me” signal on cells.

TABLE 61.1 **Revised Sapporo Classification Criteria for the Antiphospholipid Syndrome**[1]

Clinical Criteria

1. Vascular thrombosis[a]
    - (a) One or more clinical episodes[b] of arterial, venous, or small-vessel thrombosis,[c] in any tissue or organ.
2. Pregnancy morbidity:
    - (a) One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, *or*
    - (b) One or more premature births of a morphologically normal neonate before the 34th week of gestation because of eclampsia, severe preeclampsia, or recognized features of placental insufficiency[d] *or*
    - (c) Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomical or hormonal abnormalities and paternal and maternal chromosomal causes excluded.

Laboratory Criteria[e]

1. Lupus anticoagulant present in plasma, on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Haemostasis.
2. Anticardiolipin antibody of IgG and/or IgM isotype in serum or plasma, present in medium or high titer (*i.e.,* >40 GPL or MPL, or > the 99th percentile), on two or more occasions, at least 12 weeks apart, measured by a standardized enzyme-linked immunosorbent assay (ELISA).
3. Anti-β_2 glycoprotein-I antibody of IgG and/or IgM isotype in serum or plasma, (in titer > the 99th percentile) present on two or more occasions, at least 12 weeks apart, measured by a standardized ELISA.

Definite antiphospholipid syndrome (APS) is present if at least one of the clinical criteria and one of the laboratory criteria are met. Classification of APS should be avoided if less than 12 weeks or more than 5 years separates the positive antiphospholipid antibody (aPL) test and the clinical manifestation. In studies of populations of patients who have more than one type of pregnancy morbidity, investigators are strongly encouraged to stratify groups of subjects according to a, b, or c above.

[a] Coexisting inherited or acquired factors for thrombosis are not a reason for excluding patients from APS trials. However, two subgroups of APS patients should be recognized, according to (a) the presence, and (b) the absence of additional risk factors for thrombosis. Indicative (but not exhaustive), such cases include age (>55 in men and >65 in women) and the presence of any of the established risk factors for cardiovascular disease (hypertension, diabetes mellitus, elevated LDL or low HDL cholesterol, cigarette smoking, family history of premature cardiovascular disease, body mass index ≥30 kg/m^2, microalbuminuria, estimated glomerular filtration rate (GFR) <60 mL/min), inherited thrombophilias, oral contraceptives, nephritic syndrome, malignancy, immobilization, and surgery. Thus patients who fulfill criteria should be stratified according to contributing causes of thrombosis.

[b] A thrombotic episode in the past could be considered as a clinical criterion, provided that thrombosis is proved by appropriate diagnostic means and that no alternative diagnosis or cause of thrombosis is found.

[c] Superficial venous thrombosis is not included in the clinical criteria.

[d] Generally accepted features of placental insufficiency include (i) abnormal or nonreassuring fetal surveillance test(s), *e.g.,* a nonreactive nonstress test, suggestive of fetal hypoxemia; (ii) abnormal Doppler flow velocimetry waveform analysis suggestive of fetal hypoxemia, *e.g.,* absent end-diastolic flow in the umbilical artery; (iii) oligohydramnios, *e.g.,* an amniotic fluid index of 5 cm or less; or (iv) a postnatal birth weight less than the 10th percentile for the gestational age.

[e] Investigators are strongly advised to classify APS patients in studies into one of the following categories: I, more than one laboratory criteria present (any combination); IIa, LA present alone; IIb, aCL antibody present alone; IIc, anti-β_2-glycoprotein-I antibody present alone.

TABLE 61.2 **Possible Mechanisms of Antiphospholipid Antibody–Induced Thrombosis**

Endothelial Cells–Antiphospholipid Antibody (aPL) Interaction

Endothelial cell damage or activation (via increased expression of adhesion molecules)
Coexisting antiendothelial antibodies
aPL-induced monocyte adhesion to endothelial cells
Increased tissue factor expression

Platelet–aPL Interaction

Platelet activation
Stimulation of thromboxane production

Coagulation System–aPL Interaction

Inhibition of activation of protein C by the thrombomodulin–thrombin complex
Inhibition of activation of protein C via its cofactor protein S
Interaction between aPL and substrates of activated protein C such as factors Va and VIIIa
Interaction between aPL and an annexin V anticoagulant shield

Complement Activation

The commonly accepted hypothesis regarding the origin of aPL states that an incidental exposure to environmental agents, the antigens of which contain β_2GPI-like peptides, induces aPL in susceptible individuals via molecular mimicry.[5] In experimental animal models, passive or active immunization with viral peptides, bacterial peptides, and heterologous β_2GPI induces polyclonal aPL and clinical events associated with APS. β_2GPI polymorphisms influence the generation of aPL in individuals but have only a weak relationship to the occurrence of aPL-related clinical events. Persons congenitally lacking β_2GPI as well as β_2GPI knock-out mice appear normal.

In humans, although cross-sectional and prospective cohort studies demonstrate that aPL can predict future thrombosis, the pathogenic mechanism remains unknown; more than one mechanism may be involved (Table 61.2). Because high-titer antibody can persist for years in asymptomatic persons and because positive aPL tests can precede symptoms for years, it is likely that vascular injury and/or endothelial cell activation will immediately precede thrombosis in persons bearing the antibody. Platelet activation followed by binding of aPL to platelet membrane phospholipid-bound annexins may initiate platelet adhesion and thrombosis. Antiphospholipid antibodies can inhibit phospholipid-dependent reactions in the coagulation cascade, such as protein C and protein S activation. Interaction between aPL and an annexin A5 anticoagulant shield is another potential mechanism.[2] Recent studies also demonstrate that aPLs induce cellular activation through receptors such as annexin A2 and apoER2, and induce release of microparticles from endothelial cells.[6]

In experimental animal models, aPLs cause fetal resorption (a proxy for recurrent fetal loss) and increase size and duration of trauma-induced venous and arterial thrombi. Inhibiting complement activation prevents experimental aPL-induced fetal death, and C5 knock-out mice carry pregnancies normally despite the presence of aPL, implying that a complement-mediated effector mechanism is a requirement for fetal death to occur.[7]

In the "second-hit hypothesis," a second trigger event (such as oral contraceptives or surgical procedures) may be necessary for an asymptomatic aPL-positive individual to develop thrombosis. Acquired and heritable risk factors for thrombosis may increase the risk of thromboembolic events in aPL patients.

A proposed pathogenesis for aPL-mediated thrombosis and placental injury begins with activation or apoptosis (by unknown triggers, possibly infectious or traumatic) of platelets, endothelial cells, or trophoblasts. Negatively charged phosphatidylserine migrates from the inner to the outer cell membrane. Circulating β_2GPI binds to phosphatidylserine, which is followed by aPL binding to a β_2GPI dimer, activating a complement and, through C5a, initiating a signaling cascade that induces cell surface tissue factor (TF) expression and adhesion molecules (*e.g.*, ICAM-1). Other components of the innate immune system may also be activated, leading to a milieu that promotes platelet activation and thrombosis. In addition, aPL adversely affects formation of a trophoblast syncytium, placental apoptosis, and trophoblast invasion, all processes required for the normal establishment of placental function. *In vitro,* pathogenic aPL induces adhesion molecules and enhances adherence of leukocytes to cultured endothelial cells.

DIAGNOSIS

Clinical Manifestations

The clinical manifestations associated with aPL represent a spectrum from asymptomatic to catastrophic APS (Table 61.3). The principal manifestations are venous or arterial thromboses and pregnancy losses. Except for their severity, the youth of affected patients, and unusual anatomical locations (Budd-Chiari syndrome, and sagittal sinus and upper extremity thromboses), thromboses in APS do not clinically differ from thromboses attributable to other causes. Stroke and transient ischemic attack are the most common presentation of arterial thrombosis, whereas deep vein thrombosis and pulmonary embolism are the most common venous manifestations of APS. Glomerular capillary endothelial cell injury or thrombosis of renal vessels (thrombotic microangiopathy) causes proteinuria without celluria or hypocomplementemia and may lead to severe hypertension and/or renal failure.

Many patients have livedo reticularis (a lattice-like pattern of superficial skin veins) (Fig. 61.1), cardiac valve disease (vegetations, valve thickening and dysfunction), or other nonthrombotic manifestations described in several studies but not included in the revised Sapporo criteria[1] due to nonspecificity or rarity (Table 61.4). These manifestations by themselves do not classify a patient as having APS for clinical studies, but they add information to the diagnosis of individual patients. The pathogenesis of cardiac valve disease in APS is unknown; valve replacement may be necessary. A putative association of aPL and increased risk of atherosclerosis may exist, but this is controversial; in studies of atherosclerosis in patients with SLE, aPL protected against atherosclerosis.[8] Some patients develop nonfocal neurological symptoms such as lack of concentration, forgetfulness, and dizzy spells. Small hyperintense lesions can be seen on magnetic resonance imaging (MRI), primarily in the periventricular white matter, but do not correlate well with clinical symptoms (Fig. 61.2).

Pregnancy losses in patients with aPL typically occur after 10 weeks' gestation (fetal loss), but early losses also occur (preembryonic or embryonic losses).[9] Patients with antiphospholipid syndrome may develop severe early preeclampsia and HELLP (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets) syndrome. Although placental infarction may be a cause of fetal growth restriction or death, nonthrombotic mechanisms of placental dysfunction are likely more important.

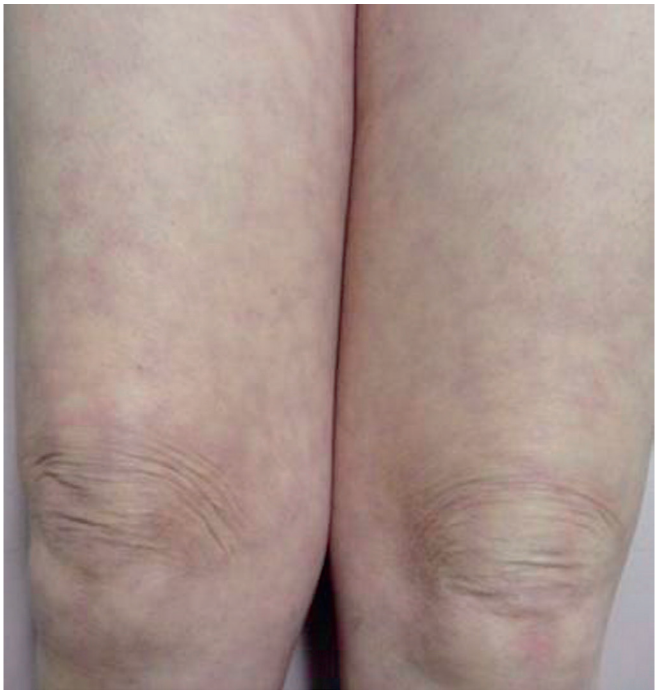

FIG 61.1 Livedo reticularis in a patient with primary antiphospholipid syndrome.

TABLE 61.3 The Clinical Spectrum of Antiphospholipid Antibodies

Asymptomatic[a] antiphospholipid antibody (aPL)–positivity
Antiphospholipid syndrome with vascular events
Antiphospholipid syndrome with only pregnancy morbidity
Asymptomatic[a] aPL-positivity with noncriteria aPL manifestations
Catastrophic antiphospholipid syndrome

[a] No history of thrombosis or pregnancy morbidity as per the Sapporo Criteria.[1]

TABLE 61.4 Noncriteria Features of the Antiphospholipid Syndrome

Type	Features
Clinical	Livedo reticularis Cardiac valve disease Autoimmune hemolytic anemia Thrombocytopenia (usually 50 000–100 000/mm^3) Multiple sclerosis–like syndrome and myelopathy Nonfocal neurological symptoms Chorea
Laboratory	IgA anticardiolipin and anti-β_2-glycoprotein-I antibodies Antiphosphatidylserine, phosphatidylinositol, phosphatidylglycerol, phosphatidylethanolamine antibodies Antiprothrombin antibodies Antiphosphatidylserine-prothrombin antibodies

Catastrophic APS (CAPS) is a rare, abrupt, life-threatening presentation. It consists of multiple thromboses of medium and small arteries occurring over a period of days, causing stroke; cardiac, hepatic, adrenal, renal, and intestinal infarction; and peripheral gangrene. Proposed diagnostic criteria for CAPS

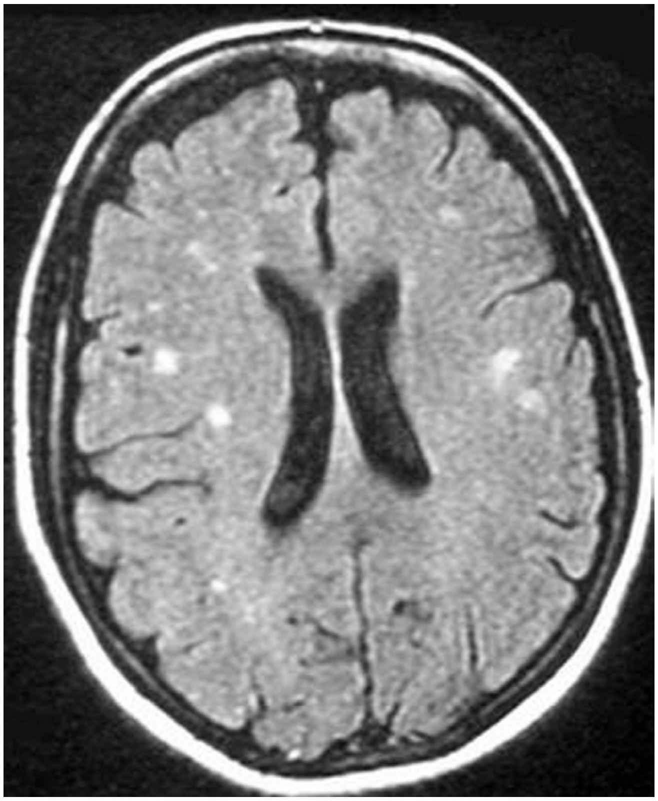

FIG 61.2 Magnetic resonance imaging demonstrating multiple periventricular white matter hyperintense lesions.

TABLE 61.5 Preliminary Criteria for the Classification of Catastrophic Antiphospholipid Syndrome

1. Evidence of involvement of three or more organs, systems, and/or tissues[a]
2. Development of manifestations simultaneously or in less than 1 week
3. Confirmation by histopathology of small-vessel occlusion in at least one organ or tissue[b]
4. Laboratory confirmation of the presence of antiphospholipid antibody (aPL)[c]

Definite Catastrophic Antiphospholipid Syndrome (APS):

- All 4 criteria

Probable Catastrophic APS:

- Criteria 2–4 and two organs, systems, and/or tissues involved;
- Criteria 1–3, except no aPL confirmation 6 weeks apart due to the early death of a patient not tested before catastrophic episode;
- Criteria 1, 2, 4; or
- Criteria 1, 3, 4, and development of a third event more than 1 week but less than 1 month after first despite anticoagulation.

[a] Usually, clinical evidence of vessel occlusions, confirmed by imaging techniques when appropriate. Renal involvement is defined by a 50% rise in serum creatinine, severe systemic hypertension, and/or proteinuria.

[b] For histopathological confirmation, significant evidence of thrombosis must be present, although vasculitis may coexist occasionally.

[c] If the patient had not been previously diagnosed as having APS, laboratory confirmation requires that the presence of aPL must be detected on two or more occasions at least 12 weeks apart (not necessarily at the time of the event), according to the proposed preliminary criteria for the classification of APS.

are shown in Table 61.5. Early diagnosis can be a challenge, especially in patients with no history of APS or aPL-positivity; diagnostic algorithms are available to guide physicians for timely diagnosis.[10] Acute adrenal failure may be the initial clinical event, heralded by unexplained back pain and vascular collapse. Patients with CAPS often have moderate thrombocytopenia; fragmented erythrocytes can be seen, but they are less frequent than in hemolytic–uremic syndrome or in thrombotic thrombocytopenic purpura. Renal failure and pulmonary hemorrhage may occur. Tissue biopsies show noninflammatory vascular occlusions involving both small- and medium-sized vessels.

Antibodies to prothrombin sometimes accompany aPLs and may cause hemorrhage by depleting prothrombin (lupus anticoagulant hypoprothrombinemia syndrome).

Laboratory Tests

In the presence of characteristic clinical events, APS is diagnosed when patients have persistent aPLs, including moderate- to high-titer IgG and/or IgM aCL, moderate- to high-titer IgG and/or IgM aβ_2GPI, and/or positive LA test.[1] Approximately 80% of patients with positive LA tests have aCL, but only 20% of patients positive for aCL have positive LA tests. Some patients are only aβ_2GPI positive. Patients with positive LA tests have higher risk for thrombosis than patients with negative tests. Several studies have shown that patients with positive aβ_2GPI tests are also at higher risk for thrombosis, but this has not been consistently observed.

LAs are detected in coagulation assays that detect the ability of aPL to interfere with phospholipid-dependent coagulation reactions. Guidelines of the International Society on Thrombosis and Haemostasis for diagnosis of LA[11] include the following:

Demonstration of a prolonged phospholipid-dependent coagulation screening test such as activated partial thromboplastin time (aPTT) or dilute Russell viper venom time (dRVVT);

Failure to correct the prolonged screening test by mixing the patient plasma with normal platelet-poor plasma, demonstrating the presence of an inhibitor;

Shortening or correcting the prolonged screening test by addition of excess phospholipid, demonstrating phospholipid dependency; and

Exclusion of other coagulopathies.

A positive screening coagulation test without confirmatory steps is not a positive LA test. Patients on anticoagulation may have false-positive or false-negative results for the LA test; thus when possible, the LA test should be ordered when the patient is not receiving anticoagulation therapy.[11]

Interpretation of positive tests should take into account the following observations: moderate- to high-titer (>40 U) aCL or aβ_2GPI is more strongly associated with clinical events than is low-titer; LA is a more specific but less sensitive predictor of thromboses than other aPL tests[12]; multiple positive aPL tests impart a worse prognosis than does any single type of test[13]; and positive aPL tests require a repeat test after 12 weeks to exclude transient aPL.[1]

Laboratory variability in these assays is moderately high: Assay stability in individual patients occurs over time in most patients. We showed that aPL results remain stable for at least three-quarters of subsequent tests during a mean follow-up of 2.4 years for the LA test, 3.5 years for the aCL test, and 1.0 year for the anti-β_2GPI test.[14] Based on same-day specimens, the consistency of aCL results among different commercial laboratories ranges from 64% to 88%, with moderate agreement for IgG and IgM, but marginal agreement for aCL IgA.[14]

Antiphospholipid antibody tests developed based on phosphatidylserine, phosphatidylinositol, phosphatidylethanolamine, or prothrombin are not well standardized or widely accepted; their clinical significance is unknown. IgA aCL can occur rarely as the only aPL in patients with APS. When positive, an IgA aCL may justify a diagnosis of APS in LA- and aCL-IgG/IgM test-negative patients with clinically typical disease. A false-positive test for syphilis is not diagnostic for APS.

Antinuclear and anti-DNA antibodies occur in approximately 45% of patients with APS who are not diagnosed as having SLE. Thrombocytopenia occurs in APS and is usually modest (>50,000/mm^3); proteinuria and renal insufficiency occur in patients with thrombotic microangiopathy. Erythrocyte sedimentation rate and hemoglobin and leukocyte count are usually normal in patients with uncomplicated APS, except during acute thrombosis. Complement levels are usually normal or only modestly low.

Imaging Studies

MRI studies show vascular occlusion and infarction consistent with clinical symptoms, without special characteristics, except that multiple otherwise unexplained cerebral infarctions in a young person suggest the syndrome. Multiple small hyperintense white matter lesions are common and do not unequivocally imply brain infarction (Fig. 61.2). Occlusions usually occur in vessels below the resolution limits of angiography; hence angiography or magnetic resonance angiography is not indicated unless clinical findings suggest medium- or large-vessel disease. Echocardiography or cardiac MRI may show severe Libman-Sacks endocarditis and intracardiac thrombi.

Pathological Studies

Skin, renal, and other tissues show noninflammatory occlusion of all caliber arteries and veins, acute and chronic endothelial injury and its sequelae, and recanalization in late lesions. The finding of inflammatory necrotizing vasculitis suggests concomitant SLE or other connective tissue disease. There are no other diagnostic immunofluorescence or electron microscopical findings.

CLINICAL PEARLS

- The clinical manifestations of antiphospholipid antibodies (aPL) represent a spectrum (from asymptomatic to catastrophic antiphospholipid syndrome [APS]); thus patients should not be evaluated and managed as having a single disease manifestation.
- Stroke and transient ischemic attack are the most common presentation of arterial thrombosis; deep vein thrombosis, often accompanied by pulmonary embolism, is the most common venous manifestation of APS.
- Pregnancy losses in patients with aPL typically occur after 10 weeks' gestation (fetal loss), but early losses also occur (preembryonic or embryonic losses).
- Catastrophic APS is a rare, abrupt, life-threatening complication of APS, which consists of multiple thromboses of medium and small arteries occurring over a period of days.
- APS diagnosis should be made in the presence of characteristic clinical manifestations and *persistently* (at least 12 weeks apart) positive aPL.

TREATMENT

Treatment recommendations for persistently aPL-positive patients are determined by the specific clinical indication (Table 61.6).

Asymptomatic Individuals

The ideal strategy for primary thrombosis prevention in asymptomatic, persistently aPL-positive individuals requires a risk-stratified approach based on aPL profile, age, systemic autoimmune diseases, traditional cardiovascular disease, or risk factors for venous thrombosis. Elimination of reversible risk factors for thrombosis (smoking, oral contraceptives) and prophylaxis during high-risk periods (surgical interventions or prolonged immobilization) is crucial for primary thrombosis prophylaxis in persistently aPL-positive individuals. The effectiveness of aspirin is not supported by the literature; in a randomized, double-blind, placebo-controlled trial, low-dose aspirin (81 mg) appeared to be no better than placebo in preventing first thrombotic episodes in persistently asymptomatic aPL-positive patients.[15] The general-population cardiovascular disease (CVD) risk prediction tools and prevention guidelines formulated based on risk–benefit calculations should play the primary role in decision making for aspirin therapy. Estrogen and estrogen-containing oral contraceptives are considered unsafe for asymptomatic women serendipitously known to bear high-titer antibody. There is no reliable information regarding the safety of progestin-only contraception, "morning after" contraception, or raloxifene, bromocriptine, or leuprolide in APS patients. However, progestin-only contraception

TABLE 61.6 Treatment Recommendations in Persistently Antiphospholipid Antibody–Positive Patients

Clinical Circumstance	Recommendation
Asymptomatic	No treatment[a]
Venous or arterial thrombosis	Warfarin international normalized ratio (INR) 2–3.0 indefinitely
Recurrent thrombosis	Warfarin INR 3–3.5 indefinitely ± low-dose aspirin
First pregnancy	No treatment[a]
Single pregnancy loss, <10 weeks	No treatment[a]
Recurrent fetal loss or loss after 10 weeks; history of no thrombosis	Prophylactic-dose[b] heparin with low-dose aspirin throughout the pregnancy, discontinue heparin 6–12 weeks postpartum
Recurrent fetal loss or loss after 10 weeks; history of thrombosis	Therapeutic-dose heparin[c] with low-dose aspirin throughout pregnancy, warfarin postpartum
Catastrophic antiphospholipid syndrome (APS)	Anticoagulation + corticosteroids + intravenous immunoglobulin or plasma exchange
Livedo reticularis	No treatment
Valve nodules or deformity	No known effective treatment; full anticoagulation if emboli or intracardiac thrombi are demonstrated
Thrombocytopenia, >50 000/mm^3	No treatment
Thrombocytopenia, ≤50 000/mm^3	Prednisone and/or intravenous immunoglobulin

[a] Aspirin 81 mg/day may be given.
[b] Prophylactic dose such as enoxaparin 30–40 mg subcutaneously (SQ) once daily.
[c] Therapeutic dose such as enoxaparin 1 mg/kg SQ twice daily or 1.5 mg/kg SQ once daily.

is theoretically safer than estrogen-based contraception. A small retrospective review of women undergoing artificial reproductive technology procedures demonstrated no thrombotic events.

Venous and Arterial Thromboembolism

Anticoagulation with unfractionated heparin or low-molecular-weight heparin (LMWH) followed by warfarin is the treatment for APS patients with vascular events. Heparin inhibits complement, a fact that makes it theoretically a preferred but impractical agent in most patients. For patients with a positive LA test that prolongs the aPTT, monitoring heparin can be accomplished by measuring antifactor Xa levels.

Two prospective controlled studies concluded that recurrence of thromboses in APS patients can be prevented with warfarin to an international normalized ratio (INR) of 2.0–3.0.[16,17] Although these studies provide strong evidence for moderate-intensity anticoagulation after an aPL-related venous event, the intensity of the anticoagulation is still debatable for APS patients with arterial events, since such patients constituted a minority in these studies. Although some APS patients may require high-intensity anticoagulation, in the absence of risk-stratified studies the definition of high risk is based currently on clinical judgment.

Most aPL-positive patients receive warfarin after ischemic strokes; however, the Antiphospholipid Antibodies and Stroke Study (APASS) concluded that for selected aPL-positive patients who have neither atrial fibrillation nor high-grade arterial stenosis, aspirin (325 mg/day) and warfarin (target INR 1.4–2.8) are equivalent in efficacy and in association with major bleeding complications.[18] The generalizability of these results is limited, as the study group had an average age of 60 years (higher than the average for APS populations), the aPL determination was performed only once at study entry, and the cutoff for assigning a patient to the positive aCL group was very low. However, based on APASS results, aspirin is an option for older patients with a single low positive aCL test who present with stroke.

Recently, four direct oral anticoagulants (DOACs) that target thrombin (dabigatran) or factor Xa (rivaroxaban, apixaban, and edoxaban) have been approved for the treatment of patients with venous thromboembolism. Use in patients with APS is limited, and cases of therapeutic failure have been reported. A prospective study investigated the use of rivaroxaban compared with standard-intensity warfarin in patients with APS, using the change in endogenous thrombin potential (ETP), a laboratory parameter, as the primary outcome. Although the ETP did not reach the noninferiority threshold, there was no increase in thrombotic events in patients taking rivaroxaban.[19] The study was not powered for clinical outcomes, however, and other studies are in progress.

Venous thrombosis in aPL-positive patients typically has a high recurrence rate if anticoagulation is discontinued, and lifelong anticoagulation is usually recommended. A recent systematic review of the literature revealed that the available evidence in support of an association between the presence of aPL and risk of recurrence is of low quality, however, suggesting that indefinite anticoagulation may not be needed by all patients.[20] For example, it is unknown whether patients whose event was triggered by an acquired, reversible risk factor for thrombosis can discontinue anticoagulation or switch to aspirin when the trigger factor is eliminated. Normalization of the LA or aCL tests is *not* an indication to discontinue anticoagulation. For well-anticoagulated patients who continue to have thromboses, antiplatelet drugs, hydroxychloroquine, statins, intravenous immunoglobulin (IVIG), and plasmapheresis have theoretical bases for efficacy and have all been used. There are no systematic studies of treatment for CAPS. Detailed reviews conclude that the most effective treatment combines full-dose anticoagulation, high-dose corticosteroids, plasma exchange, and IVIG.

Pregnancy Morbidity

Pregnancy is a prothrombotic state; management strategies in persistently aPL-positive patients should focus on prevention of both pregnancy morbidity and maternal thrombotic complications.[9] In pregnancy, heparin and low-dose aspirin combination increases fetal survival rate from 50% to 80% among women who have had a fetal loss and tests positive for aPL. If patients fail this regimen, the next step is to add IVIG, an approach not supported by controlled studies. Most experts in the field use LMWH (*e.g.,* enoxaparin) due to lower risk of thrombocytopenia and osteoporosis—prophylactic doses for women who have had only pregnancy morbidity, or full anticoagulant doses for women who have had prior thromboses (Table 61.6). Treatment begins after confirmation of pregnancy, continues until 48 hours before anticipated delivery (to allow epidural anesthesia), and resumes for 8–12 weeks postpartum (if no prior thromboembolism), or else the patient is transitioned to warfarin for continued therapy. No studies unequivocally justify treatment of women with aPL during a first pregnancy, women with only very early losses, or women whose aPL titers are low or transient. Nonetheless, it is common to offer such patients low-dose aspirin.

Other Clinical Manifestations of APS

There is no consensus for the treatment of patients with noncriteria and/or nonthrombotic manifestations of aPL. Corticosteroids and/or IVIG are the first-line treatments for platelet counts less than 50 000/mm^3. An open-label phase IIa pilot study of aPL found that rituximab may be effective in controlling some but not all noncriteria manifestations of APS, although aPL profiles did not change with treatment.[21]

Perioperative Management

Serious perioperative complications may occur despite prophylaxis. Patients with APS are at additional risk for thrombosis when they undergo surgery. Thus perioperative strategies should be clearly identified before any surgical procedure or before pharmacological and physical antithrombosis interventions are vigorously employed; in addition, periods without anticoagulation must be kept to an absolute minimum, and any deviation from a normal course must be considered a potential disease-related event.[22]

Additional Therapeutic Considerations

There is experimental and clinical evidence in lupus patients that hydroxychloroquine (HCQ) might decrease the incidence of thrombosis, and recent *in vitro* studies have demonstrated that HCQ might protect endothelial cells and syncytialized trophoblast cell lines from the disruptive effect of antiphospholipid antibodies.[23] In patients with systemic autoimmune diseases (particularly lupus), HCQ is commonly employed for disease control and should be considered independent of patients' aPL status. However, further controlled studies are needed to determine the effectiveness of HCQ for primary prophylaxis in aPL-positive patients.

Although statins have been used in primary and secondary cardiovascular disease prevention, no data exist for their use in thrombosis prevention in aPL-positive patients. Experimental evidence in APS mouse models and the clinical trials demonstrating rosuvastatin's protective effect against a first major cardiovascular event and venous thrombosis in a general population without hyperlipidemia but with elevated high-sensitivity C-reactive protein levels[24] justifies clinical studies of statins in nonpregnant aPL-positive patients.

Antiplatelet agents other than aspirin or long-term LMWH treatment, empirically used, have not been formally tested in clinical trials. Ongoing prospective, randomized clinical trials investigating the role of the direct oral anticoagulants in the treatment of thromboembolism in patients with APS are eagerly awaited, and other strategies, including complement inhibitors and novel antithrombotic therapies, may be candidates for future clinical trials.

CONCLUSIONS AND TRANSLATIONAL RESEARCH

ON THE HORIZON

Translational Research in Antiphospholipid Syndrome

- A better understanding of the cellular mechanisms of antiphospholipid antibody (aPL) mediated clinical events that will help us design more specifically targeted treatments.
- Identification of patients who are at risk for future aPL-related events.
- Controlled studies of theoretically useful medications such as hydroxychloroquine, statins, complement inhibitors, or anti-B-cell therapies.

APS is a systemic autoimmune disease consisting of thromboses, pregnancy losses, and persistent high-titer aPL. Inflammation and complement activation are established mechanisms of aPL-related manifestations in murine models; however, definitive studies in humans do not exist. The disease is too variable clinically, and its mechanisms too diverse, to expect that a single mechanism defined in a single model will apply to all aspects of this disease. Given that the mechanisms of aPL-induced thrombosis are not well understood and that thrombosis is multifactorial and that controversies exist about the strength of association between aPL and clinical events, drug development specific for aPL-positive patients has been challenging. Anticoagulation is the primary treatment today, but a future therapeutic approach will likely include immunomodulatory agents.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following statements concerning treatment options for a patient with antiphospholipid antibodies is correct?
   - **A.** Aspirin is an effective thromboprophylactic strategy for asymptomatic individuals with antiphospholipid antibodies.
   - **B.** Patients with arterial thromboembolism and APS should be treated with aspirin and a direct oral anticoagulant
   - **C.** Patients with venous thromboembolism and APS should be treated with warfarin with a target INR of 2-3
   - **D.** A woman with prior pregnancy loss and APS should receive intravenous immunoglobulin and steroids during subsequent pregnancies

2. A lupus anticoagulant is identified by which of the following laboratory test results?
   - **A.** Elevated antibody levels to prothrombin
   - **B.** An antibody that interferes with phospholipid-dependent coagulation reactions
   - **C.** An antibody that induces an increased thrombin potential
   - **D.** The presence of a specific factor inhibitor

3. Which of the following patients should be tested for possible APS?
   - **A.** A 65 year old man with a stroke
   - **B.** A 22 year old woman taking oral contraceptives with a pulmonary embolism
   - **C.** A 34 year old woman who presents with fetal demise at 34 weeks gestation
   - **D.** A 27 year old man new-onset seizures

Immunohematological Disorders

Jay N. Lozier, Pierre Noel

Congenital (primary) or acquired (secondary) immunodeficiencies, medications, and lymphoproliferative and rheumatological disorders are frequently associated with immune-mediated cytopenias. These processes can affect erythrocytes, leukocytes, and platelets (individually or in combination). In this chapter, we address immune-mediated cytopenias of each hematological component, discussing pathophysiology, clinical presentation, differential diagnosis, and treatment options.

IMMUNE-MEDIATED HEMOLYTIC ANEMIA

Immune-mediated hemolysis can be autoimmune, alloimmune, idiopathic, or secondary to drugs or other diseases. Regardless of the underlying cause, immunoglobulin G (IgG) or IgM (rarely IgA) antibodies are directed against antigens on the red blood cell (RBC) membrane (Table 62.1).[1,2] These disorders can be categorized on the basis of the underlying cause and the type of antierythrocyte antibody that mediates the process.

Autoimmune Hemolysis Mediated by Warm Antibody

Although warm-antibody autoimmune hemolytic anemia is rare, it increases in prevalence above the age of 50 years and tends to be more common in women than in men, as is typical of most autoimmune diseases. In this condition, IgG autoantibodies and complement components are present on the RBC surface (see below). Although the autoantibody target is most commonly the Rh antigen, a variety of other targets are known. The specificity of the antibody, however, does not affect the clinical presentation or management of hemolysis.

Drug-Induced Immune Hemolysis

Over 125 drugs have been associated with immune hemolysis.[3] Cefotetan, ceftriaxone, and piperacillin currently account for over 80% of cases. The prognosis of drug-related immune hemolysis is much better than that of idiopathic hemolysis because the hemolysis stops once the offending drug has been removed. The drugs most commonly associated with fatal hemolytic anemia are cefotetan (8%) and ceftriaxone (6%).[3] Fludarabine and cladribine have been associated with immune hemolysis. Following multiple courses of alkylating agents, fludarabine causes autoimmune hemolytic anemia in 20% of patients with chronic lymphocytic leukemia (CLL). The combination of fludarabine and cyclophosphamide with or without rituximab (FC, FCR) may protect against the development of autoimmune hemolytic anemia.[3,4]

Although the biochemical mechanisms of drug-related immune hemolysis are not completely clear, several hypotheses are generally accepted. Most commonly, complexes of drug and IgG and/or IgM that adsorb to the RBC surface and fix complement. The resultant intravascular hemolysis is acute and often severe enough to cause renal failure from toxicities of hemoglobin to renal epithelium.

A second less common mechanism develops primarily in patients receiving very high doses of penicillin (rarely used) for at least 1 week. High-titer antipenicillin IgG develops and binds to penicillin that is covalently attached to the RBC membranes. The resultant hemolysis is less acute than that caused by immune complexes but can be life-threatening.

In a third mechanism, a drug stimulates the production of an antibody that reacts with the patient's RBCs independently from the drug. Serologically, this antibody is indistinguishable from an idiopathic autoantibody. This has become rare as the use of the primary causal agent, methyldopa (an antihypertensive medication), has declined. Although these autoantibodies commonly cause positive clinical antibody tests (see below), they rarely cause hemolysis *in vivo,* and when they do, it usually ceases within 2 weeks of discontinuing the drug.

Cold Agglutinin Diseases

This type of hemolytic anemia is mediated predominantly by anti-I or anti-i IgM that agglutinates red cells at temperatures well below 37°C.[5] These antibodies engage the complement pathway resulting in C3b-mediated RBC phagocytosis mainly by Kupffer cells, whereas membrane-associated complex is a minor mechanism at low IgM titers. The severity of the clinical illness depends on the concentration of the IgM and its "thermal amplitude." Thermal amplitude describes the temperature range over which it binds to RBCs: for example, antibodies that exclusively bind at 4°C are only active *in vitro,* whereas those that bind at >30°C can bind to RBCs as they circulate in the periphery and begin the process of complement fixation, which can persist even as the cells return to body core temperatures. The activity of the IgM is also determined by its relative affinity for the I- and i-antigens, which varies from one individual to the next.

Two general types of cold agglutinin disease are recognized: a chronic idiopathic disease presenting in patients over age 50 years, caused by monoclonal anti-I IgM, and a transient disease secondary to certain infections (*e.g.,* mycoplasma, Epstein-Barr virus [EBV], cytomegalovirus [CMV]), caused by polyclonal anti-i and anti-I (see Table 62.1). Avoidance of cold environments is important in both categories of cold agglutinin disease. In addition, cold agglutinin disease can be associated with B-cell lymphoproliferative disorders, and this typically is responsive to rituximab and/or rituximab combined with fludarabine.[6]

Paroxysmal Cold Hemoglobinuria

Paroxysmal cold hemoglobinuria (PCH) is caused by anti-P IgG that is very effective in fixing complement and producing intravascular hemolysis.[2] Although rare, it is most common in

children following a viral illness and can be managed by avoidance of cold. In the past, it was more commonly associated with syphilis (see Table 62.1). There is also an autoimmune variety of PCH that may require immunosuppression with corticosteroids. Splenectomy is not helpful as a consequence of the fact that the hemolysis is intravascular.

Hemolytic Transfusion Reactions

Because individuals with group O RBCs have preformed iso-anti-A and -B, they must only be transfused with group O cells. Similarly, individuals with group A RBCs with preformed anti-B isoantibodies must only receive group A RBCs, and individuals with group B RBCs must only receive group B RBCs. Because of the absence of either group A or B antigens on the surface of group O RBCs, such cells can be used in transfusion of A, B, or AB individuals in emergency situations. Failure to abide by these rules results in acute intravascular hemolysis that can cause renal failure, disseminated intravascular coagulation, and death.

Other hemolytic transfusion reactions are caused by alloantibodies, predominantly IgG. Therefore a multiply transfused patient is at risk for hemolysis from alloantibodies if the patient receives incompatible blood. Multiparous women are at similar risk because of exposure to paternal fetal RBC antigens. Fortunately, for unclear reasons, most RBC antigens do not elicit an immune response although the Rh, Kell, Kidd, and Duffy antigens are clearly immunogenic. Exposure particularly to Kidd or Duffy antigens may stimulate alloantibody formation that can rise to sufficient titer to cause hemolysis with an onset typically delayed by approximately 1 week. Such delayed transfusion reactions may be subtle or cause an abrupt drop in hemoglobin with jaundice and hemoglobinuria.

Immune Hemolysis Associated With Transplantation

Any transplanted tissue may contain “passenger” lymphocytes from the donor that will survive and proliferate in the recipient if the recipient is sufficiently immunosuppressed.[7] When the RBCs of the recipient carry A or B antigen and the donor is ABO incompatible, the transplanted lymphocytes will respond to the recipient RBCs as foreign, and allogeneic anti-A or anti-B antibodies will be produced and can lead to significant hemolysis. If the transplantation involves hematopoietic stem cells (HSCs), this dilemma will resolve once the donor’s erythropoiesis prevails and the donor lymphocytes are no longer exposed to the recipient RBCs.

Immunopathogenesis

The antigens for antierythrocyte IgG are usually proteins, the most clinically important of which are the Rh-associated glycoproteins (RhAG), D, C, c, E, and e.[8] In contrast, antierythrocyte IgM is directed at polysaccharides, which include the ABO and I-antigens (I, i) found on the anion and glucose transporter proteins in the RBC membrane.[9,10]

Antibodies are distinguished by being “warm” and “cold” reactive, respectively, meaning that they bind antigens at core body temperature (warm) or they bind antigens preferentially at lower temperatures (cold) in the peripheral circulation or *ex vivo*. This distinction results from the different thermodynamics of binding to protein (hydrophobic) and polysaccharide (electrostatic) antigens.[10]

IgG antibodies typically bind at warm temperatures and IgM antibodies typically bind at cold temperatures, although there can be overlap and exceptions (*e.g.,* the Donath-Landsteiner IgG antibodies that are seen in paroxysmal cold hemoglobinuria). IgG and IgM also differ in their ability to fix complement, and this affects the resulting mechanism of hemolysis. To attach the first component of the classical complement pathway, two IgG molecules must bind in close proximity on the RBC. However, because of its pentameric structure, a single IgM molecule can initiate complement activation.

Erythrocyte-bound IgG becomes attached to the Fc receptors of splenic macrophages, which may engulf all or part of the cell or release lysosomal enzymes that digest its membrane (antibody-dependent cell-mediated cytotoxicity [ADCC]).[11] RBC fragments escaping from this encounter lose more membrane than cytoplasm and become spherical (spherocytes) as a consequence of this change in the surface-to-volume ratio. If IgG has initiated complement activation on the cell surface, binding of C3b to splenic macrophages will augment erythrocyte phagocytosis in the spleen.[12]

When IgM fixes complement, the process begins in the cooler peripheral circulation, where IgM binds to RBCs. If the amount of IgM bound is relatively high with at least some of it remaining on the cell at 37°C (*e.g.,* anti-A or anti-B isoantibodies), the cascade of complement activation goes to completion. Doughnut-shaped holes are formed in the cell membrane that allow the influx of water and sodium, inducing intravascular osmotic rupture of the cell.[11] However, if the IgM elutes from the RBC as it returns to body core temperature, the complement reaction attenuates. In this circumstance, the components remain on the cell but do not cause intravascular hemolysis. Instead, the cells are cleared by hepatic macrophages via complement-binding sites.[13]

This has important implications for clinical tests for the presence of antibody and complement on the RBC surface during the workup of immune-mediated hemolysis. Antibody-mediated hemolysis causes variable degrees of anemia and reticulocytosis. Intravascular hemolysis releases hemoglobin into the circulation, but this is too small an amount to cause measurable hemoglobinemia, although it will result in consumption of haptoglobin, which is rapidly depleted. In contrast, when hemolysis results from complement-mediated lysis, such as follows an ABO-incompatible blood transfusion, hemoglobinemia becomes massive, overcoming the scavenging capacity of plasma hemoglobin binders (haptoglobin, hemopexin, albumin), resulting in hemoglobinuria. Because hemoglobin is toxic to the renal tubular epithelium, renal function may become impaired. RBC membrane fragments released by massive intravascular hemolysis are a rich source of procoagulant phosphatidylserine and can precipitate disseminated intravascular coagulation.

In contrast, the consequences of extravascular hemolysis (*i.e.,* via phagocytosis in the reticuloendothelial system of the liver and the spleen) are much less severe. In macrophages, iron is removed from the hemoglobin and recycled to the circulation to support a compensatory reticulocytosis and the heme porphyrin is metabolized to bilirubin.

Patients with immune-mediated anemia have an increased incidence of venous thromboembolism, and detection of a lupus anticoagulant in these patients places them at a particularly high risk for this complication.[14]

Diagnosis

With few exceptions, if the mechanism of hemolysis is immune mediated, an anti-RBC antibody can be demonstrated, either on the RBC surface, in serum, or both.[1,2] With autoimmune hemolysis, IgG or IgM and/or complement components can be identified by a direct antibody test (DAT), originally known as a *direct Coombs test* (Fig. 62.1). For this assay, a patient's RBCs are washed and suspended in buffer. Surface-bound IgG is detected by adding anti-IgG antibody, which, being divalent, can bind to IgG on adjacent RBCs and agglutinate them into visible aggregates. Because of its pentameric structure, IgM on the cells can cause agglutination without the addition of a second antibody. Even when IgM has been previously eluted from the cell surface as a result of warming in the central circulation, its earlier presence *in vivo* can be detected by telltale remnants of complement that are fixed to the RBC. In this setting, detection requires the addition of anticomplement (*e.g.,* anti-C3dg) antibody.

Alloantibodies can also be detected by the DAT if allogeneic RBCs from a previous transfusion are still circulating. If these have been cleared, however, RBC antibodies can be identified in the patient's serum by adding the serum to a panel of RBCs carrying different antigens. Agglutination is detected as described above; this constitutes the indirect antibody test.

FIG 62.1 **The Direct Antibody Test (DAT).** The test is positive when immunoglobulin G (IgG: light blue triangles)–coated red blood cells are cross-linked by anti-IgG antibody (dark blue triangles) to form visible cell aggregates. Cell-bound complement and/or IgM can be detected by using anticomplement or anti-IgM reagent antibodies.

CLINICAL PEARLS

In the workup of hemolytic anemia, the following clinical laboratory studies provide important clues as to mechanism and may lead to a diagnosis of an immune hemolytic anemia.

Direct antibody test (DAT): The presence of antibodies on the surface of red blood cells (RBCs) suggests an immune-mediated hemolysis. The presence of antibody and complement on the surface of the RBC suggests drug-related hemolysis, whereas the presence of complement alone may suggest an immunoglobulin M (IgM) or cold antibody-related hemolysis.

Peripheral blood smear: Examination of the peripheral smear and various RBC indices (chiefly the mean corpuscular volume [MCV]) give mechanistic clues to the etiology of the hemolytic process. Immune-mediated hemolysis is characterized by spherocytosis, even microspherocytosis in severe cases, as antibody-coated RBCs traversing the reticuloendothelial system assume a spherical form, rather than that of a normal biconcave disc. The appearance of other pathological forms, such as schistocytes, sickle cells, targets, or tear drop forms (dacrocytes), suggest other causes of hemolysis, such as thrombotic thrombocytopenic purpura (TTP), or mechanical, shear-induced hemolysis (*e.g.,* aortic stenosis), sickle cell disease, thalassemia, or extramedullary hematopoiesis from bone marrow fibrosis, metastasis, or failure. Nucleated RBCs can be seen in any form of hemolytic anemia if it is severe enough.

Reticulocytes: Evaluation of the reticulocyte count indicates whether bone marrow is capable of making new erythrocytes in response to hemolysis.

Lactic acid dehydrogenase (LDH): The LDH is typically elevated with ongoing hemolysis, since LDH is an important housekeeping enzyme found in erythrocytes. LDH is found in cells from all tissues, each having a characteristic isoenzyme form of LDH. It is rarely necessary to distinguish LDH from RBCs from other tissue sources, but LDH isoenzyme 1 is the predominant form found in RBCs.

Bilirubin: As heme is released from RBCs, it is metabolized to bilirubin, which is glycosylated and then excreted via hepatic metabolism. Initially, as large amounts of heme are released and metabolized, the bilirubin is predominantly indirect bilirubin (unconjugated), and then it is converted to direct (conjugated) bilirubin. This can be altered by cholestasis, either from biliary obstruction or hepatic disease or Gilbert disease, or hepatic immaturity in the premature infant or newborn.

Haptoglobin: Haptoglobin is extremely sensitive to even small amounts of hemolysis. Its absence merely confirms that there is a significant hemolysis, but not its extent. The presence of normal haptoglobin effectively rules out significant hemolysis, and the return of measurable amounts of haptoglobin usually signals the end of hemolysis.

Therapy

The first line of therapy is corticosteroids, and 80% of patients achieve a partial or complete response to 1 mg/kg/day of prednisone (orally). Once a response is achieved, the prednisone dose is tapered slowly. Approximately 50% of patients require prednisone at a dose of 15 mg/day or less to maintain the hemoglobin level >10 g/dL, and it may take up to 3 weeks for patients to achieve a response. Patients who do not respond in 3 weeks should be started on second-line therapy. It is estimated that long-term complete responses not requiring prednisone can be achieved in 20% of patients.[15]

THERAPEUTIC PRINCIPLES

Autoimmune Anemia

- Hemolytic anemia induced by "warm" antibody
  - Acute: corticosteroids, transfusion if severe
  - Chronic: splenectomy, rituximab, immunosuppression
- Hemolytic anemia induced by "cold" antibody
  - Cold agglutinin disease: avoidance of cold; rituximab +/– fludarabine
  - Paroxysmal cold hemoglobinuria: avoidance of cold; corticosteroids
- Hemolytic disease of the newborn
  - Neonatal exposure to fluorescent light
  - Intrauterine transfusion or exchange transfusion

Splenectomy and anti-CD20 antibody (rituximab) are considered second-line therapy. Splenectomy is associated with short-term partial or complete responses in two-thirds of patients. The overall response rate to rituximab is approximately 80%, but rituximab is contraindicated in patients with untreated hepatitis B. The rare, but most severe, long-term complication of rituximab therapy is progressive multifocal leukoencephalopathy.[15]

Danazol, a synthetic anabolic steroid, has been used as a first-line agent in conjunction with prednisone; its effectiveness appears to be less in relapsed or refractory disease. The role of high-dose intravenous immunoglobulin (IVIG) remains controversial; its effectiveness remains to be determined in larger trials. Third-line therapy consists of immunosuppressive agents (*e.g.,* azathioprine, cyclophosphamide, alemtuzumab, mycophenolate mofetil, cyclosporine).[1,15]

IMMUNE-MEDIATED NEUTROPENIA

Immune neutropenia constitutes a heterogeneous group of acquired diseases in which the immune system responds to circulating neutrophils, selectively reducing their level to below 1500 cells/mm^3 (Table 62.2).

KEY CONCEPTS

Immune Neutropenia

- Immune neutropenia in children is caused by antineutrophil antibodies (ANAs).
- Immune neutropenia in adults has a more complex etiology.
- Immune complex-mediated neutrophil clearance and cell-mediated suppression of myelopoiesis often play a major role.

Isoimmune Neonatal Neutropenia

Transient neutropenia analogous to neonatal immune hemolysis or thrombocytopenia develops when IgG antineutrophil antibodies (ANAs) from an allosensitized or autoimmune mother cross the placenta and destroy fetal neutrophils.[16] Neutropenia is typically present at birth and resolves spontaneously, as maternal antibodies usually disappear within 12–15 weeks, but occasionally it can persist as long as 24 weeks after delivery.

TABLE 62.2 **Causes of Immune Neutropenia**

Primary
Isoimmune neonatal neutropenia
Autoimmune neutropenia of childhood
Adult autoimmune neutropenia
Secondary
Systemic autoimmune disease
Rheumatoid arthritis (*i.e.,* Felty syndrome)
Systemic lupus erythematosus
Sjögren syndrome
Lymphoproliferative malignancy
Large granular lymphocyte (LGL) leukemia
Lymphoma
Drug-Induced
Antiplatelets—ticlopidine
Inflammatory bowel disease drug—sulfasalazine
Antipsychotic—clozapine, phenothiazines
Antithyroid medications—propylthiouracil, methimazole
Retrovirals
Antibiotics—beta-lactams, cefepime, trimethoprim-sulfamethoxazole, vancomycin, rifampicin, quinine/quinidine
Diuretics—furosemide, spironolactone
Antiepileptic—lamotrigine
Rituximab, infliximab, etanercept

Primary Autoimmune Neutropenia

Primary autoimmune neutropenia is an antibody-mediated disease that presents commonly in early childhood.[17] Patients typically have normal blood counts at birth and develop neutropenia at 3–36 months of age. Children presenting at <2 years of age most commonly recover spontaneously within 2–3 years of diagnosis. Nevertheless, some children, particularly those presenting at older ages or manifesting other autoimmune findings, develop a chronic neutropenia disorder. Primary immune neutropenia (in the absence of other disease manifestations) is less common in adults. Rigorous incidence data are lacking, but a small retrospective study in Sheboygan County, Wisconsin, found an annual incidence of 5–10 cases of primary or secondary neutropenia per 100 000 people.

Neutropenia Associated With Systemic Autoimmune or Lymphoproliferative Diseases

Most patients with active systemic lupus erythematosus (SLE) develop neutropenia as part of a more global leukopenia (Chapter 51).[18] Separately, a smaller subset develops severe neutropenia, presumably mediated by ANAs. Sjögren syndrome (Chapter 54) and other systemic autoimmune diseases are also sometimes complicated by immune neutropenia. Lymphoproliferative disorders, such as chronic lymphocytic leukemia (Chapter 78), can occasionally be complicated by immune neutropenia as well.

Felty Syndrome

Immune neutropenia develops in about 1% of patients with rheumatoid arthritis, most commonly (but not exclusively) in association with splenomegaly, a combination designated as Felty syndrome.[19] Patients typically express human leukocyte antigen–DR4 (HLA-DR4) and have long-standing seropositive rheumatoid

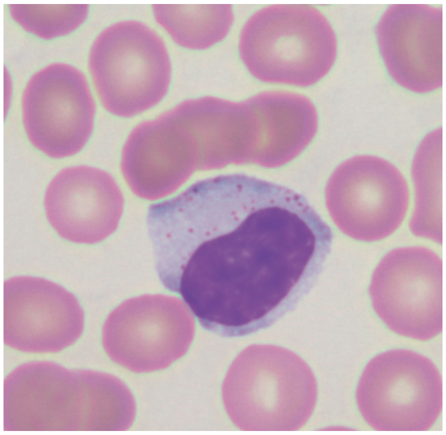

FIG 62.2 The Large Granular Lymphocyte (LGL) Is a Moderate-Sized Lymphocyte Containing Several Distinctive Azurophilic Granules. Additional immunophenotyping is required to distinguish the CD3$^+$, CD8$^+$, CD57$^+$ T-LGL associated with neutropenia from CD16$^+$, CD56$^+$ natural killer (NK)–LGL.

arthritis complicated by erosive joint disease, subcutaneous nodules, and/or leg ulcers. The natural history is often marked by repeated infection, with 5-year mortality rates of >30% reported in some studies. The complex pathophysiology of this disorder is discussed elsewhere in detail (Chapter 52).

T-Cell Large Granular Lymphocyte Leukemia

Large granular lymphocytes (LGL) are medium to large lymphocytes recognizable on light microscopy by their distinctive azurophilic granules (Fig. 62.2). These cells normally constitute <15% of circulating leukocytes and are composed of two major subsets. One is the natural killer (NK) LGLs that express CD2, CD16, and CD56 and is not linked to neutropenia. The other, T-cell (T) LGLs, expresses CD2, CD3, CD8, and CD57 with or without CD16, a phenotype typical of antigen-stimulated mature CD8 effector T cells. Polyclonal and transient monoclonal expansions of these cells sometimes appear in response to viral infection or other immune stimuli without adverse effect. However, some patients develop an indolent lymphoproliferative disease characterized by the accumulation of an autonomous T-LGL clone in blood and in other lymphoid organs, particularly bone marrow, the liver, and/or the spleen. Patients with this disease have a remarkably high incidence of immune neutropenia.[20,21] Even in the absence of gross marrow involvement, over 80% have a neutrophil count of <2000/mm^3 at presentation, and at some point 30–40% develop severe neutropenia with <500 neutrophils/mm^3.[20,21] The pathophysiology resembles Felty syndrome in many respects.

Clinical Overlap Between Felty Syndrome and T-LGL Leukemia

At the extremes these syndromes are easily separable. Patients with classical Felty syndrome have severe rheumatoid arthritis, usually requiring antiinflammatory therapy, incidentally complicated by late neutropenia. This is quite different from the pattern in patients with isolated T-LGL leukemia with neutropenia in the absence of clinical autoimmune disease. Nonetheless, confusing overlap can occur in two settings:

1. More than half the patients with a clinical Felty syndrome may have detectable T-LGL clones in their blood when studied with sensitive flow cytometric or molecular techniques.[20] There have been attempts in the past to classify this pattern as pseudo-Felty syndrome, but the clinical findings and course are often indistinguishable from “classic” Felty syndrome.
2. About half the patients with clinically apparent T-LGL leukemia have circulating rheumatoid factor and immune complexes in their blood; about a third, usually patients expressing HLA-DR4, develop clinically significant arthritis, sometimes requiring antiinflammatory agents.

Although the reason why clonal T-LGL disorders and autoimmunity often coexist is unclear, the tendency toward overlap is clear. Since the pathophysiology and therapy of both conditions are similar, these problems in classification usually have little impact on the initial management of neutropenia. When a patient with “Felty syndrome” develops aggressive T-LGL leukemia or a patient with T-LGL manifests severe rheumatological symptoms, the clinician must be prepared to alter therapy, as needed, to fit the clinical picture.

Although some clinicians have attempted to develop criteria for distinguishing Felty syndrome from T-LGL with pseudo-Felty syndrome, there is now substantial evidence that clonal T-LGL disorders are commonly found in rheumatology patients and that patients with clonal disorders seldom develop a progressive, neoplastic disorder. Conversely, although patients with T-LGL leukemia have a malignancy, it is typically quite indolent and in these cases, the clinical course is often dominated by rheumatological complication and/or neutropenia and not by progressive neoplastic disease.

Drug-Induced Immune Neutropenia

A wide variety of medications cause neutropenia.[22] In some cases, it may be antibody-mediated (see Table 62.2 for common examples); in others, it may be a direct toxic effect on marrow precursors. Often, the mechanism for neutropenia is unclear. A detailed discussion of this topic is beyond the scope of this chapter, but drug-induced neutropenia must always be considered in the differential diagnosis of acquired neutropenia. Rituximab (anti-CD20) is occasionally associated with late-onset neutropenia (LON).[23] LON is typically self-limiting and of no significant clinical consequence; the occurrence and severity of LON may be associated with the total dose of rituximab and the myelotoxicity of the accompanying chemotherapy administered. LON appears to coincide with post-rituximab B-cell recovery. In patients receiving DA-EPOCH (dose-adjusted etoposide/vincristine/doxorubicin/cyclophosphamide/prednisone regimen) chemotherapy for lymphoma, the incidence of LON was 8%, the median time of onset was 175 days (range of 77–204 days), and the duration was 11–16 days. A list of the most common agents associated with drug-induced neutropenia is included in Table 62.2.

Immunopathogenesis

Regulation of Antineutrophil Antibody Production

Isoimmune ANA production in pregnant women represents an “appropriate” immune response to foreign antigens. The production of autoimmune ANAs in other settings reflects immune dysregulation. Older studies attributed primary immune neutropenia of childhood to delayed maturation of T cells responsible for regulating B-cell responses. In this view, the spontaneous recovery usually observed reflects the eventual appearance of mature regulatory or inhibitory T cells. However, this hypothesis is not well supported with clinical laboratory data; the cause of antibody production in other autoimmune diseases remains unclear.

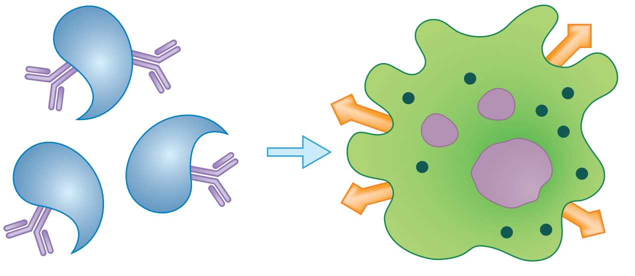

FIG 62.3 Antibody-Bound Platelets Are Cleared From the Circulation by Binding of the Fc Domain of Immunoglobulin G (IgG) to FcγIIA Receptors on Macrophages and Other Cells. The cross-linking of the macrophage receptors sets off a cascade of internal signaling that leads to increased expression of the inhibitory FcγIIB receptors (not shown).

Antibody Specificity

The most important target for antibody responses is the Fcγ receptor IIIb (FcγRIIIb), a low-avidity granulocyte-specific Fcγ receptor that binds IgG immune complexes (Fig. 62.3). This cell surface protein, a glycosyl phosphatidylinositol-linked variant of CD16 selectively expressed on neutrophils, contains several highly immunogenic polymorphisms.[24]

Human neutrophil antigen 1a (HNA-1a) and HNA-1b (previously designated NA1 and NA2) are two related polymorphic forms of FcγRIIIb. Antigenic differences are attributed to a cluster of five base substitutions, all found within exon 3. The two products can be distinguished because two of the base substitutions in HNA-1a disrupt sites of N-linked glycosylation, thereby lowering the size of the protein by ~30 000 Daltons (Da). The frequency of the gene for HNA-1a (*FCGR3B*) varies from 0.3 to 0.55 in different ethnic groups.

HNA-1c (previously designated SH) is another immunogenic polymorphism related to FcγRIIIb. This antigen, present in 5% of northern Europeans, is attributable to an amino acid polymorphism at position 266 in a (reduplicated) copy of the HNA-1b allele of FcγRIIIb.

FcγRIIIb-null phenotype, present in 0.1% of the northern European population, occurs in individuals homozygous for an extensive gene deletion involving all of FcγRIIIb. Because affected individuals have never been exposed to endogenous FcγRIIIb, they often develop a broad antibody response after neutrophil exposure through transfusion or pregnancy.

Other HNAs have also been identified.[25] Perhaps most clinically relevant is HNA-2a (previously NB1), a neutrophil glycoprotein designated CD177. Antibodies against this target have been reported in isoimmune and autoimmune neutropenia. HNA-3a (previously 5b) and HNA-4a (previously MART), an epitope on CD11b, are also immunogenic, but antibody formation against these is seen primarily in heavily transfused individuals and not in autoimmune neutropenia. As described below, individuals with chronic immune neutropenia may develop antibodies against other surface antigens, including CD11b/CDI8 and CD35.[26]

Using a sophisticated antigen discovery strategy, patients with Felty syndrome were found to have a high incidence of antibodies against an intracellular antigen eukaryotic elongation factor 1A-1 (eEF1A-1). Although the finding has been confirmed, this antibody probably is not specific for neutropenia, since it is also present in patients with autoimmune disease who do not have neutropenia.

Patterns of Autoantibody Specificity

Isoimmune neonatal neutropenia is associated with maternal IgG iso- or autoantibodies that can be generated in response to each of the polymorphic alloantigens noted above, particularly polymorphisms affecting FcγRIIIb.

Immune neutropenia in childhood is most commonly associated with IgG directed against the autoantigens HNA-1a and/or HNA-1b.[26] Sera from affected patients often also bind (albeit more weakly) to neutrophils expressing the alternative allele, and in some series, more than half the patients with this entity were shown to produce antibodies capable of binding to nonpolymorphic elements within FcγRIIIb. Using monoclonal antibody (mAb)–specific immobilization of granulocyte antigens (MAIGA) to search for antibodies directed against other neutrophil surface molecules, more complex patterns can be recognized. In one study, autoantibodies against FcγIIIb were seen in 27%, against CD11b/CDI8 (CR3) in 21%, against CD35 (CR1) in 14%, and FcγRII in 2% of patients' sera.[27] Prognostically, patients with antibody responses confined to HNA-1a and/or HNA-1b are more likely to have uncomplicated, self-limiting disease; patients with specificity for nonpolymorphic determinants on the FcγRIIIb molecule and other antigens more often have a generalized immune disorder and more persistent neutropenia.[26] Although antineutrophil assays are not highly quantitative, a recent retrospective study has suggested that patients with low levels of ANAs may have a more favorable long-term prognosis.[28]

In adults, it is often difficult clinically to distinguish immune neutropenia from nonimmune idiopathic neutropenia. Consequently, the sensitivity and specificity of antibody assays in this setting are uncertain. In general, antibodies against HNA-1a or HNA-1b are less common, and antibodies against surface receptors, such as CD11b/CD18 (CR3), are more common in older children and adults than in young children.

Sera from patients with Felty syndrome[20] and T-LGL leukemia[21] are often positive in ANA assays. Interpretation of these results is complicated by the high incidence of nonspecific immune complexes in these populations, which may bind nonspecifically through Fc and complement receptors to the neutrophil surface. Indeed, because it is difficult to distinguish these two types of binding, the incidence of "true" ANAs in these syndromes remains uncertain. Detectable antineutrophil antibodies are low in titer or absent in most patients carefully studied with either diagnosis.[20,21]

Impact of Antibodies and Immune Complexes on Neutrophil Survival

There is good experimental evidence that both ANAs and immune complexes can induce neutropenia *in vivo.* The relative importance of reversible sequestration and neutrophil destruction in inducing neutropenia varies with the experimental model, the character of the antibody/immune complex, spleen size, and presumably other factors as well.

The detection of antineutrophil antibodies in serum, however, does not automatically predict accelerated immune clearance of neutrophils *in vivo.* Some antibodies bind well to neutrophils under *in vitro* assay conditions, without provoking neutrophil destruction *in vivo.*[29] In part, this reflects the inability of these crude assays to distinguish effective from ineffective binding of immunoproteins.

Myelopoiesis in Immune Neutropenia

In primary immune neutropenia, bone marrow is typically normocellular or mildly hypercellular with an increased proportion of early myeloid forms (particularly myelocytes and promyelocytes) and decreased mature forms (neutrophils, bands, and metamyelocytes), a pattern designated maturation arrest. Although maturation arrest can also be seen in a number of other diseases, in this setting, it suggests an expansion in immature precursors with early release of mature components into blood. Rigorous kinetic studies in children with primary neutropenia are not available, but the available data suggest myelopoiesis in this setting is increased.

The findings are more complex in Felty syndrome and T-LGL leukemia. *In vivo* neutrophil kinetic studies and *in vitro* assays of marrow function often document reduced myelopoiesis in these settings.[20,21] This has been attributed to T-cell–mediated and cytokine-mediated suppression. T-LGL leukemia cells constitutively express Fas ligand on their surface and also release significant quantities of soluble Fas ligand into plasma *in vivo.* Reduced myelopoiesis in T-LGL leukemia and some patients with Felty syndrome may be linked to apoptosis instigated by the binding of Fas ligand expressed on the abnormal cells to Fas expressed on the surface of myeloid precursors.[21] Whatever the precise mechanism, reductions in myelopoiesis appear to be a common element in patients with these forms of secondary immune neutropenia.

Diagnosis

Clinical Presentation

Isoimmune neutropenia presents at birth and may persist for up to 6 months. Self-limiting primary autoimmune neutropenia typically presents in early childhood. In older children and adults, neutropenia is more commonly associated with other systemic autoimmune disease, especially rheumatoid arthritis and SLE or T-LGL leukemia. Drug-induced neutropenia must always be considered in patients taking medications.

Laboratory Findings

Blood counts typically demonstrate isolated neutropenia, sometimes with monocytosis. More generalized leukopenia, anemia, and/or thrombocytopenia suggest concurrent SLE or a primary bone marrow disorder, especially aplastic anemia or myelodysplasia.

Examination of the blood film for evidence of abnormalities in other cell lines or increased numbers of LGL is essential. The persistent presence of >2000 LGL/mm^3 for 6 months in itself is diagnostic of T-LGL leukemia; however, normal LGL counts in blood do not preclude this diagnosis. Perhaps a quarter of patients with T-LGL leukemia and immune neutropenia have fewer than 500 monoclonal LGL/mm^3 in blood.[21] The evaluation of patients with small T-LGL clones detected in blood on flow cytometric or molecular testing without clear tissue infiltration remains problematic. At least some of these patients probably have self-limiting “T-cell gammopathies of unknown origin” (Chapter 80) unassociated with overt lymphoproliferation or autoimmunity.

Bone marrow findings in immune neutropenias (as briefly reviewed above) can vary substantially. Perhaps the most important function of the bone marrow examination is to rule out hypoplasia/aplasia, myelokathexis, marked megaloblastic dysplastic changes, or abnormal infiltration with nonhematopoietic cells, which might suggest an alternative diagnosis. The marrow examination may also be helpful in confirming T-LGL leukemia.[30]

Detection of antineutrophil antibodies. Antibodies are assayed clinically using indirect assays (*i.e.,* by measuring the binding of antibodies from patient sera to fixed granulocytes from unrelated individuals). The granulocyte immunofluorescence test (GIFT), which exploits flow cytometry for detection, is most commonly used because of its high sensitivity. The granulocyte agglutination test (GAT) is less sensitive but is particularly valuable used in conjunction with GIFT to detect antibodies against HNA-3a or HNA-1b. Once the presence of an antibody has been confirmed, MAIGA is a valuable technique in identifying the target molecule recognized by the antibody, information that may be very helpful in identifying antibody specificity and in distinguishing granulocyte-specific antibodies from alloantibodies directed against HLA determinants. More precise epitope typing still requires a panel of granulocytes of varied phenotype. Unfortunately, to date, granulocyte panels are both difficult to prepare and impossible to store. Consequently, antibody typing remains a laborious, difficult task. At the second international granulocyte serology workshop, 12 centers independently tested a series of unknown sera. Many laboratories could detect strong HNA-1a antibodies, but the success rate was much lower in defining HNA-1b or HNA-2a antibodies, and individual laboratories varied greatly in their proficiency.[25]

Clinical use of antineutrophil antibody studies. In young children with neutropenia, a positive result is very helpful in distinguishing between immune-mediated and congenital causes. Isoimmune and congenital disease may be apparent from birth, and the former usually resolves within 2–6 months. Using GIFT or GAT assays, ANAs can be detected in more than 70% of children with primary immune neutropenia. When both are used in tandem the yield increases further. A strong positive result strongly supports the diagnosis of immune neutropenia. However, a negative result does not exclude the diagnosis.[28]

Primary autoimmune neutropenia in adults is difficult to distinguish from the ill-defined entity chronic idiopathic neutropenia.[1] Because there is no “gold standard” for distinguishing immune disease from nonimmune disease in this setting, the diagnostic sensitivity and specificity of the ANA assays are unclear. Assays are positive in perhaps a third of adults referred with chronic neutropenia, and a positive result in the absence of other systemic autoimmune disease certainly supports a diagnosis of immune neutropenia. Again, a negative result does not preclude an immune etiology, but it is more consistent with chronic idiopathic neutropenia.

In patients with systemic autoimmune disease or T-LGL leukemia, hyperglobulinemia and circulating immune complexes greatly complicate laboratory evaluation. ANA assays are frequently positive even in the absence of neutropenia. Since the specificity of a positive result is low, its diagnostic value is very limited, and the clinician must be vigilant for other possible causes, especially drug-induced neutropenia.

Therapy

Overview

All patients with neutrophil counts below 1000/mm^3 have some increased risk of infection, but some remain asymptomatic even with absolute neutrophil counts of 500/mm^3 or less. Growth factors can usually improve neutropenia and reduce the risk of infection, but given their expense, inconvenience, and possible side effects, they should be reserved for use in patients with a very low count, or a previous pattern of frequent infection. The indications for immunosuppressives, steroids, and splenectomy are more complex.

THERAPEUTIC PRINCIPLES

Immune Neutropenia

- Palliative treatment of neutropenia is reserved for patients with a neutrophil count below $500/\text{mm}^3$ or recurrent infection.
- Recombinant granulocyte–colony-stimulating factor (G-CSF) is the most effective single agent for palliating neutropenia.
- Immunosuppressive agents, steroids, and splenectomy are reserved for patients with persistent or refractory neutropenia or with other detrimental manifestations of systemic autoimmunity.

Colony-Stimulating Factors

Controlled trials are lacking in this disease setting, but granulocyte–colony-stimulating factor (G-CSF) or granulocyte macrophage–colony-stimulating factor (GM-CSF) usually enhance neutrophil counts in each of the clinical groups discussed. Because of their safety, speed, and efficacy, they have replaced steroids and splenectomy as first-line symptomatic therapy. They should be used at the lowest effective dose, with particular caution in patients with systemic autoimmune disease, as they are prone to leukocytoclastic vasculitis as a complication of therapy.[18]

Immunosuppressive Agents

Because disease is usually self-limiting and responsive to G-CSF, immunosuppressive agents are seldom used in children with primary immune neutropenia. Chronic low-dose methotrexate is considered first-line therapy for patients with Felty or LGL leukemia–associated neutropenia. Cyclophosphamide and cyclosporine are considered second-line therapy for LGL leukemia, and purine analogues, splenectomy, and alemtuzumab are considered third-line therapy for LGL leukemia.

Other Therapy

Each of the following treatments can be effective in reversing neutropenia, but their use has diminished considerably in recent years. IVIG can temporarily reverse neutropenia, particularly in children, probably by blocking Fc receptors responsible for triggering neutrophil destruction. However, G-CSF, which is more convenient to administer and at least as effective, has largely replaced use of IVIG.

Splenectomy and steroids can each reduce immune destruction by suppressing the body's capacity to clear IgG- and complement-coated cells. Over a longer time frame, these treatments can also suppress antibody production, in the first case by removing a major site of production and in the second by reducing antineutrophil antibody production and blocking T-cell–mediated myelosuppression. They can reverse neutropenia in many patients, but their long-term impact on outcome remains unclear. Given their risk and side effects, both modalities are generally reserved for patients resistant to CSFs and low-dose immunosuppressives.

Prophylactic Antibiotics

Where recurrent infection is a problem, oral trimethoprim–sulfamethoxazole (TMP-SMX) is commonly used for prophylaxis, particularly in children. This approach is very reasonable, given its success in other immunocompromised groups, but it has not been tested in a controlled trial. Immunization with pneumococcal vaccine is also recommended in situations where therapeutic splenectomy has been used or is being planned.

IMMUNE-MEDIATED THROMBOCYTOPENIAS

Immune Thrombocytopenia

KEY CONCEPTS

Immune Thrombocytopenic Purpura

- Antibody-mediated destruction or decreased production of platelets
- Both B and T cells important in etiology
- Clearance of platelets mediated by Fcγ receptors
- Diagnosis depends on:
  - Clinical presentation of low platelets
  - Exclusion of other causes of thrombocytopenia

Immune thrombocytopenia (ITP) is an autoimmune syndrome involving antibody and cell-mediated destruction of platelets.[31] ITP can occur in the absence of an identified predisposing factor (primary ITP) or in association to drug exposure or other identified cause (secondary ITP). Recent recommendations from an international working group recommend that a platelet count of $<100 \times 10^9$/L be required for diagnosis.[32]

ITP During Pregnancy and the Neonatal Period

Gestational thrombocytopenia is the most common cause of thrombocytopenia in pregnancy, affecting 5% of all pregnancies and accounting for 75% of cases of pregnancy-associated thrombocytopenia. Gestational thrombocytopenia develops in the late second or third trimester and is not associated with an increased incidence of pregnancy-related complications or the delivery of thrombocytopenic offspring. Preeclampsia and HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome are also present in the third trimester and are associated with thrombocytopenia. Thrombotic thrombocytopenic purpura (TTP) and hemolytic uremic syndrome need to be considered in the differential diagnosis of thrombocytopenia of pregnancy. ITP accounts for 5% of pregnancy-associated thrombocytopenia.[33] Lack of hypertension, fever, hemolytic anemia, uremia, and liver function abnormalities serve to distinguish ITP from these other conditions.

Neonatal Alloimmune Thrombocytopenia and Posttransfusion Purpura

Neonatal alloimmune thrombocytopenia (NAT) caused by antihuman platelet antigen 1a (HPA-1a) antibodies occurs in 1 : 1250 pregnancies in the Caucasian population. Severe hemorrhage occurs in 1 : 12 500–1 : 25 000 pregnancies. NAT is caused by maternal antibodies against paternally derived antigens on fetal platelets, most commonly HPA-1a. These antibodies cross the placenta and sensitize fetal HPA-1a–positive platelets, which are then removed in the spleen. Two percent of Caucasian women carry the less frequent HPA-1b and can be immunized against HPA-1a during pregnancy (25%) or at the time of delivery (75%). The HPA-1a antigen is most efficiently presented by HLA-DRB3*0101; 35% of the women at risk (with HPA-1b and HLA- DRB3*01:01) are immunized.[34] In most circumstances, first-time cases of NAT are identified following the birth of a markedly thrombocytopenic neonate; antenatal management is, thus, only possible in subsequent pregnancies. Screening all pregnancies for NAT is under evaluation in several countries. Treatment of NAT consists of maternal administration of high doses of IVIG and corticosteroids.[35]

Platelet transfusions can induce antibodies to either HPA or antigens encoded by the major histocompatibility complex

(MHC). Eight percent of transfused patients mount detectable antibodies to HPA antigens and 45% to HLA antigens. Platelet antibodies cause rapid clearance of transfused platelets and lead patients to become refractory to platelet transfusions.[36] Post-transfusion purpura (PTP) can follow transfusion with platelets or RBCs (in which platelets are found in numbers sufficient to sensitize the recipient).

Drug-Induced Thrombocytopenia

Drug-induced thrombocytopenia (DITP) is an idiosyncratic immune-mediated reaction. The drug-dependent antibodies bind to specific epitopes on platelet surface glycoproteins only in the presence of the sensitizing drug. The drugs bind noncovalently and reversibly to platelets, commonly to GPIIb-IIIa and GPIb-V-IX, and also to the antibody. The Fab domains of the antibodies bind to the drug-platelet epitope. Drug-dependent antibodies inducing thrombocytopenia typically develop 1–2 weeks after exposure to a drug; exceptions to this rule include eptifibatide, tirofiban, and abciximab, as naturally occurring antibodies to these drugs can cause thrombocytopenia within a few hours of the first exposure. Thrombocytopenia with platelet counts frequently below 20×10^9/L develops acutely, recovery occurs 1–2 days after discontinuation of the drug and is usually complete after 1 week, but rarely thrombocytopenia persists for several weeks. Quinidine, quinine, rifampin, tegretol, TMP-SMX, vancomycin, danazol, acetaminophen, abciximab, eptifibatide, tirofiban, and gold salts are the most common culprits. Treatment consists of discontinuing the offending drug; platelet transfusions are sometimes necessary.[37,38]

Heparin-induced thrombocytopenia (HIT) is a special case that is caused by antibodies to platelet factor 4 (PF4)–heparin complexes. It can be associated with life-threatening thrombosis. The antibody–PF4–heparin complex activates platelets, resulting in a high risk of both arterial and venous thrombotic events.[39] Thrombocytopenia occurs as a result of clearance of platelet aggregates induced by the antibody and usually appears 5–7 days after treatment with heparin (or low-molecular-weight heparin) unless a patient has been previously exposed to heparin. In the event of prior exposure, especially within the last 100 days, thrombocytopenia can occur within 1 day of heparin administration. Even small doses of heparin given as "flushes" to maintain intravenous catheter patency can be sufficient to cause HIT with thrombosis. In cases of suspected HIT, all heparins should be stopped, and an alternative anticoagulant agent, such as the direct thrombin inhibitors argatroban and lepirudin, should be used. Fondaparinux is an anticoagulant synthesized from the pentasaccharide core of the heparin molecule and may be another option for the treatment of HIT, since it binds to HIT antibodies but does not activate platelets and cause thrombosis. In cases of confirmed or strongly suspected HIT, anticoagulation should be continued for 3 months because the risk of thrombosis persists in this group of patients. Coumadin is generally used for long-term anticoagulation; it should be started concomitant with a heparin alternative because of the increased risk of thrombosis during the initial depletion of anticoagulant factors (proteins C and S) by warfarin (Coumadin). The role of direct oral anticoagulants that target thrombin or activated factor X remains to be defined.

Pathogenesis

In the majority of patients the underlying defects leading to autoantibody production remain unclear. In some patients, ITP follows exposure to viral or bacterial antigens. Molecular mimicry appears to play a role in the development of self-reactive platelet antibodies following infections. Human immunodeficiency virus (HIV), hepatitis C virus (HCV), and *Helicobacter pylori* infections have been associated with ITP. *H. pylori* CagA antigen appears to cross-react with platelet antigens,[40] which may explain the association with ITP and *H. pylori* infection. Interestingly, empiric treatment of *Helicobacter* infection with amoxicillin, clarithromycin, and proton pump inhibitors in patients suspected of infection leads to 53% remission of ITP whether or not *Helicobacter* is eradicated, suggesting immunomodulatory effects of treatment that do not involve elimination of the bacterial antigen with cross-reactivity to platelet antigens.[41] Patients who are not infected with *H. pylori* but are treated empirically with antibiotics do not have a significant platelet response rate (6.5%), which suggests that empiric therapy is not useful in the absence of a documented infection.[41]

NAT is caused by maternal antibodies against the HPAs that the fetus carries but which the mother lacks (most commonly HPA-1a). It is more likely to cause intracerebral hemorrhage (10–20% of cases) than is maternal ITP, and it is very likely to recur if it has occurred in a previous pregnancy.[42] IVIG and platelet transfusions using maternal platelets (to ensure that the offending antigen is not present in the transfused product) are often necessary.

Antibodies against human platelet antigens are also responsible for PTP, in which the recipient has an acquired antibody directed against a platelet antigen on the donor platelets. It is not understood why the antibodies also destroy the patient's own "antigen-negative" platelets. Treatment consists of IVIG and corticosteroids, and sometimes plasma exchange.[34] Transplantation-mediated alloimmune thrombocytopenia (TMAT) may occur as the result of donor-origin antibodies produced by passenger B cells directed against the recipient platelet alloantigen (HPA-1a).[43]

The most common epitopes for platelet antibodies in ITP are the platelet GPIIb/IIa and GPIb-IX receptors.[44] The autoantibodies serve as opsonins resulting in the clearance of platelets by FcγR-bearing cells in the reticuloendothelial system (see Fig. 62.3). There is upregulation of genes involved in cell-mediated cytotoxicity via $CD3^+CD8^+$ T lymphocytes,[45] with T-helper 1 (Th1)–associated cytokines predominating.[46] Regulatory T cells (Tregs) are decreased,[47] and B-cell activation is increased.[48] There is evidence of suppression of megakaryopoiesis by both T lymphocytes[49] and ITP plasma/IgG.[50] In addition, megakaryocyte and platelet production are dependent on thrombopoietin signaling through binding to the Mpl receptor, and patients with ITP have reduced thrombopoietin levels despite the presence of low platelet counts.[51]

Laboratory Diagnosis[52]

Peripheral blood smear examination is important to evaluate for the presence of schistocytes, leukocyte adhesion bodies in MYH-9-related disease, and giant or large platelets in inherited thrombocytopenias and to exclude ethylenediaminetetraacetic acid (EDTA)–dependent platelet agglutination.

Bone marrow aspirate, biopsy, flow cytometry, and cytogenetics should be considered in patients older than 60 years of age and in patients with systemic symptoms. The detection of *H. pylori* with the urea breath test is recommended in adults, and testing in children is recommended in high prevalence areas. Routine serological evaluation for HIV and HCV is recommended in adults. Baseline Igs (IgG, IgA, IgM) should be measured in both adults and children to diagnose such conditions as common variable immunodeficiency and selective IgA deficiency (Chapter 34), in which ITP is a common complication.

Antiplatelet antibody testing to specific platelet glycoproteins is not routinely recommended; the test is neither sensitive nor specific for ITP. Routine testing for anticardiolipin antibodies is not recommended in the absence of symptoms of antiphospholipid syndrome. DAT should be obtained if hemolytic anemia is suspected and in patients in whom anti-D antiglobulin treatment is considered. Blood group Rh(D) typing should be obtained if anti-D antiglobulin treatment is considered.

Where a microangiopathic process is evident, especially with concomitant renal failure, fever, or cognitive impairment, measurement of ADAMTS13 (ADintegrin-like And Metalloprotease with ThromboSpondin type 13 motifs) is warranted to rule out TTP.

Therapy of ITP[53]

THERAPEUTIC PRINCIPLES

Immune Thrombocytopenic Purpura (ITP)

- Primary goal—prevent bleeding
- Treatment not usually necessary if platelets >30 000/µL
- Prednisone and/or intravenous immunoglobulin (IVIG) usual first medications
- Anti-D may avert/delay splenectomy
- Treat refractory ITP with immunosuppressives
  - Mycophenolate mofetil, cyclosporine, alemtuzumab, cyclophosphamide, rituximab (not approved by the US Food and Drug Administration [FDA] for this use)
  - Splenectomy for persistent disease (immunize patient with pneumococcal vaccine before surgery)

In most circumstances, the goals of therapy are to keep the platelet count above 30×10^9/L and to minimize toxicity. In the absence of hemostatic comorbidity, trauma, or surgery, intracranial hemorrhage is rare in patients with a platelet count above 20×10^9/L. Treatment of ITP should be individualized, but first-line therapy usually consists of corticosteroids supplemented with either IVIG or anti-Rh(D) in Rh(D)-positive, nonsplenectomized patients. Intravascular hemolysis, disseminated intravascular coagulation, and renal failure have been reported with the use of anti-Rh(D). Anti-Rh(D) should be avoided in patients with underlying hemolysis or a positive result of the DAT that is not the result of prior therapy. Several uncontrolled studies suggest that bolus oral therapy with oral dexamethasone for 1–4 cycles increases response rates and prolongs remission duration.

Second-line therapy should be initiated if there is absence of a robust response at 1 month or once significant steroid related toxicity supervenes. Two-thirds of patients obtain a durable long-term remission following splenectomy, and these patients should receive immunizations with the pneumococcal, *Haemophilus influenzae* type b, and the quadrivalent meningococcal vaccines before splenectomy. A single course of rituximab (anti-CD20) (375 mg/m^2 weekly for 4 weeks) is associated with 40% complete remission at 1 year and 15–20% complete remission at 5 years. Patients who relapse after an initial response usually respond to a second course. Rituximab is contraindicated in patients with active hepatitis B. Cases of multifocal leukoencephalopathy have been reported in HIV-negative patients treated with rituximab. The thrombopoietin receptor agonists (TRAs) romiplostim and eltrombopag have shown significant sustained activity in patients with ITP. Romiplostim is administered subcutaneously and eltrombopag orally. Increased bone marrow reticulin fibrosis has been described in some patients receiving TRAs. Initial dosing of eltrombopag should be reduced by 50% in patients of Southeast Asian origin. Danazol is an attenuated androgen administered orally and has been used, with some success, as a steroid-sparing agent. Third-line therapy is reserved for patients who are unresponsive to or ineligible for first- and second-line therapies. These agents include cyclophosphamide, azathioprine, mycophenolate mofetil, cyclosporine, alemtuzumab, and vinca alkaloids. One novel approach to ITP consists of blockade of the FcγIIIA receptors on macrophages in the spleen that mediate uptake of antibody-bound platelets. Prior attempts at FcγIIIA receptor blockade to ameliorate ITP using mAbs to FcγIIIA have improved platelet counts in half the patients refractory to other treatments but were abandoned because of nausea, vomiting, fever, and rarely anaphylaxis that were presumed to be caused by immune stimulation from cross-linking of FcγIIIA receptors by bivalent IgG. Preclinical studies suggest monovalent anti-FcγIIIA fused to albumin (to prolong the half-life) may block the FcγIIIA receptor without stimulating the immune system, and this approach may be tested clinically, again.[54]

Therapy of ITP During Pregnancy and the Neonatal Period

Patients with ITP with platelet counts higher than $20\text{–}30 \times 10^9$/L usually do not require treatment during the first and second trimesters of pregnancy; platelet counts should be monitored more closely as delivery approaches. Obstetrical anesthesiologists recommend a minimum platelet count of 75×10^9/L to allow administration of spinal or epidural anesthesia. A platelet count of at least 50×10^9/L is generally considered adequate to allow a Cesarean section.[52]

First-line therapy consists of prednisone and IVIG. Prednisone is initiated at a low dose (10–20 mg) and then adjusted to the minimum dose that produces a hemostatically effective platelet count. Corticosteroids may exacerbate hypertension, diabetes, and osteoporosis during pregnancy and are associated with weight gain and psychosis. Corticosteroid use in the first trimester has been associated with congenital anomalies, such as orofacial clefts, and low-dose corticosteroids have no impact on the fetal platelet count. IVIG is an effective means of increasing the platelet count rapidly and is preferred over prednisone in this setting. The American Society of Hematology (ASH) guidelines consider IVIG to be an appropriate first-line agent for severe thrombocytopenia or for thrombocytopenic bleeding in the third trimester. Anti-Rh(D) is safe and effective for the mother and fetus in nonsplenectomized Rh(D)-positive patients.[33,52]

Second-level therapy before delivery may require utilizing higher doses of corticosteroids combined with IVIG to achieve an adequate platelet count. Splenectomy is an option for patients who fail corticosteroids and IVIG. Remission of ITP is achieved in 75% of patients. Splenectomy is optimally performed during the second trimester. The risk of inducing premature labor is high during the first trimester, and the enlarged uterus renders the procedure difficult if not impossible during the third trimester. Vinca alkaloids, rituximab, danazol, thrombopoietin receptor agonists, and immunosuppressive drugs (other than azathioprine) should be avoided during pregnancy.[33,52]

Management of parturition is based on the finding that there is no correlation between platelet counts or ITP status of the mothers and the development of neonatal thrombocytopenia. The most reliable predictor of neonatal thrombocytopenia is a history of thrombocytopenia at delivery in a prior sibling.[33] In a large meta-analysis, fetal platelet counts below 50×10^9/L were observed in 10.1%, and fetal platelet counts below 20 × 10^9/L were observed in 4.2%.[42] The risk of intracranial hemorrhage is below 1%, and the risk of fetal platelet count determination by either fetal scalp sampling or umbilical blood sampling likely exceeds the risk of fetal intracranial hemorrhage, negating its clinical utility. The mode of delivery has no impact on the incidence of intracranial hemorrhage.

Platelet counts should be monitored for 1 week following delivery. In a study of 61 patients, 66% of neonates had a further drop in platelets following delivery; the nadir occurred at day 2, and the counts stabilized or began to rise at day 7.[34] ASH guidelines recommend that children with a platelet count below 20 × 10^9/L or those with hemorrhage be treated with IVIG. The concurrent use of corticosteroids is controversial because of the risk of neonatal sepsis. Neonates with platelet counts below 50 × 10^9/L should have brain imaging performed to detect occult intracranial hemorrhage.

ON THE HORIZON

- For many years immunosuppressive therapy for immune thrombocytopenic purpura (ITP) has consisted of corticosteroids and infusions of intravenous immunoglobulins (IVIGs), and more recently anti-Rh antibodies (in suitable candidates), and/or rituximab in patients whose disease is refractory to first-line therapy. Splenectomy may be indicated in those who fail medical therapy altogether.
- All ITP seems to be mediated by interaction of antibody-coated platelets with Fc receptors in the reticuloendothelial system of the spleen (and the liver). Many investigators have sought to interrupt the interaction between immunoglobulin (Ig)–coated platelets and Fcγ receptors by use of monoclonal antibodies to the Fcγ receptor itself. However, the use of traditional murine monoclonal antibodies (mAbs) to Fcγ has been associated with adverse events, perhaps as a result of cross-linking of Fcγ receptors on the surface of macrophages, resulting in undesirable immune stimulation and even anaphylaxis. One strategy to circumvent these problems would be to use monovalent Fab fragments that would bind but not cross-link the Fcγ receptors. Yu et al.[54] have reported on the design of a monovalent fusion protein composed of the single chain variable region (scFv) of the anti-FcγRIIIA antibody, fused to human serum albumin so as to increase its size and prolong its half-life. These investigators have shown in a mouse model of ITP that the novel construct can prevent IgG-platelet interaction with FcγRIIIA receptors without harmful immune stimulation.[54] If this can be replicated in larger animal models, it may be eventually tested for use in humans with ITP. Further, in theory this approach could be applied to other diseases, such as autoimmune hemolytic anemia.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following treatments is LEAST likely to improve platelet counts in an patient with type A- blood and immune thrombocytopenic purpura (ITP)?
   - **a.** Rituximab 375 mg/m2 IV
   - **b.** Prednisone 1 mg/kg PO
   - **c.** WinRho 250 IU/kg (50 micrograms/kg) IV
   - **d.** IVIG, 2 g/kg continuous IV infusion over 48 hours

2. Which is true of hemolysis caused by a "cold" antibody elicited by exposure to drugs?
   - **a.** Usually caused by immunoglobulin G (IgG) antibody against Rh antigens
   - **b.** Usually accompanied by a direct antibody test (DAT) (Coombs test) that is positive for IgM and IgG and negative for complement
   - **c.** Usually accompanied by a DAT (Coombs test) that is negative for IgM and IgG and positive for complement
   - **d.** Usually caused by a Donath-Landsteiner IgG against Rh antigen on the surface of the red blood cell (RBC)

3. Hemolytic anemia of the newborn:
   - **a.** Usually occurs when the mother of the infant is Rh^+ and the father is Rh^-
   - **b.** Is more likely in a first pregnancy than subsequent pregnancies between the same two parents
   - **c.** May be prevented by administration of RhoGam at week 28 of pregnancy when the parents are Rh incompatible
   - **d.** Is more common if the parents are ABO incompatible

4. Neutropenia associated with administration of rituximab:
   - **a.** Is usually self-limiting
   - **b.** Precludes future use of rituximab
   - **c.** Typically occurs 7–10 days after administration of rituximab
   - **d.** Does not respond to administration of granulocyte–colony-stimulating factor (G-CSF)

Bullous Diseases of the Skin and Mucous Membranes

Adela Rambi G. Cardones, Russell P. Hall III

PEMPHIGUS

Pemphigus is a group of cutaneous autoimmune blistering diseases characterized by intraepidermal blistering of the skin and mucous membranes. Pemphigus comprises four distinct conditions: pemphigus vulgaris (PV), pemphigus foliaceus (PF), paraneoplastic pemphigus, and immunoglobulin A (IgA) pemphigus.

Pemphigus Vulgaris

The most common and most severe form of pemphigus, PV is still a rare disease, with an incidence estimated at 0.5–1.6 per 100 000.[1-3] PV presents most often in the fourth to sixth decades but can occur at any age. PV is characterized by the presence of flaccid blisters and erosions of the skin and mucous membranes (Fig. 63.1). Virtually all patients with PV develop oral erosions at some point during the course of their disease. Most present with oral erosions, and for many, these are their only disease manifestation for months to years (Fig. 63.2). These erosions are often persistent and shaggy; they can involve all areas of the oral mucosa and extend into the esophagus. In severe cases, the conjunctiva, nasal, anal, cervical, or urethral mucosae may be affected.

PV blisters are flaccid and easily ruptured; they can occur on inflamed or noninflamed skin. Once broken, these blisters leave large, nonhealing erosions. Blisters can occur on any area of skin, most often beginning on the head, neck, or trunk. Generalized blistering is not uncommon, especially if diagnosis and/or treatment have been delayed.

Pemphigus vegetans is an unusual variant of PV, in which lesions develop mainly in the axilla, groin, and other flexural areas. The characteristic lesions are plaques of hypertrophic granulation tissue with occasional pustules. These can occur *de novo* or after healing of PV lesions. The etiology of this unusual clinical presentation is unknown.

Before the advent of glucocorticoids, PV was almost uniformly fatal, with patients developing large areas of denuded skin and dying from overwhelming sepsis. Since the introduction of systemic glucocorticoids, the mortality rate has fallen to approximately 10%. The residual mortality is largely due to the side effects of the high doses of glucocorticoids required to treat the disease, particularly in debilitated or older patients.[4]

Histologically, PV is characterized by intraepithelial blisters, with acantholysis (breaking apart of the suprabasilar portion of the epidermis). Biopsy of early PV lesions shows that basal epidermal cells remain attached to the dermis, forming a “row of tombstones,” with loss of attachment of individual keratinocytes to each other, resulting in intraepidermal blisters.

In the early 1960s, investigators found IgG antibodies bound to the epithelial keratinocyte cell surface in the skin of patients with PV and showed that the serum of these patients contained IgG antibodies that bound in an identical pattern to normal human skin.[5] These findings demonstrated that PV is an autoimmune disease directed against a normal component of stratified squamous epithelium.

Pemphigus Foliaceus

PF is characterized by blisters within the epidermis, resulting in superficial erosions with scaling and crusting (Fig. 63.3). In contrast to patients with PV, patients with PF rarely develop mucous membrane lesions. Because the blisters are superficial, many patients present with erythematous, scaling, and crusted plaques, which occur principally on the head, neck, and trunk (Fig. 63.4). The prognosis for patients with PF is markedly better than that for patients with PV, although patients with severe PF do occasionally die as a result of infections and/or the side effects of therapy.

An unusual variant of PF is the endemic form of the disease, fogo selvagem (FS) (which is the Portuguese term for “wild fire”). Although clinically identical to the sporadic form of PF, FS only occurs in certain rural areas of South America and North Africa.[6] The epidemiology suggests an infectious etiology, and an arthropod vector may be involved in spreading the disease.

Pemphigus erythematosus, or Senear-Usher syndrome, is another PF variant. These patients have typical features of PF with additional characteristics suggestive of systemic lupus erythematosus (SLE) (Chapter 51), such as malar involvement and antinuclear antibodies. The clinical course tends to parallel that of PF, and most patients do not develop SLE. The pathogenesis of this form of PF is poorly understood.

PF can also be associated with drugs. The most common agents that induce pemphigus are D-penicillamine and angiotensin-converting enzyme inhibitors.[7] Although these drugs can induce a PV-like picture, the clinical manifestations are most often similar to PF. Patients with drug-induced pemphigus have autoantibodies directed against the keratinocyte cell surface; the mechanism(s) causing these antibodies are unknown, but reactive sulfhydryl or amide groups on the drugs are thought to be responsible.[7]

Histological examination of PF blisters reveals intraepidermal blisters with acantholysis of the most superficial portion of skin (the granular cell layer), resulting in blisters with an epithelial base rather than the basal cell layer as seen in PV.

The immunohistological features of PF are indistinguishable from those of PV (Fig. 63.5). Cell-surface IgG deposits are present,

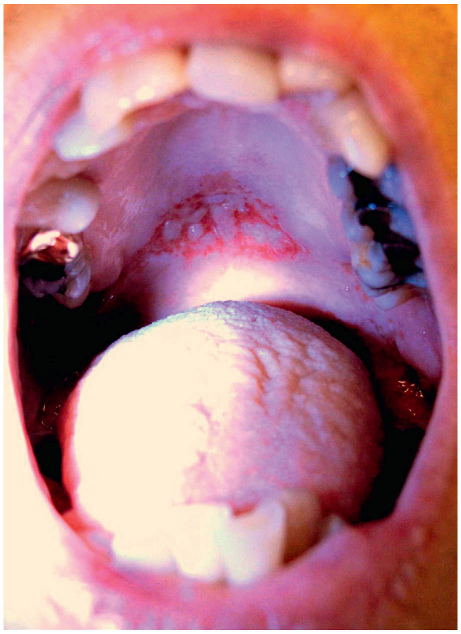

FIG 63.2 Patient with pemphigus vulgaris showing ulceration of the soft palate.

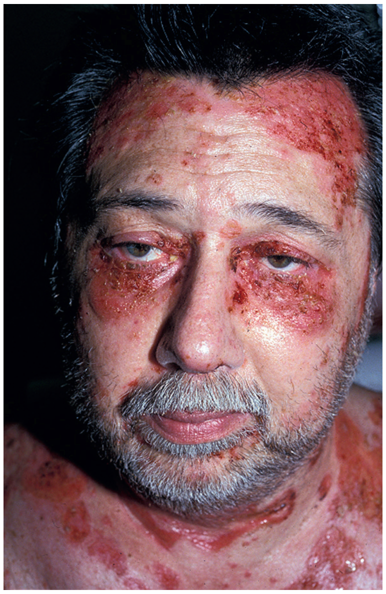

FIG 63.3 Patient with pemphigus foliaceus showing superficial erosions and crust formation on the head and neck.

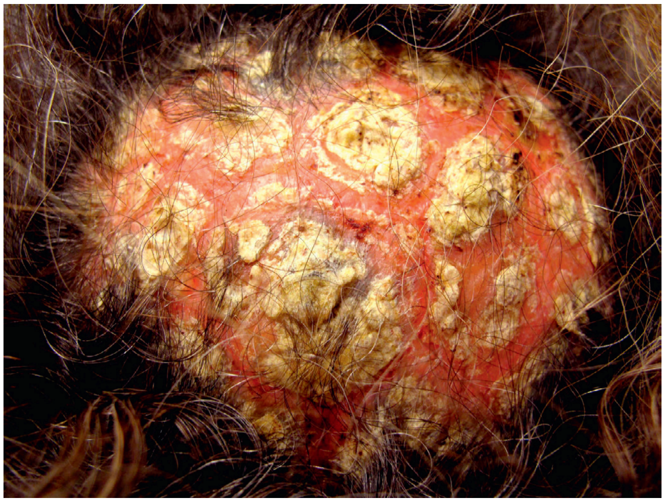

FIG 63.4 Patient with pemphigus foliaceus showing involvement of the scalp with erosions and adherent crust with alopecia. The patient's hair regrew fully after initiation of treatment.

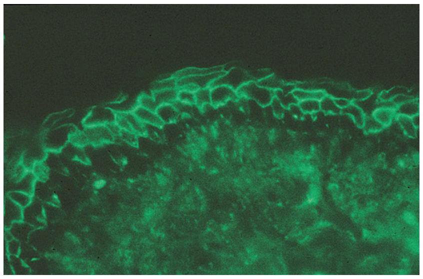

FIG 63.5 Direct immunofluorescence of perilesional normal-appearing skin from a patient with pemphigus foliaceus using antibodies directed against human immunoglobulin G (IgG). Cell-surface IgG deposits are seen on the epidermal keratinocytes. A similar pattern is seen in patients with pemphigus vulgaris.

and serum from patients with PF contains IgG antibodies, which bind to normal stratified squamous epithelium. Although the immunofluorescence patterns of PF and PV are virtually identical, the antigenic targets of these autoantibodies are different (see below).

Paraneoplastic Pemphigus

Anhalt described a series of patients with severe oral erosions and polymorphic skin lesions suggestive of coexistent PV and erythema multiforme.[8] All these patients had associated malignancies, which were mostly lymphoreticular, including lymphoma, chronic lymphocytic leukemia, and thymoma. The histological features of the skin lesions in these patients resembled PV, including suprabasilar blister formation, but with additional keratinocyte cell necrosis as found in erythema multiforme. Skin biopsies from these patients revealed IgG bound to keratinocyte cell surfaces, and granular–linear deposits of IgG and C3 at the basement membrane. Serum contained circulating IgG antibodies, which bound to normal keratinocyte cell surfaces of squamous epithelium. Although initial reports suggested that these antibodies bound to stratified and nonstratified squamous epithelium, this is not always the case. The antigenic targets of these antibodies were also distinct from both PV and PF (see below).

IgA Pemphigus

IgA pemphigus presents as an annular, vesiculopustular eruption characterized by intraepidermal blisters with numerous neutrophils. Intercellular deposits of IgA are present. This entity is also known as *intraepidermal neutrophilic IgA dermatosis, intercellular IgA vesiculopustular dermatosis,* and *intercellular IgA dermatosis.*[9]

IgA pemphigus is a distinct clinical entity with two subtypes that differ in histology and epidermal IgA deposition patterns: subcorneal pustular dermatosis (SPD) and intraepidermal neutrophilic IgA dermatosis (IEN). Biopsy specimens from SPD show subcorneal acantholysis and pustules, with intercellular IgA deposition mainly in the upper epidermis. The IEN subtype is characterized by pustules deeper in the epidermis, with intercellular IgA deposition throughout the epidermis. Circulating IgA antibodies to intraepidermal structures are present in ~50% of cases. Desmocollin 1 (a desmosomal cadherin) has been identified as a target autoantigen in most cases with the SPD phenotype. In some IEN-type cases, desmoglein-1 (Dsg1) and Dsg3 are autoantibody targets, but in most IEN cases the autoantigen remains unknown. Patients of both types commonly present with flat pustules, often on a slightly erythematous base, which tend to coalesce to form annular patterns. IgA pemphigus mainly affects the trunk, axillae, and groin but not the mucosa. Histology of lesional skin reveals subcorneal or intraepidermal blisters, with acantholytic cells and a neutrophilic infiltrate.[9]

Pathogenesis

The antigenic targets in pemphigus have been identified as components of desmosomes, key structures involved in keratinocyte adhesion (Table 63.1). IgG from patients with PF binds to a 160-kilodalton (kDa) glycoprotein, Dsg1. IgG from patients with PV with only mucosal lesions binds predominantly to Dsg3, an epithelial cadherin with significant homology to Dsg1. Patients with PV who have both skin and mucosal diseases have IgG antibodies directed against both Dsg1 and Dsg3.[10] In paraneoplastic pemphigus, IgG antibodies bind to members of the plakin family of desmosomal/hemidesmosomal proteins (desmoplakin I, desmoplakin II, envoplakin, periplakin, plectin, and BPAG1) as well as to Dsg1 and Dsg3.[8]

It has been clearly shown that these autoantibodies are pathogenic. Neonatal mice injected with IgG from patients with PV, PF, or paraneoplastic pemphigus develop cutaneous blisters, histological changes, and immunofluorescence findings consistent with pemphigus.[8,11]

The causes of the autoimmune response remain unknown. An increased frequency of human leukocyte antigen (HLA)-DR4

TABLE 63.1 Immunopathology of Autoimmune Blistering Diseases

Disease	Direct IF (Patient's Skin)	Indirect IF (Patient's Serum)	Antigen(s)
Pemphigus vulgaris	IgG keratinocyte cell surface	IgG binds keratinocyte cell surface (normal stratified squamous epithelium)	Dsg3, +/– Dsg1
Pemphigus foliaceus	IgG keratinocyte cell surface	IgG binds keratinocyte cell surface (normal stratified squamous epithelium)	Dsg1
Paraneoplastic pemphigus	IgG keratinocyte cell surface; C3, granular/linear at epidermal basement membrane (normal stratified and nonstratified squamous epithelium)	IgG binds keratinocyte cell surface	Plakin proteins, Dsg1, Dsg3
Bullous pemphigoid	Linear IgG, C3 at epidermal basement membrane	IgG binds in linear pattern normal stratified squamous epithelium basement membrane (epithelial side)	180-kDa, BPAG2 230-kDa, BPAG1
Herpes gestationis	Linear C3 at epidermal basement membrane (in 30–50% of patients linear IgG also seen)	IgG binds in linear pattern normal stratified squamous epithelium basement membrane (epithelial side)	180-kDa, BPAG2
Linear IgA bullous dermatosis	Linear IgA at epidermal basement membrane	IgA binds in linear pattern normal stratified squamous epithelium basement membrane (epithelial side)	97-kDa protein (portion of BPAG2)
Epidermolysis bullosa acquisita	Linear IgG epidermal basement membrane (IgA rarely)	IgG binds in linear pattern normal stratified squamous epithelium basement membrane (dermal side)	Type VII collagen (noncollagenous domain)
Dermatitis herpetiformis	Granular IgA dermal papillary tips	Negative	Epidermal TGase-3

Dsg, desmoglein; IF, immunofluorescence; Ig, immunoglobulin; kDa, kilodalton; TGase-3, transglutaminase-3.

and HLA-DR14 is found in patients with PV, although the individual susceptibility gene differs with ethnic origin: PV is associated with PV HLA-DRB1*04:02 in Ashkenazi Jews; DRB1*14:01/04 and DQB1*05:03 in non-Jewish patients of European or Asian descent. T cells from patients with PV have been observed to secrete high levels of interleukin-4 (IL-4) and IL-10 in response to specific Dsg3 peptides presented by DRB1*04:02. T cells reactive against Dsg3 are found in patients with PV and also in some normal healthy subjects with HLA DRB1*04:02. Which additional factors are required for HLA-susceptible individuals to develop clinical disease remains unknown.

Both the sporadic and endemic (FS) forms of PF are associated with HLA class II alleles. Susceptibility has been correlated with the presence of DR4, DR14, and DR1 alleles, but no single DR4 or DR14 allele has been associated with the disease. The HLA-DRB1 alleles DRB1*04:04, *14:02, *14:06, or *01:02 have been identified as risk factors for FS (relative risk >14).[12] These alleles all share a common sequence in the third hypervariable domain of the *DRB1* gene.

Environmental factors have been implicated in FS, the endemic form of PF. Healthy people living in endemic areas in South America have anti-Dsg1 IgG antibodies. The proportion of normal individuals with anti-Dsg1 IgG decreases with distance from the endemic focus of FS.[13] In addition, normal controls and patients with FS from endemic areas have IgM against the nonpathogenic extracellular domain of Dsg1. This is uncommon in other pemphigus phenotypes or in patients with FS who have migrated to urban centers, suggesting exposure to an environmental antigen that may share epitopes with Dsg1.[14] An IgG4 response seems important: In endemic areas, both normal subjects and those with preclinical disease or in remission had anti-Dsg1 antibodies that were predominantly IgG1[15]; in those with active disease, anti-Dsg1antibodies were predominantly IgG4.[15]

FS has been linked to bites from bloodsucking black flies found in the endemic areas of Brazil. Pathogenic IgG4 antiDsg1 antibodies from patients with FS cross-react with the LJM11 sand fly salivary gland antigen.[12,16] This suggests that FS may be triggered in HLA-susceptible individuals by an immune response that is cross-reactive with Dsg1.

Although autoantibodies are clearly important in pathogenesis, the mechanism by which they cause acantholysis is unknown. Complement components (C3, C1q) are often present in lesional skin, but autoantibodies can induce acantholysis *in vitro* and in neonatal mice without complement activation. Overall, it seems that complement may augment acantholysis, but pemphigus IgG on its own can bind keratinocytes and induce loss of cell–cell adhesion. It has been suggested that urokinase plasminogen activator is necessary for skin lesions to develop, but pemphigus antibodies remain pathogenic in plasminogen-activator knock-out mice.[17] Acantholysis may be triggered by intracellular signaling after antibodies bind to cell-surface desmogleins: p38MAPK inhibition prevents disease in the mouse model.[18]

Therapy

Before the introduction of glucocorticoid therapy, pemphigus was uniformly fatal. The introduction of high-dose systemic glucocorticoids and improvements in wound care have markedly reduced mortality caused by PV, but it remains a serious condition. Most blistering can be controlled with prednisone (1–2 mg/kg/day, usually in divided doses). The dose can be slowly tapered toward alternate-day therapy. Although this will control disease in many patients, in others, PV may flare up during corticosteroid therapy taper and require additional immunosuppression.

Azathioprine, mycophenolate mofetil, cyclophosphamide, methotrexate, and cyclosporine are the additional immunosuppressive agents most often utilized. Azathioprine and cyclosporine have steroid-sparing effects in long-term treatment, but adding these agents to steroids does not induce long-term remission any better than steroids alone.[19] In small trials, mycophenolate mofetil, used alongside prednisone, induced disease control more quickly compared with prednisone alone. However, a recent larger study of this failed to show statistical significance.[20] Because of its relatively low toxicity, azathioprine (1–3 mg/kg/day) is frequently chosen for adjuvant immunosuppression. Other possible adjunctive therapies include parenteral gold, plasmapheresis, and extracorporeal photochemotherapy. Treatment for PF is similar to that for PV, but therapy can be less aggressive, as PF is usually less severe than PV and rarely fatal. Dapsone is used for intraepidermal IgA neutrophilic dermatosis.[9] Occasionally, systemic glucocorticoid therapy is needed, either alone or with dapsone. Therapy for paraneoplastic pemphigus has been disappointing and usually unsuccessful.

Various biological agents, including etanercept, infliximab, high-dose intravenous immunoglobulin (IVIG), and rituximab, have been tried in pemphigus, with some success. Trials with etanercept showed mixed results with heterogeneous responses. In a trial comparing infliximab plus prednisone versus prednisone alone, neither group achieved their primary endpoints,[21] but at 26 weeks, three of 10 patients given infliximab showed positive responses, compared with none who received prednisone alone. Median anti-Dsg1 and anti-Dsg3 levels were lower in the infliximab group at 18 and 26 weeks. A single course of IVIG was effective in a double-blind study of patients with steroid-refractory PV.[22]

There are numerous case reports of successful use of rituximab in severe or recalcitrant pemphigus. In most cases, rituximab was added to systemic corticosteroid therapy. Three prospective studies of rituximab in pemphigus, alongside corticosteroids or other immunomodulatory agents, have reported dramatic improvement or total clearance in most patients.[23,24] The mean time to achieve disease control, with re-epithelialization of mucosal and cutaneous erosions, was 3 months.[24] The response to rituximab appears durable, with 58% of patients remaining in complete remission 6 years after therapy.[24]

KEY CONCEPTS

Pemphigus

- Clinical presentations correlate with the antigenic target of the autoantibodies.
- Pemphigus foliaceus presents with superficial intraepidermal blisters and antibodies directed against Dsg1 alone.
- Pemphigus vulgaris with only oral mucosal lesions most often has antibodies against Dsg3.
- Pemphigus vulgaris with skin and mucosal lesions most often has antibodies against both Dsg1 and Dsg3

BULLOUS PEMPHIGOID

Clinical Features

Bullous pemphigoid (BP) is characterized clinically by extremely pruritic, tense blisters on inflamed or noninflamed skin. These lesions range from small (1–5 mm) vesicles to large bullae several

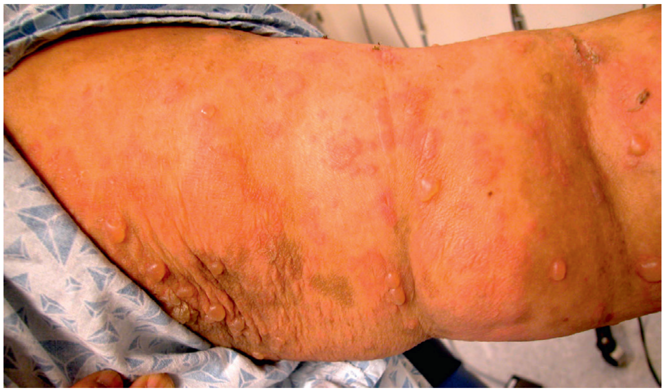

FIG 63.6 Patient with bullous pemphigoid showing erythematous plaques with tense subepidermal bullae.

centimeters in diameter (Fig. 63. 6). Patients with BP can also present with other skin lesions, including urticarial or eczematous dermatitis. Blisters can occur anywhere on skin, but often on skin in the extremities, groin, and axillae.

Oral and ocular mucosal lesions are infrequent in BP, in contrast to patients with mucous membrane pemphigoid (see below), in which mucosal lesions predominate.

Most patients with BP are over 60 years of age, although it can develop at any age. BP has been reported in association with other diseases, including neurological disease, diabetes mellitus, psoriasis, autoimmune diseases, and malignancy. Recent studies have suggested that only neurological disease is actually more prevalent, being over two-fold more common in patients with BP.[25] Drug-related BP is recognized, with furosemide and phenacetin being the most frequent offenders. BP has also been linked to ultraviolet light and therapeutic radiation. In general, the prognosis for BP is good, with a 1-year survival rate of 90% in the United States. Higher mortality rates are reported in Europe, but the reasons for this difference are not currently understood.

Biopsy of an early lesion of BP can show several different patterns consistent with the polymorphic appearance of the eruption. The classic finding is a subepidermal blister with a dermal inflammatory infiltrate, comprised predominantly of eosinophils with some lymphocytes, histiocytes, and neutrophils. The epidermis over this blister is often intact with minimal abnormality, whereas the blister cavity is filled with inflammatory cells. Sometimes neutrophils predominate, or there may be cell-poor lesions with very few inflammatory cells.

Occasionally, there may only be mild epidermal edema, with eosinophil infiltration but no blister. The polymorphic histology of BP means the diagnosis is not based solely on the histological and clinical findings.

The diagnosis of BP can be confirmed by direct immunofluorescence of perilesional skin. Over 90% of patients with BP have linear C3 deposits at the dermal–epidermal junction (DEJ), whereas 70–90% have linear IgG deposits at the DEJ (Fig. 63.7). In some patients, only C3 is seen in the skin. In 70–90% of patients with BP, circulating IgG is present and binds in a linear pattern at the DEJ of normal human skin. Anti-BP180 (BPAG2) antibody titers indicate disease activity, especially at disease onset. Anti-BP230 (BPAG1) antibodies are a fairly sensitive and specific diagnostic marker but do not correlate strongly with disease activity.

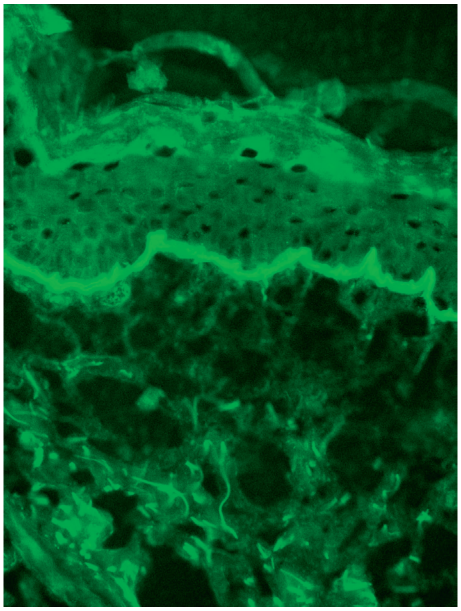

FIG 63.7 Direct immunofluorescence of perilesional normal-appearing skin from a patient with bullous pemphigoid using antibodies directed against human immunoglobulin G (IgG). A linear band of IgG is present at the basement membrane.

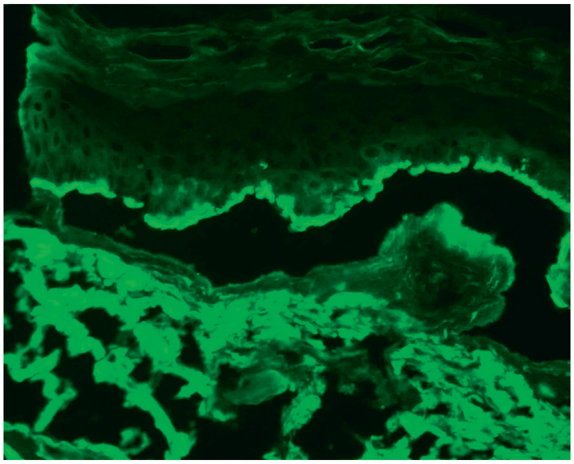

FIG 63.8 Direct immunofluorescence sample from a patient with bullous pemphigoid after incubation with 1 mol/L sodium chloride (NaCl), showing localization of immunoglobulin G (IgG) immunoreactants to the roof (epidermal side) of the blister cavity.

Although the immunofluorescence findings in patients with BP are characteristic, they are not diagnostic. Other blistering diseases, such as bullous lesions in SLE, pemphigoid gestationis (PG), and epidermolysis bullosa acquisita (EBA), can have similar patterns of immunoreactivity. Saline treatment splits skin within the lamina lucida: IgG from patients with BP binds predominantly to the epidermal side, whereas antibodies from patients with EBA bind only to the dermal side. Saline-treated skin from patients with BP also shows that IgG is deposited *in vivo* on the epidermal side of the split skin (Fig. 63.8).

Pathogenesis

Immunofluorescence microscopy demonstrates IgG in the lamina lucida of the basement membrane. The target antigens are components of hemidesmosomes. These are the major attachment sites of epidermal basal cells and where cytoskeletal proteins link through the plasma membrane to the dermis. Two predominant antigens have been identified: 230-kDa and 180-kDa proteins. These have been cloned and sequenced, confirming that they are distinct proteins, associated as a complex within the hemidesmosome. The 230-kDa BP antigen (BPAG1) is an intracellular protein with sequence homology to desmoplakin I, a member of an adhesion junction plaque protein family. The 180-kDa BP antigen (BPAG2) contains both intracellular and extracellular domains joined by a transmembrane region. The extracellular portion of BPAG2 has alternating collagen and noncollagen domains and has been termed *type XVII collagen.* Epitope mapping studies of BPAG2 have identified an immunodominant epitope on an extracellular noncollagen linker domain that is also targeted by IgG antibodies in PG.

Although patients with BP have antibodies against BPAG1 and BPAG2, the pathogenic role of these autoantibodies remains uncertain. Targeted disruption of the gene encoding BPAG1 did not result in blister formation or epidermal–dermal adhesion abnormalities. This suggests that anti-BPAG1 antibodies may not directly inhibit the function of BPAG1 but may maintain or enhance the inflammatory response in BP. Interestingly, targeted knockout of BPAG1 in mice causes progressive deterioration in motor function and sensory neurodegeneration. Additionally, certain portions of BP230 (BPAG1n1 and BPAG1n3) seem to play important roles in organizing cytoskeletal networks *in vivo.*[26] These findings complement prior studies implicating BP230 (BPAG1) in the function of the central nervous system of humans and may explain the overlap between BP and neurological diseases.[27]

Patients with BP (and PG) develop antibodies against a noncollagenous, extracellular portion of BPAG2.[28] Serum levels of BPAG2 autoantibodies correlate with disease activity in patients with BP. Interestingly, patients with an inherited form of skin blistering (generalized atrophic benign epidermolysis bullosa) have a mutation in BPAG2 resulting in a dysfunctional or missing protein.[29]

In an animal model of BP, rabbits were immunized to produce antibodies directed against mouse BPAG2. Passive transfer of this rabbit IgG to newborn mice resulted in blisters, an inflammatory infiltrate, and deposition of immunoreactants. In this model, complement activation, mast cell degranulation, and neutrophil infiltration are important in blister formation.

Complement activation and other extracellular mediators are also implicated in the pathogenesis of BP skin lesions. Complement and the terminal components of the complement cascade are present in the skin of patients with BP. Early lesions in these patients contain eosinophil granule proteins and eosinophil-derived gelatinase, suggesting an early role for eosinophils in the lesion development. Taken together, these findings suggest that IgG autoantibody binds, most likely, to BPAG2 and activates complement and local cytokine production. This attracts eosinophils and neutrophils that release enzymes leading to blister formation. IgE antibodies against BPAG2 have also been found in sera from patients with BP and are implicated in the early lesions of BP, the development of eosinophilic infiltration, and degradation of the basement membrane zone.[30]

The factors that induce development of autoantibodies in patients with BP are unknown. T cells from these patients respond *in vitro* to the extracellular region of BPAG2; this reactivity is restricted by HLA-DQB1*03:01. Subjects with normal HLA-DQB1*03:01 showed similar T-cell reactivity but produced only T-helper-1 (Th1-type) cytokines, whereas T cells from patients with BP produced both Th1-type and Th2-type cytokines. These results suggest that the ability to mount Th2-pattern responses to BP antigen(s) may be critically important.

Therapy

The mainstay of therapy for BP is treatment with systemic glucocorticoids: most patients respond rapidly to oral prednisone (0.5–2.0 mg/kg/day), but starting prednisone at doses >0.75 mg/kg/day confers no advantage. Mild or localized disease can sometimes be managed with potent topical corticosteroids (confirmed in controlled trials).[31]

When new blister formation has stopped and healing has begun, systemic steroids can be tapered slowly. The speed of tapering is dictated by the severity of the patient's initial disease and any flare-ups that occur during tapering. Most patients can stop systemic steroids completely within 6–18 months, but recurrence of disease activity is not uncommon. Flare-ups should be managed with the lowest dose of systemic steroids possible; occasionally topical corticosteroids are enough. Usually, BP is self-limiting, lasts between 1.5 and 5 years, and responds promptly to systemic glucocorticoids.[31]

A minority of patients requires prolonged high-dose systemic glucocorticoids. In these individuals, adding azathioprine, cyclophosphamide, or methotrexate will often allow tapering or discontinuation of systemic steroids, but data on which is best for steroid sparing are limited.[31] Other unproven adjunctive therapies that may help in some patients include dapsone, cyclosporine, and rituximab. Our preferred options for additional therapy are azathioprine (1–2 mg/kg/day) or mycophenolate mofetil (1000–2000 mg/day).[32]

A recent review of IVIG for BP concluded that 70% of patients experienced some improvement but there was no clinical benefit in the remainder. IVIG 2 g/kg over 5 days at monthly intervals for 3 months has been commonly used; typically more than one cycle is needed to prevent recurrence. In some patients, IVIG appears to be steroid sparing. IVIG was ineffective if patients received low-dose IVIG or only a single infusion.

Rituximab eliminates $CD20^+$ B cells through complement-dependent and antibody-dependent cell-mediated cytotoxicity, as well as by inducing structural changes and apoptosis. The targeted B cells remain absent from the circulation for 6–12 months. Several groups have reported clinical success with the use of rituximab for pemphigus, but it has only had limited success in the treatment of BP.[33]

An open-label trial of anti-IgE (omalizumab) demonstrated benefit in 5 of 6 patients with BP,[34] albeit with varying degrees of success.

KEY CONCEPTS

Bullous Pemphigoid

- Most common autoimmune blistering disease that presents in older adults
- Severely pruritic with clinical presentations, including urticarial lesions, small vesicles, and/or large tense vesicles
- Linear immunoglobulin G (IgG) and C3 present at the epidermal basement membrane, binding to the epidermal side of "1 M NaCl split" skin
- Disease activity correlates best with IgG anti-BP 180 antibodies

EPIDERMOLYSIS BULLOSA ACQUISITA

EBA is a chronic subepidermal blistering disease that typically presents in the fourth to sixth decades. There are two forms of EBA—a noninflammatory type with blisters on distal extremities and an inflammatory type that closely resembles BP. Patients with non-inflammatory EBA have peripherally distributed blisters that heal with scarring and milia formation. Their skin is extremely fragile, often resulting in numerous erosions in areas of mechanical trauma, such as hands, feet, elbows, and knees. Lesions are often seen on oral mucous membranes, sometimes including the esophagus. Patients with classic EBA may also develop ocular, vaginal, urethral, and rectal mucosal lesions. Ocular changes are common, clinically resembling mucous membrane pemphigoid (MMP). Other cutaneous manifestations include scarring alopecia and variable degrees of nail dystrophy. Patients with nonclassic (inflammatory) EBA often present similarly to those with BP, with widespread tense bullae on an erythematous base, which heal without scarring (Fig. 63.9).[35]

EBA has been associated with several diseases, particularly inflammatory bowel disease (IBD) and bullous SLE. These associations may partly result from the association of EBA with HLA-DR2.[36]

Skin biopsies of early lesions from patients with EBA show subepidermal blisters with variable degrees of inflammation. In patients with classic EBA, lesional skin biopsies often have minimal inflammatory cell infiltrate. In contrast, patients with inflammatory EBA may have substantial collections of mononuclear cells, neutrophils, and eosinophils in the superficial dermis.

Direct immunofluorescence of perilesional skin biopsies from patients with EBA shows linear deposits of IgG at the DEJ, as in BP. Linear deposits of C3, IgM, IgA, and fibrinogen have also been reported.[35] However, in EBA, these deposits are localized exclusively below the lamina lucida. Direct immunofluorescence of saline-split perilesional skin shows IgG in the blister floor in EBA (Fig. 63.10); in BP, IgG is in the blister roof.

Indirect immunofluorescence using normal human skin shows circulating anti–basement membrane zone antibodies in 30–50% of patients with EBA. However, IgG antibody can be detected in 85% of patients when using saline-split skin, which is the more sensitive and specific substrate. As expected from the *in vivo* deposition pattern, IgG from patients with EBA localizes to the blister floor. Sera from these patients recognize the 300-kDa protein, type VII collagen, primarily targeting its immunodominant NC1 domain.

Pathogenesis

Immunoelectron microscopy of EBA biopsy specimens has shown immunoglobulin deposits localized to the lamina densa zone of the basement membrane, below the lamina lucida. Transmission electron microscopy of lesional EBA skin shows decreased or absent anchoring fibrils. Anchoring fibrils are implicated in epidermal–dermal adherence via linkage of the hemidesmosome through the basement membrane, and their absence may explain the observed skin fragility. The lack of inflammatory infiltrate in many patients with EBA suggests that autoantibodies may disrupt the interaction between anchoring fibrils and dermal matrix proteins.

The target antigen for the IgG autoantibodies present in the sera of patients with EBA is type VII collagen, a 300-kDa glycoprotein composed of a 145-kDa noncollagenous domain (NC1) at the amino-terminal end, an 18-kDa noncollagenous domain (NC2) at the carboxy terminus, and a central collagenous domain. IgG antibodies from patients with EBA appear specific for epitopes within the NC1 noncollagenous domain. Type VII collagen is the major structural component of anchoring fibrils and is produced by both epithelial keratinocytes and dermal fibroblasts. Passive transfer experiments in mice and active immune models

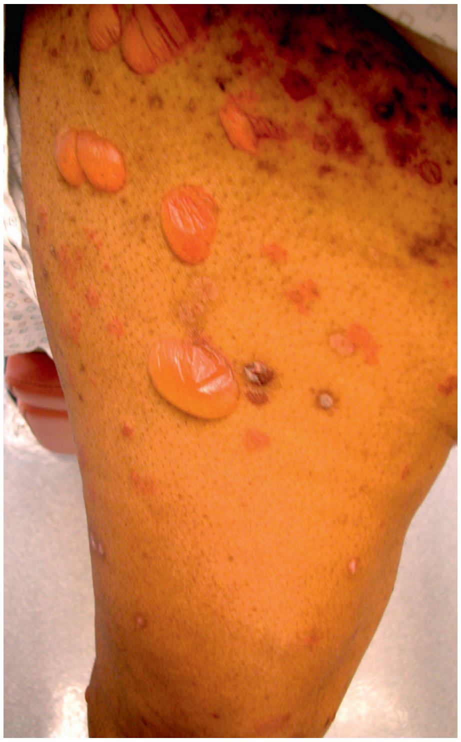

FIG 63.9 Patient with epidermolysis bullosa acquisita showing extremity involvement with tense bullae. Note the similarity to lesions of bullous pemphigoid, with somewhat less inflammation surrounding the base of bullae.

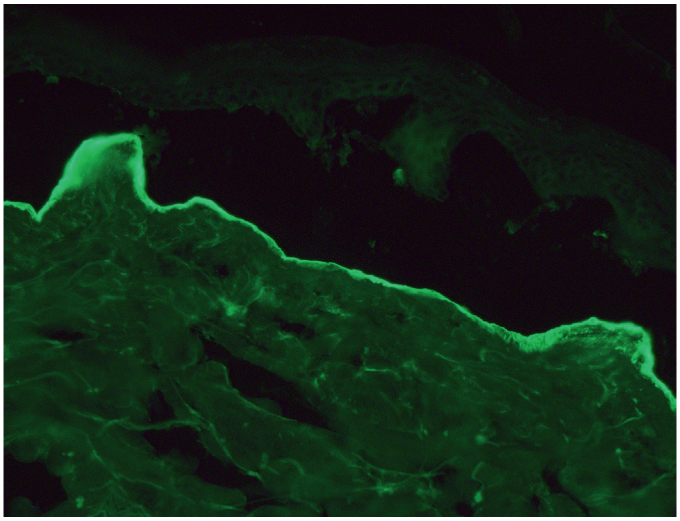

FIG 63.10 Direct immunofluorescence sample from a patient with epidermolysis bullosa acquisita (EBA) after incubation with 1 mol/L sodium chloride (NaCl), showing localization of immunoglobulin G (IgG) immunoreactants to the floor (dermal side) of the blister cavity.

have provided additional support for the critical role of anti-type VII collagen antibodies in the pathogenesis of EBA.[35] In experimental mouse-model EBA, induction of specific types of antibodies is linked to the MHC haplotype suggesting future work may identify non-MHC EBA susceptibility genes.[37] Utilizing a four-way, autoimmune-prone, advanced mouse intercross line immunized with a COL7 fragment to induce EBA, investigators identified quantitative trait loci (QTLs) on chromosomes 9, 12, 14, and 19 associated with disease development and QTLs on chromosomes 1, 15, and 19 associated with maximum disease severity.[4] In this model, gene–microbiota interactions appear to promote disease development.[38] Finally, identification of other mediators in inflammatory EBA, such as heat shock protein-90 (HSP-90), granulocyte macrophage–colony-stimulating factor (GM-CSF), chemokine ligand-1 (CXCL1), CXCL2, or IL-1, suggests other possible candidates for therapeutic targeting.[38]

Treatment

Spontaneous resolution is infrequent in EBA, and management is difficult. The main goals of therapy are to minimize blistering and scar formation, with particular attention to ocular and oral mucosal lesions. Systemic glucocorticoids are the mainstay of therapy, especially for patients with inflammatory EBA. Unfortunately, even high-dose systemic steroids do not usually improve skin fragility and trauma-induced blister formation. Mucosal lesions often respond to systemic steroids (prednisone 0.5–1.5 mg/kg/day) but may recur with tapering and/or discontinuation of steroids. Several adjunctive agents, including azathioprine, cyclophosphamide, colchicine, dapsone, hydroxychloroquine, and plasmapheresis, have been proposed, but none has been consistently effective. Cyclosporine has been used to treat patients with EBA with some success, although toxicity can limit therapy. Photopheresis, IVIG, and rituximab have also been reported to be effective in some patients with refractory EBA.[35] Mucous membrane lesions can prove particularly difficult to manage and may require systemic therapy. Patients with ocular lesions need ophthalmologist review and may require systemic glucocorticoids to prevent conjunctival scarring. Oral mucous membrane lesions can sometimes be managed with frequent application of potent topical steroid ointments or gels (0.05% clobetasol propionate, 0.05% fluocinonide). If this fails and the degree of oral erosions inhibits appropriate nutrition, systemic glucocorticoid therapy may be required. Clinicians should also be aware of possible involvement of esophageal mucosa and/or tracheal mucosa and involve appropriate specialists to monitor and treat these potentially severe complications.

As well as therapies targeting B cells, novel therapeutic targets addressing autoreactive T cells are being studied in the treatment of EBA. These include inhibitors of the stress-inducible HSP-90.[39] Strategies targeting other features of EBA, such as neutrophil recruitment and complement activation, are also being explored.

The management of chronic skin wounds is vital in EBA. Protection of skin from trauma and early use of topical and systemic antibiotics are critical to improving the rate of healing. The development of new biological dressings for chronic ulcers has also proven helpful in the management of these wounds.

PEMPHIGOID GESTATIONIS

PG is a rare, itchy, blistering disease of pregnancy and the puerperium characterized by linear deposits of IgG and C3 at the DEJ. Formerly known as "herpes gestationis," PG has no relationship to herpes virus infections. The term *pemphigoid gestationis* eliminates this confusion and emphasizes the pathophysiological similarity of PG to BP.

PG is rare, occurring in <1 in 50 000 pregnancies in North America. It usually presents in the third trimester or in the immediate postpartum period. Disease flare-ups beyond the immediate postpartum period do occur, and patients have been reported to develop blisters when menses return or when oral contraceptives are used. Although PG may recur in subsequent pregnancies, this is not absolute.

PG presents as tense blisters, often on an urticarial base, ranging in size from small (3–5 mm) vesicles to large (1–2 cm) bullae. The blisters often begin on the abdomen, although the entire body can be involved. Pruritus is common and can be severe.

PG is associated with maternal and fetal morbidity. In the mother, morbidity mainly relates to skin disease, with extensive itching and blister formation. Recent data indicate a better prognosis for the fetus than previously reported, with a 20% risk for premature delivery. Small-for-gestational-age birth weight and spontaneous abortion are only marginally increased in frequency. Similar effects have been found in pregnant women receiving systemic corticosteroid treatment for allergy, asthma, inflammatory bowel disease, and so on. Low birth weights and prematurity are significantly associated with early onset of PG (in first or second trimester), rather than exposure to corticosteroids during pregnancy.[40] Up to 10% of children born to mothers with PG develop skin lesions similar to those in the mother, likely as a result of transplacental crossing of maternal autoantibodies. The typical presentation is an erythematous urticarial or vesicular rash; yellowish plaques on erythematous base and frank bullae have also been reported. The disease is generally mild and resolves spontaneously over days to weeks as maternal antibodies are cleared.

The histopathology of PG lesions is not diagnostic. Subepidermal blisters are seen with necrotic basal keratinocytes and a perivascular infiltrate containing eosinophils, neutrophils, lymphocytes, and monocytes.

Direct immunofluorescence studies of the skin of patients with PG shows linear deposition of C3 at the DEJ. In addition, 30–50% of patients have linear IgG deposits in a similar pattern. Occasionally IgA, IgM, C1q, C4, properdin, factor B, and C5 may be present in the lamina lucida. Indirect immunofluorescence reveals circulating IgG antibodies directed against the epidermal basement membrane in only ~30% of patients. In contrast, 50–75% of patients have IgG antibody directed against epithelial basement membrane as shown by complement fixation techniques. This IgG anti–basement membrane antibody fixes complement *in vitro* but is not detected by routine indirect immunofluorescence because of its low concentration. These autoantibodies can cross the placenta: Infants born to mothers with PG often have C3 deposits at the DEJ, but without any clinical skin disease. These IgG antibodies bind the epithelial side of saline-split skin, as seen in BP.

Pathogenesis

Sera from most patients with PG bind to BPAG2 but do not react with BPAG1. The role of pregnancy and other hormonal factors in the development of PG is not understood.

Patients with PG have an increased frequency of HLA-DR3; the greatest relative risk is when HLA-DR3 and HLA-DR4 are both present. Patients with PG have an increased frequency of anti-HLA antibodies compared with multiparous control subjects. Some studies have suggested that paternal haplotype is important in PG pathogenesis, but further prospective studies are needed. Patients with PG also have increased frequency of the C4 null allele, although this may just secondary to the increased frequency of HLA-DR3.[41]

Treatment

Therapy of PG is directed at relieving pruritus and preventing the development of new blisters. If the extent of disease is limited, patients can be managed with topical glucocorticoids and antihistamines. However, most patients with PG have extensive disease and need systemic glucocorticoids. Prednisone 20–60 mg/day is usually sufficient to control both pruritus and new blister formation; once control has been achieved, the dosage should be reduced to the lowest possible effective dose. Occasionally, it may be possible to stop prednisone before delivery. However, PG often flares up in the immediate postpartum period. Only rarely do patients require therapy beyond the initial postpartum period. In patients who do require prolonged therapy after delivery, immunosuppressive agents should be considered, as in the case of the other blistering diseases. Patients being treated with systemic steroids or immunosuppressive drugs should be counseled regarding breastfeeding restrictions.

MUCOUS MEMBRANE PEMPHIGOID

MMP, formerly termed *cicatricial pemphigoid,* is a rare, chronic, scarring blistering disease that predominantly affects the oral and conjunctival mucosae. Conjunctival involvement ranges from mild conjunctivitis to severe inflammation leading to symblepharon formation, entropion, trichiasis, corneal scarring, and, in some cases, to blindness. Oral lesions include gingivitis, often with erosions and desquamation, as well as erosions and ulcerations on the buccal and palatal mucosa. Esophageal and laryngeal involvement is rare but can cause scarring and stenosis. MMP can also affect the genitalia, rectum, and nasopharynx. Cutaneous involvement occurs in 10–25% of patients, although it is often limited in extent and predominantly on the scalp, back, or face.[42]

Mucosal biopsy reveals subepidermal blisters with a cellular infiltrate, usually consisting of lymphocytes and plasma cells. Increased numbers of neutrophils and/or eosinophils have also been reported. Skin biopsy specimens of lesions in patients with MMP are indistinguishable from those of BP.

Direct immunofluorescence of perilesional skin or mucosal samples reveals linear deposition of immunoreactants at the basement membrane zone. In most patients with MMP, these are IgG and C3, although IgA, IgM, and fibrin deposits have also been reported. In patients who have ocular or oral mucosal MMP but no skin lesions, undirected skin biopsy for immunofluorescence is unhelpful. Similarly, conjunctival biopsy can yield negative immunofluorescence in patients with otherwise typical MMP. This may be attributed to conjunctival inflammation. Careful evaluation for mucosal lesions and biopsy of perilesional mucosae is often diagnostic. On immunoelectron microscopy, immunoreactants have been found in the lamina lucida and the lamina densa.

Circulating anti–basement membrane zone antibodies may be present in low titers but are usually absent in patients with MMP. The diagnostic yield of indirect immunofluorescence is not improved by using different tissue substrates, including oral and conjunctival mucosae, normal human skin, and saline-split normal human skin. A BP180 C-terminal domain enzyme-linked immunosorbent assay (ELISA) has been evaluated as a method of characterizing MMP, although direct immunofluorescence remains the most sensitive test for diagnosing BP-180 MMP.[43]

Pathogenesis

Understanding the pathogenesis of MMP has been hampered by the heterogeneous clinical presentation and the relative lack of antibodies in serum. The presence of different immunoglobulin classes at the basement membrane on immunofluorescence and the variable localization of these immunoglobulins on immunoelectron microscopy support the hypothesis that MMP is a heterogeneous disease, in which a variety of basement membrane zone proteins are targeted. In a group of patients with immune-mediated subepithelial blistering disorders of the mucous membranes, immunoreactants were found on direct immunofluorescence in about 90% with both skin and mucous membrane lesions or with mucous membrane lesions alone.[44] In contrast, only 40% of patients with isolated ocular disease had C3 and/or IgG deposits. This may reflect the difficulty encountered in biopsy of inflamed conjunctiva. On indirect immunofluorescence, 11 of 14 (81%) patients with skin and mucous membrane disease had circulating IgG anti–basement membrane zone antibodies, of which nine were identified as having BPAG1 and BPAG2 by immunoblot and/or immunoprecipitation. In contrast, only 3 of 24 patients with only oral mucosal lesions or ocular lesions had positive results on indirect immunofluorescence, and one of the sera reacted with the BP antigens.

Sera from some patients with MMP react with BPAG2, whereas others have antibodies against type VII collagen. Sera from patients with ocular MMP react with a 205-kDa protein that has homology with the cytoplasmic domain of β_4 integrin and a 45-kDa protein. Some patients have antibodies against epiligrin (laminin 5), a ligand for major keratinocyte integrins ($\alpha_3\beta_1$ and $\alpha_6\beta_4$). Patients with MMP who have anti-epiligrin antibodies need a careful workup, as they have an increased risk of malignancy.[45] Additionally, >80% of patients with anti-epiligrin antibodies show laryngeal involvement, something seen in <10% of all patients with MMP.[46] These data suggest that the clinical presentation of MMP is associated with diverse autoantibodies that react with multiple antigens of the skin basement membrane zone. The different clinical presentations may therefore result not only from different target antigens but also perhaps from different antibody-binding sites on these antigens.

MMP has been linked to many different HLA class II alleles. It has been suggested that HLA-DR4 substantially increases the risk of ocular disease. An increased prevalence of HLA-DQB1*03:01 was described in patients with isolated ocular MMP,[46a] but this allele was later found to be associated with all clinical sites of involvement and possibly to anti–basement membrane IgG production as well as overall disease severity.

Therapy

Treatment of MMP is difficult and directed at minimizing the scarring and resultant ocular complications. Dapsone (100–200 mg/day) is effective at controlling the early inflammatory response. Tetracyclines can also control MMP and are often combined with nicotinamide. If these are unsuccessful, treatment with systemic glucocorticoids (1–2 mg/kg/day) may be needed, often with adjunctive immunosuppressive therapy, such as with azathioprine, mycophenolate mofetil, or cyclophosphamide. IVIG may be useful: It starts to work rapidly and is especially helpful in patients with progressive ocular MMP whose vision is threatened. In some patients, IVIG has arrested the progression of eye disease, maintaining vision and preventing blindness. However, no controlled studies have yet been performed. Case reports suggest some benefit with plasmapheresis, etanercept, and infliximab. Growing numbers of case series have suggested that rituximab may effective, with most patients showing complete response after a single course, but, again, no controlled trials have been published.[47] A retrospective study of MMP patients given rituximab showed that all patients achieved disease control, compared with 40% of those who received conventional therapy.[48]

The clinical course of MMP is difficult to predict, and the response to treatment is often suboptimal. Some patients achieve long-lasting remissions, but MMP frequently recurs, and patients in remission should be monitored closely.

Ocular mucosal lesions are often severe in MMP and can cause significant morbidity. Consultation with an ophthalmologist is important in managing the potentially severe ocular complications. Physicians should also be aware of the risk of esophageal and tracheal involvement; patients with severe disease often need consultation with relevant specialists. Oral mucosal lesions can often be managed with frequent application of potent topical corticosteroids (0.05% clobetasol propionate or 0.05% fluocinonide). In severe cases, dapsone or systemic glucocorticoids may also be needed. Patients with limited skin disease can often be managed with topical therapy alone. If this fails, treatment as for BP is usually successful.

LINEAR IGA BULLOUS DISEASE

Linear IgA bullous disease (LABD) is a clinically heterogeneous blistering disease in which direct immunofluorescence of perilesional skin biopsies reveals linear deposition of IgA at the basement membrane zone. The majority of patients with LABD presents with pruritic vesicles and papules, localized primarily to the extensor surfaces, similar to the clinical pattern seen in patients with dermatitis herpetiformis (DH). Patients with LABD do not, however, have associated gluten-sensitive enteropathy, their disease is not improved on a gluten-free diet, and they do not have the characteristic HLA associations of patients with DH.

Other patients with linear IgA deposits present a clinical picture more suggestive of BP, with pruritic tense blisters on an erythematous base. Other clinical presentations have been described, with clinical, histological, and immunopathological overlap among patients with LABD, MMP, and EBA. Children can develop a subepidermal blistering disease with linear IgA basement membrane deposits, a condition previously termed *chronic bullous disease of childhood.* In these juvenile cases, blisters occur mainly in flexural surfaces, around the genitalia, and on the face, especially the perioral region. A drug-induced form of LABD can occur, mainly in association with vancomycin, but also with other medications.[49]

Histopathology of lesional skin of patients with LABD reflects the clinical heterogeneity seen in these patients. Biopsy usually reveals collections of neutrophils in the dermal papillary tips in a pattern virtually identical to DH. However, subepidermal blisters with eosinophils may also be seen, as in BP.

Direct immunofluorescence of perilesional skin in patients with LABD reveals a linear band of IgA, almost exclusively IgA1, at the basement membrane zone. These IgA skin deposits contain both κ and λ light chains, indicating that the antibodies are polyclonal. J chain is not present, suggesting that the IgA is monomeric and not of gut origin. Immunoelectron microscopy most often reveals IgA deposits in the lamina lucida; but IgA deposits have also been seen below the lamina densa. Circulating IgA antibodies against the basement membrane zone of stratified squamous epithelium are detected in only 10–30% of both adult and pediatric patients with linear IgA deposits. Other immunoreactants, especially IgG and C3, have been found in 30–40% of patients.

Pathogenesis

The paucity and heterogeneity of circulating antibody has made it difficult to determine the antigenic target in LABD. Sera from adults and children with linear IgA deposits within the lamina lucida reacted with a 97-kDa protein that is identical to part of BPAG2.[50] In patients with LABD or linear IgA disease of childhood with IgA deposits below the lamina densa, antibodies have been identified reactive to type VII collagen and an unknown 285-kDa dermal protein.[50] These findings support the hypothesis that there are heterogeneous target antigens in LABD and linear IgA disease of childhood. Regardless of the location of IgA deposits or the specific antigenic target, the mechanism of lesion formation in patients with LABD remains unknown.

Therapy

Dapsone (25–200 mg/day) is the mainstay of therapy of patients with all forms of LABD. Although dapsone is well tolerated by most patients, it has significant pharmacological and idiosyncratic adverse effects. Occasionally, patients do not respond to dapsone alone. In these cases, adding low doses of prednisone (10–20 mg/day) may result in significant improvement.

THERAPEUTIC PRINCIPLES

Treatment of Autoimmune Blistering Diseases

Systemic corticosteroids are the initial mainstay of treatment.

Dapsone is the mainstay of therapy for linear immunoglobulin A (IgA) dermatosis and dermatitis herpetiformis.

Steroid-sparing agents, including azathioprine, mycophenolate mofetil, methotrexate, and intravenous immunoglobulin (IVIG), are often needed for treatment.

Rituximab and other anti-CD20 biologics have been proven to be very effective as steroid-sparing agents in clinical studies.

DERMATITIS HERPETIFORMIS

Clinical Features

DH is an intensely pruritic blistering disease that typically presents in the second or third decade with erythematous papules and/or vesicles over extensor surfaces (Fig. 63.11). Patients often present with a broad spectrum of lesions. The severe pruritus leads to scratching, resulting in erosions that may be the presenting feature. Patients can also present with urticarial plaques or, less commonly, frank bullae. Lesions are usually symmetrically distributed over the extensor surfaces, especially the elbows, knees, buttocks, back, and posterior hairline. Symptomatic mucous membrane lesions are rarely present. Extreme pruritus is a clinical hallmark of DH. Patients characteristically report severe burning or stinging 12–24 hours before the appearance of lesions, which persists until vesicles break and crusts form. DH is generally considered a life-long dermatosis, although clinical remission can occur in as many as 12% of patients.[51] The wide variety of clinical presentations of DH often suggests a long differential

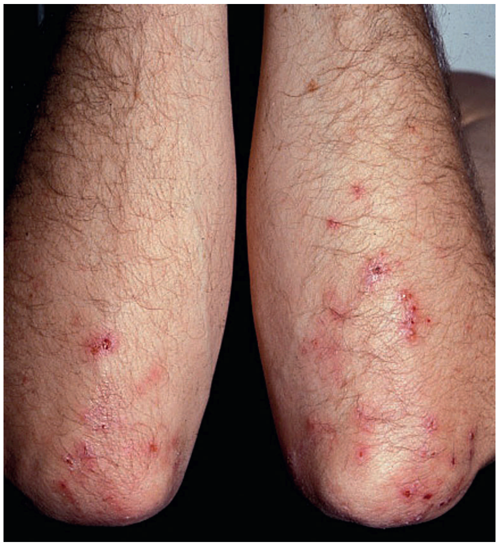

FIG 63.11 Patient with dermatitis herpetiformis showing erythematous papules with crusts on the elbows. Rare intact vesicles are present.

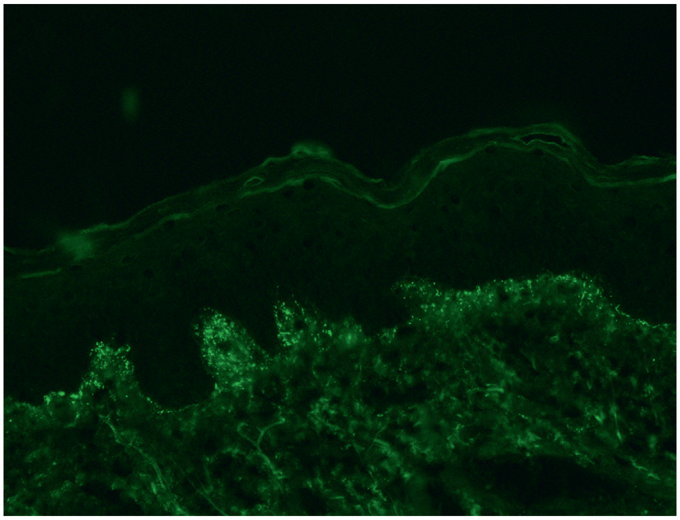

FIG 63.12 Direct immunofluorescence of normal-appearing perilesional skin of a patient with dermatitis herpetiformis using antibodies against human immunoglobulin A (IgA). Granular deposits of IgA are present at the dermal–epidermal junction.

diagnosis, including erythema multiforme, PG, BP, transient acantholytic dermatitis, papular urticaria, scabies, bug bites, and neurotic excoriations.

The frequency of DH varies in different ethnic groups. It is between 10 and 39 per 100 000 in Anglo-Saxon and Scandinavian populations, but up to 75 per 100 000 in Finland, although its incidence in the UK appears to be decreasing.[52,52a] DH occurs much less frequently in other populations (*e.g.,* those of Asian or African descent). This relates, in part, to differing frequencies of the DH-associated HLA antigens in different populations, as detailed below.

Biopsy of early DH lesions reveals neutrophilic infiltration of dermal papillae with fibrin, neutrophilic fragments, edema, and variable numbers of eosinophils. This histological pattern is not specific and has been reported in BP, linear IgA disease, bullous eruption in SLE, and leukocytoclastic vasculitis.

Granular IgA deposits can be found at the DEJ on direct immunofluorescence of DH skin biopsy specimens (Fig. 63.12). These granular deposits of IgA at the DEJ are specific for DH and have not been found in gluten-sensitive enteropathy (GSE, also known as celiac disease; Chapter 75) without DH or in asymptomatic relatives of patients with DH.[53] Although some patients with DH have circulating antibodies against tissue transglutaminase, identification of granular IgA deposits at the DEJ remains the gold standard for diagnosing DH. To maximize the diagnostic yield, biopsies for direct immunofluorescence studies should be taken from normal-appearing perilesional skin.

A gastrointestinal (GI) abnormality similar to that seen in isolated GSE was identified in 60–70% of DH patients.[54] This abnormality was reversible by avoiding dietary gluten, confirming that DH was a gluten-sensitive disease. Small bowel histological changes in DH include flattening of the normal villous architecture of the jejunal epithelium, with elongation of intestinal crypts and mononuclear cell infiltrates within the lamina propria and epithelium. These findings are often patchy and less severe than in isolated GSE. In effect, all patients with clinical DH and granular IgA deposits have associated GSE.

Most patients with DH have no GI symptoms. Only 10% of DH patients have typical symptoms of isolated GSE, such as bloating, diarrhea and malabsorption, while 20–30% have mild steatorrhea. However, many patients with DH have asymptomatic abnormal intestinal function, as shown by abnormal absorption of D-xylose, iron, folate, glucose, water, and bicarbonate.

GSE clearly plays a critical role in the pathogenesis of DH. Patients with DH who adhere to gluten-free diets can control their skin disease, normalize the morphological changes of the small intestine and, after years of gluten avoidance, lose their cutaneous IgA deposits. However, the exact relationship between the skin disease, cutaneous IgA deposits and GSE remains unknown.

HLA-DR3 is expressed in 90–95% of patients with DH, compared with ~23% controls. In addition, 95–100% of patients with DH express HLA-DQ2 (which is in linkage disequilibrium with HLA-B8 and HLA-DR3), compared with 40% of controls. The HLA-DR and HLA-DQ alleles involved in the pathogenesis of DH are DQB1*02:01, DQA1*0501, and DRB1*03:01, which are essentially identical to those associated with isolated GSE.

Patients with DH also have an increased frequency of gastric atrophy and gastric hypochlorhydria. Thyroid abnormalities, including hypothyroidism, hyperthyroidism, thyroid nodules, and thyroid cancer, also occur more frequently in these patients. Various other autoimmune diseases, including SLE, dermatomyositis, myasthenia gravis, Sjögren syndrome, and rheumatoid arthritis, have also been reported in patients with DH. It is thought that many of these associations relate to the high frequency of the HLA-B8, HLA-DR3, and HLA-DQ2 haplotypes in these patients. A five- to sixfold increased incidence of non-Hodgkin lymphoma has been reported among patients with DH, without any increased mortality.[55,56]

Pathogenesis

The pathogenesis of DH rests on three distinct associations: *(i)* granular deposits of IgA in the skin at the DEJ; *(ii)* gluten-sensitive enteropathy (albeit often asymptomatic); and *(iii)* increased frequency of the HLA-DR3/DQ2 haplotype. Attempts to understand DH must integrate all these factors.

The mechanism of IgA binding to DH skin is uncertain. Circulating antibodies that bind to normal human skin *in vitro* have not been detected in DH. Also, the IgA deposits do not appear to be caused by IgA-containing circulating immune complexes. Another mechanism by which IgA might bind to DH skin is that IgA produced in the gut, in response to wheat or other dietary antigens, may reach the circulation, where it could bind to wheat protein deposited in skin or cross-react with normal skin structures or molecules. DH sera contain IgA antibodies against endomysium, a connective tissue element surrounding smooth muscle, and are directed against tissue transglutaminase.[57] Patients with DH also have IgA antibodies against epidermal transglutaminase, with higher avidity compared with those found in patients with isolated GSE. The IgA deposits in DH skin colocalize with epidermal transglutaminase, suggesting epidermal transglutaminase-3 (eTG3) is the IgA target in the skin of patients with DH. Development of IgA anti-eTG3 antibodies is associated with prolonged periods of gluten exposure, suggesting that these antibodies result from epitope spreading. In a mouse model in which normal human skin is grafted onto SCID mice, human IgA anti-eTG3 antibody binds in a pattern identical to that seen in patients with DH. These observations suggest that IgA anti-eTG binds and slowly accumulates in the dermis, resulting in the pathognomonic IgA deposits seen in patients with DH.[58]

The presence of an ongoing mucosal immune response in patients with DH has been shown to result in systemic signs of inflammation, including elevated serum levels of soluble IL-2 receptor and IL-8, increased neutrophil expression of CD11b, and increased expression of endothelial cell E-selectin in skin.[59] These findings suggest that the mucosal immune response results in a proinflammatory environment in skin, which, when coupled with cutaneous IgA deposits, can result in development of typical DH skin lesions.

Therapy

DH can be treated either with dapsone or a gluten-free diet; the choice of therapy should be individualized to each patient. The treatment of choice for most patients with DH is dapsone or sulfapyridine because of the lack of GI symptoms in most cases and difficulty adhering to a strict gluten-free diet. Dapsone (100–200 mg/day) is sufficient to control cutaneous eruptions in most cases, with minimal side effects. Dapsone therapy results in almost immediate cessation of DH skin symptoms, but it does not affect the GI mucosal defect or symptoms. Patients with DH who are on dapsone therefore have ongoing (albeit low-grade) GSE. Dapsone is potentially toxic, and if the disease flares up, patients should not increase the dose without consulting their physician.

Strict adherence to a gluten-free diet will also control DH skin lesions. Nearly 80% of patients with DH who follow such a diet can stop or substantially reduce the dose of dapsone required to control their skin disease.[59] Patients may need to be on a gluten-free diet for at least 5 months before being able to reduce their dose of dapsone; being on this diet for 8–48 months is necessary before discontinuation of dapsone. Gluten-reduced diets, in which gluten content is not totally eliminated, are less effective in controlling DH skin lesions but may provide some relief. Patients on gluten-reduced diets are able to decrease their dapsone dosage by approximately 50% compared with ≥75% reduction in patients on gluten-free diets. Strict adherence to a gluten-free diet controls the cutaneous manifestations of DH in most patients, reverses the morphological changes in the small intestine and, after many years, may result in disappearance of the cutaneous IgA deposits. Cutaneous IgA has been shown to return after rechallenge with dietary gluten.[59]

Rarely, patients with DH fail to respond to a gluten-free diet despite what appears to be total dietary compliance. This has also been reported in patients with isolated GSE and other dietary factors have been postulated to play a role. In support of this concept, the skin lesions and GI changes of DH may also respond to an elemental diet, often within only 2–3 weeks of starting the diet. These results imply that other proteins besides gluten play a role in the DH pathogenesis. Although a gluten-free diet is an attractive alternative to medication for many patients, it is difficult to maintain. Gluten is present in most common grains (wheat, rye, barley) but not in rice and maize. Eating oats appears to be safe for patients with DH, but oat products may be contaminated with wheat protein. Patients should be informed that the success or failure of the diet cannot generally be assessed until they have been on the diet for at least a year.

TRANSLATIONAL RESEARCH

ON THE HORIZON

Precise characterization of the antigenic targets of autoantibodies and correlation with clinical presentations and outcomes

Identification of markers or disease activity and response to therapy

Specific immunoabsorption therapy with faster responses and less treatment-associated morbidity

Increased use of targeted biologic therapy (*e.g.*, anti–B-cell therapy) to provide rapid, long-lasting remission while minimizing morbidity and mortality.

The next 5–10 years should see further advances in the treatment of autoimmune blistering skin diseases. Anti–B-cell therapies, such as rituximab, offer a more targeted, steroid-sparing approach, and we can expect to see the development of more efficient ways of delivering these therapies. Translational studies of immunological changes among patients successfully treated with anti–B-cell therapies will yield insights into the role of different B-cell populations in the pathogenesis of autoimmune blistering disease. We can expect to see more precise determination of the antigenic targets of the autoantibodies and correlation with clinical presentations, response to therapy, and clinical outcomes.

An improved understanding of the clinical response to biologics and the mechanisms of those responses will lead to discovery of new combinations and earlier initiation of biological therapy. Early or immediate use of specific biological therapies, such as rituximab, may allow shorter courses of systemic corticosteroid therapy, long-lasting remissions, and potentially lead to "cures" of these severe autoimmune diseases.

MULTIPLE-CHOICE QUESTIONS

1. In the evaluation of a patient with suspected autoimmune blistering skin disease diagnosis requires which of the following (may have more than one correct answer):
   A. Direct immunofluorescence testing of lesional skin
   B. Routine histology of lesional skin
   C. Direct immunofluorescence testing of normal appearing perilesional skin
   D. A and B
   E. B and C

2. Which of the following statements regarding bullous pemphigoid are correct? May have more than one correct answer.
   A. Most common autoimmune blistering disease and most often presents in patients 20–40 years of age
   B. Can present as a vesicular, bullous, or urticarial eruption
   C. Patients have few if any clinical symptoms of their skin eruption
   D. Characterized by linear immunoglobulin G (IgG) and/or C3 at the basement membrane of stratified squamous epithelium by direct immunofluorescence testing of patient's skin
   E. Associated with gluten sensitive enteropathy

3. Patients with pemphigus vulgaris are characterized by (may have more than one correct answer):
   A. Subepidermal blister with eosinophils by routine histology
   B. Oral mucosal ulcerations are common either alone or in combination with skin lesions
   C. Immunoglobulin G (IgG) antibodies can be found against desmoglein-1 (Dsg1) and/or Dsg3
   D. Occurs in older adults more frequently and may be associated with neurological disease
   E. Recent evidence suggests that therapy directed at CD20 expressing cells may be very effective

Immunology of Psoriasis

Cristina Albanesi

CLINICAL AND HISTOLOGICAL FEATURES OF PSORIASIS

Psoriasis is a common chronic, relapsing immune-mediated disease involving skin and small joints of genetically predisposed individuals. It affects approximately 2% of the general population, with >50% of patients presenting in the first three decades of life. There is a wide spectrum of cutaneous manifestations of psoriasis. Individual lesions vary from pinpoint to large plaques, or even generalized erythroderma. More specifically, the clinical spectrum of psoriasis includes the plaque, guttate, small plaque, inverse, erythrodermic, and pustular variants.[1] The most common and well-recognized morphological presentation of psoriasis is that of the plaque type (Fig. 64.1). The disease is characterized by the formation of demarked erythematous plaques with large scaling. The scales are a result of a hyperproliferative epidermis with premature maturation of keratinocytes and incomplete cornification, with retention of nuclei in the stratum corneum (parakeratosis). The mitotic rate of the basal keratinocytes is increased compared with that of normal skin. As a result, the epidermis is thickened (acanthosis), with elongated rete ridges that form finger-like protrusions into the dermis. The granular layer of the epidermis (the starting site of terminal keratinocyte differentiation) is strongly reduced or missing. The epidermis is infiltrated by neutrophils and activated CD8 T lymphocytes, whereas within the dermis there is an inflammatory infiltrate composed mainly of $CD3^+$ T cells, dendritic cells (DCs), macrophages, mast cells, and neutrophils. Elongated and dilated blood vessels in the dermal papillae represent a further histological hallmark of psoriatic skin lesions (Fig. 64.2).[1]

IMMUNE-RELATED GENETIC FACTORS PREDISPOSING TO PSORIASIS

The genetic basis of psoriasis has long been recognized, since family members of patients with psoriasis are at greater risk of developing the disease. The concordance rate of psoriasis is approximately 70% in monozygotic twins and 20% in dizygotic twins, depending on the study and population.[2] The mode of inheritance is complex. It is thought that there is no single disease gene, but, rather, a complex set of gene variants, resulting in an aberrant response to environmental factors. At least nine chromosomal loci with statistically significant linkage to psoriasis have been identified, termed *psoriasis susceptibility loci 1* through *9* (*PSORS1* through *PSORS9*).[2] *PSORS1* is the major genetic determinant of psoriasis and is located within the human leukocyte antigen (HLA) complex on chromosome 6p (Chapter 5). An association with HLA-B13 was first identified and later with other class I molecules HLA-B17, HLA-B37, HLA-B57, HLA-Cw6, and HLA-Cw7, and class II molecules HLA-DR4 and HLA-DR7. Among these, the highest and most consistently reported relative risk is for HLA-Cw6 haplotype. A significantly higher frequency of HLA-Cw6 is associated with early-onset (type I) psoriasis compared with late-onset psoriasis (type II). Current data suggest that HLA-Cw6 is the susceptibility allele within *PSORS1,* but no disease-specific mutations have been identified, and variants in regulatory sequences potentially affecting several downstream genes cannot be ruled out. HLA-C might be involved in immune responses at the levels of both antigen presentation and natural killer (NK)–cell regulation. Recently, compelling evidence has emerged for an interaction between the HLA-C and *ERAP1* (involved in major histocompatibility complex (MHC) class I peptide processing) loci in psoriasis.[3] 36763*ERAP1* variants only influenced psoriasis susceptibility in individuals carrying the HLA-C risk allele.

Other predisposing polygenes were found in the *PSORS2* region, on chromosome 17q25. Two distinct regions harboring susceptibility loci have been identified: the first contains the genes *SLC9A3R1* and *NAT9* and the second the gene *RAPTOR.*[4] The *SLC9A3R1* gene encodes a PDZ domain-containing phosphoprotein, implicated in several biological processes occurring in T cells. *NAT9* encodes an N-acetyltransferase involved in MHC class I antigen-presentation and in immunological processes related to autoimmune diseases. Additionally, between *SLC9A3R1* and *NAT9* is a polymorphism for the binding site of a transcription factor RUNX1 that may affect regulation of the immune synapse.[4] Associations with alleles of interleukin (IL)-12, IL-23 receptor (IL-23R), IL-19/20, and IRF2 have also been described. Interestingly, IL-12 and IL-23R single nucleotide polymorphisms do not have interactions with HLA-Cw6.[4] Recently, polymorphisms have been found in two genes, *IL-36RN* and *CARD14,* and to be independently associated with psoriasis.[4,5] For *CARD14* (caspase recruitment domain-containing protein 14) gene, many missense mutations, leading to elevation of CARD14 mRNA in patients, were initially found in pediatric patients with a severe clinical presentation of psoriasis. CARD14 gene mutation protein, in association with an inflammatory stimulus, may induce aberrant activation of nuclear factor (NF)-κb, a transcription factor that controls the expression of many genes, including key chemokines upregulated in psoriasis, such as chemokine (C-X-C motif) ligand (CXCL)8 and CC chemokine ligand (CCL)20. Mutations in *IL-36RN* gene were described in patients with severe pustular psoriasis. This gene encodes the antiinflammatory protein IL-36Ra, antagonist of IL-36γ, a cytokine highly produced in psoriatic lesions and with important proinflammatory function.

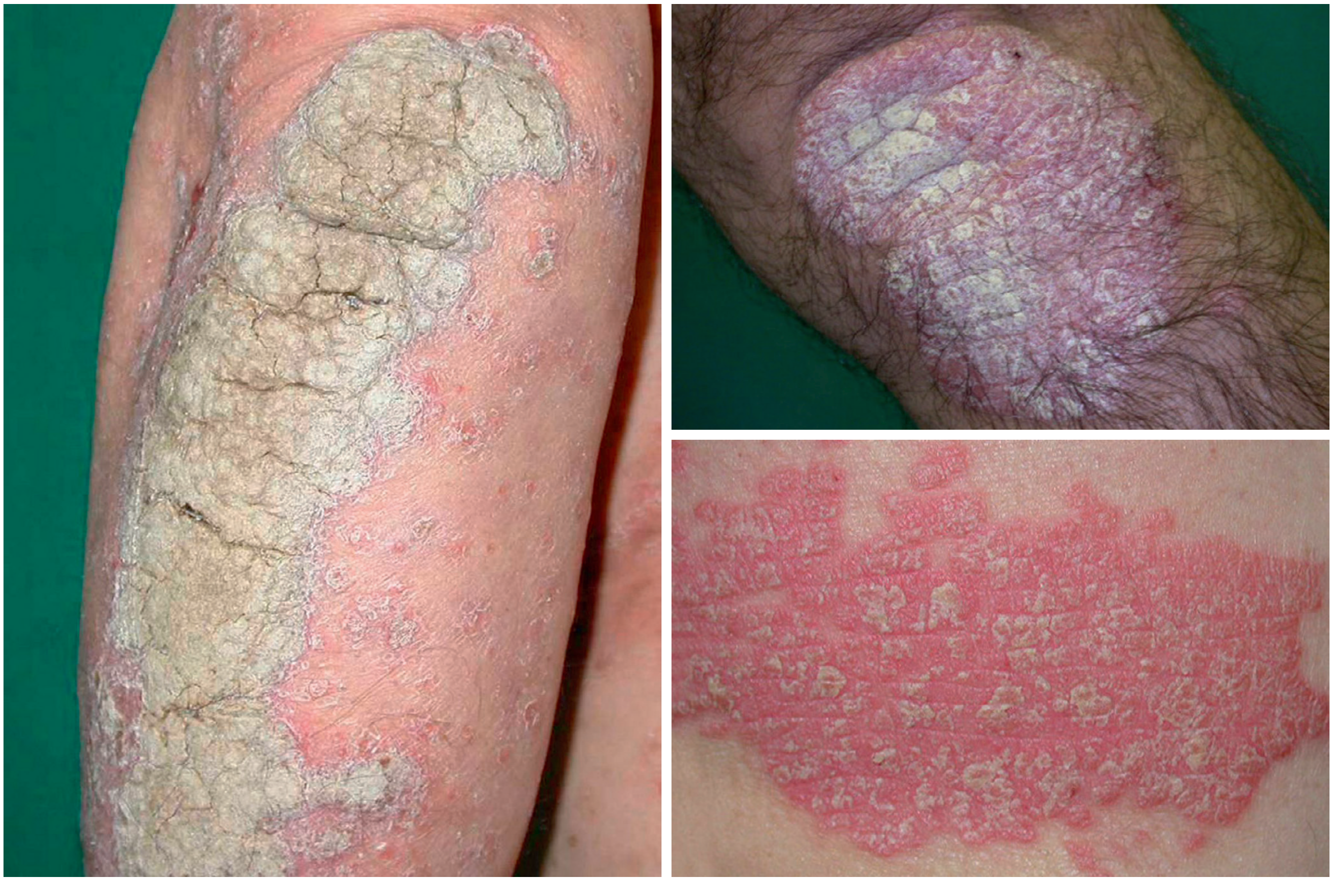

FIG 64.1 **Clinical Features of Plaque Psoriasis.** Scaly, erythematous, sharply demarcated plaques in different sizes and shapes are hallmarks of psoriasis.

KEY CONCEPTS

Psoriasis is a common chronic-relapsing immune-mediated skin disease affecting approximately 2% of the general population.

There is strong evidence that psoriasis is determined by genetic predisposition. A complex set of gene variants, rather than a single gene, are responsible for an aberrant response to environmental factors.

Psoriasis is a disease caused by the infiltration of effector immune cells in both the epidermis and dermis, which determines hyperproliferation of the epidermis with premature maturation of keratinocytes and incomplete cornification. As a result, the epidermis is thickened, with elongated rete ridges forming protrusions into the dermis.

Primary effector cells are dermal dendritic cells (DCs), in particular plasmacytoid DCs (pDCs), whose activation can depend on DNA-LL-37 or RNA-LL-37 complexes released by injured keratinocytes and leads to a massive production of interferon (IFN)-α.

pDC-released IFN-α or RNA-LL-37 complexes released by keratinocytes activate myeloid DCs (mDCs), which in turn induces type-1 and -17 T-cell responses. T-helper 22 response is also pathogenetically induced.

Pathological cytokines include T-cell-derived lymphokines, such as IFN-γ, tumor necrosis factor (TNF)-α, IL-17, IL-22, IL-21, and antigen-presenting cell–derived cytokines, such as IL-12 and IL-23.

Intrinsic alterations of keratinocytes in the activation of signal transduction pathways (*i.e.,* STAT3, IKK-2, AP-1, etc.) are fundamental for the amplification of psoriatic processes.

EFFECTOR CELLS AND IMMUNE MECHANISMS OPERATING IN PSORIASIS

Even though successful treatment regimens for the therapy of psoriasis are long established, the primary pathogenetic mechanism and the cell types involved in the onset of the disease are still under debate. Psoriasis is classically responsive to trigger factors that can induce psoriasis *de novo* or exacerbate skin lesions.[6] Trigger factors range from nonspecific stimuli, such as skin trauma (termed the *Koebner effect*) to more specific triggers, such as pathogens (*i.e.,* streptococci) or drugs (*i.e.,* lithium, interferon (IFN)-α). All of these factors generate a pathogenic cascade culminating in the expansion of lesional and/or circulating T cells in the psoriatic skin (Fig. 64.3). Much effort has been devoted to understanding the link between the trigger stimuli and the pathogenic T-cell cascade that leads to psoriasis. Recent evidence suggests that type-1 IFN may represent the missing link. The prototypical type I IFN, IFN-α, is abundantly produced by plasmacytoid dendritic cells (pDCs) during the early phase of psoriasis development (see Fig. 64.3A).[6,7] In turn, IFN-α indirectly stimulates the pathogenic T-cell cascade by promoting the activation and maturation of myeloid DCs (mDCs) or by direct stimulation of IFN-α–sensitive pathogenic T cells (see Fig. 64.3B). The T-cell infiltrate present in active psoriatic skin establishes a cytokine milieu that dictates specific and pathogenic gene signatures in resident skin cells. Thus cytokine-activated keratinocytes overexpress a number of inflammatory mediators that aberrantly amplify and sustain the psoriasiform tissue reactions (see Fig. 64.3C). Intrinsic defects and/or alterations of keratinocytes in their immune response to proinflammatory cytokines are fundamental to the induction of psoriatic processes, as demonstrated in genetically manipulated mouse systems.

FIG 64.2 Histological Components of a Mature Psoriatic Plaque. Psoriatic skin lesions are characterized by a hyperproliferative epidermis showing an increased mitotic rate of the basal keratinocytes (A, Ki67 immunostaining). As a consequence, the epidermis is thickened, with elongated rete ridges that form typical finger-like protrusions into the dermis. The epidermis becomes infiltrated by activated CD8 T lymphocytes and neutrophils (B and C, immunostaining for CD8 and CD15, respectively). Within the drmis, an inflammatory infiltrate mainly composed of $CD3^+$ T cells (D), $CD11c^+$ dendritic cells (E), BDCA-2^+ plasmacytoid dendritic cells (F), c-kit^+ mast cells (G), and neutrophils (C) is observed. Elongated and dilated ICAM-1^+ (H) blood vessels in the dermis represent another histological hallmark of psoriatic skin.

FIG 64.3 Scheme of Pathogenic Mechanisms Operating in Psoriasis. The psoriatic lesion starts to evolve after keratinocytes are injured, for instance by physical trauma or bacterial products. Thereafter, a cascade of events including the formation of complexes formed by keratinocyte-derived DNA and the cathelicidin LL-37 leads to the activation of plasmacytoid dendritic cells (pDCs), which routinely patrol psoriatic skin (A). Other pDCs are recruited in the early phase psoriasis development by the chemokine chemerin, derived primarily from dermal fibroblasts and, to a lesser extent, from mast cells and endothelial cells, and induced to release high amounts of IFN-α. IFN-α locally activates keratinocytes and participates in the activation processes affecting myeloid DCs. In turn, DCs migrate into draining lymph nodes and induce the differentiation of naïve T cells into effector cells, such as type 17 T-helper (Th) 17 or type 17 T cytotoxic (Tc) cells and type 1 Th1 or Tc1 cells. Effector cells recirculate and proliferate into psoriatic skin and produce massive amounts of proinflammatory cytokines, such as interferon (IFN)-γ and tumor necrosis factor (TNF)-α (B). The latter cytokine is also abundantly released by dermal DCs, mainly represented by TNF-α and inducible nitric oxide synthase-producing-DCs (TIP-DC). SlanDCs also reinforce immunity in psoriasis by interacting with and potentiating the activity of both neutrophils and natural killer (NK) cells, as well as inducing Th1 and Th17 responses. IFN-γ and TNF-α are responsible for the activation of resident skin cells, in particular keratinocytes, which respond to cytokines with a stereotypical set of genomic responses leading to synthesis of inflammatory mediators (C). Keratinocytes are also targets of T cell–derived IL-22, which induces proliferation and de-differentiation of psoriatic keratinocytes in a signal transducer and activator of transcription 3 (STAT3)-dependent manner. Keratinocyte-derived chemokines, cytokines, and membrane molecules have a major role in maintaining the recruitment of leukocytes into inflammatory sites. Because of their intrinsic defects, psoriatic keratinocytes aberrantly respond to cytokines and show altered intracellular signaling pathways, including STAT3 cascade (C). The uncontrolled hyperproliferation and differentiation observed in psoriatic skin could also derive from dysregulated production of tissue growth factors and regulators, such as transforming growth factor (TGF)-α, keratinocyte growth factor (KGF), amphiregulin, granulocyte macrophage–colony-stimulating factor (GM-CSF), fibroblast growth factor-10 (FGF-10), interleukin (IL)-19, IL-20, IL-36 produced by keratinocytes and fibroblasts. Psoriatic keratinocytes produce autoantigens (*i.e.,* keratin (K)17, K13, nucleic acid/LL-37 complexes) capable of inducing clonal T-cell responses. Finally, the inflammatory cytokine milieu also influences the immune functions of fibroblasts and endothelium, with the latter being critical for leukocyte trafficking and extravasation.

Plasmacytoid DCs as Inducers of Primary Immune Responses in Psoriasis

pDCs are characterized by a plasma cell morphology and a distinctive surface phenotype (CD4$^+$, CD45RA$^+$, CD123$^+$, BDCA-2$^+$, BDCA-4$^+$, CD62L$^+$, cutaneous lymphocyte-associated antigen (CLA)$^+$, and CD11c$^-$). They are considered as key effector cells in antiviral defense because of their ability to produce large amounts of type I IFN.[8] Upon viral stimulation, pDCs differentiate into a unique type of mature DC and induce an IFN-α–dependent activation of bystander mDCs with the ability to induce Th1-responses (Chapter 16), thus providing a necessary link between innate and adaptive immunity.[8] Several studies have demonstrated that pDCs infiltrate psoriatic skin, and that pDC-derived IFN-α initiates the expansion of autoimmune T cells, leading eventually to the skin lesions of psoriasis.[6,7,9,10] Blocking of type I IFN signaling with neutralizing antibodies to IFN-α/β receptors inhibited the development of psoriasis in symptomless pre-psoriatic skin engrafted onto immunodeficient AGR129 mice.[10] Moreover, inhibition of IFN-α release by pDCs through anti–BDCA-2 antibody prevented the activation and expansion of pathogenetic T cells and the development of a psoriatic phenotype. The detailed mechanisms responsible for the IFN-α-induced expansion of T cells in psoriasis are currently unknown, but it appears that IFN-α favors cross-presentation of sequestered tissue-specific autoantigens by mDCs. pDC-derived IFN-α may also enhance the survival of autoreactive T cells through the induction of IL-15 or by promoting a Th1 cell bias through the induction of T-bet and IL-12Rβ_2 expression. The pathogenetic role of IFN-α is also suggested by the observations that its signaling signature is present in resident skin cells of psoriatic plaques[11] and that psoriasis is exacerbated if patients with psoriasis are treated with recombinant IFN-α for unrelated conditions (*i.e.,* viral infections or tumors), or with imiquimod, a Toll-like receptor (TLR) agonist that induces production of IFN-α by pDCs.[12] In addition, excessive activation of type I IFN signaling in mice deficient for IFN regulatory factor (IRF)-2, a transcriptional repressor of IFN signaling, causes an inflammatory skin disease resembling psoriasis. Recently, a genome-wide analysis conducted on paired lesional and nonlesional psoriatic skin and on the skin of healthy donors revealed a significant overexpression of many components of the IFN-α pathway in patients with psoriasis, including the receptor subunits for type I IFN, IFN-AR1, and IFN-AR2, the transcriptional activators of IFN-α-inducible genes, signal transducer and activator of transcription (STAT) 1, IRF1, and IRF7.[11] All of these molecules are master regulators of IFN-α-mediated immune responses.

The molecular mechanisms leading pDCs to produce type I IFN involve the activation of TLR7 and TLR9, intracellular receptors that recognize viral/microbial nucleic acids within endosomal compartments. pDCs do not normally respond to self-DNA, but this restriction breaks down in some human autoimmune diseases. In psoriatic skin, pDCs can be activated to produce massive amounts of type I IFN in response to extracellular self-DNA fragments.[13] However, this process requires the coupling of self-DNA to the endogenous antimicrobial peptide LL-37, known to be overexpressed in psoriatic skin. LL-37 breaks innate tolerance to self-DNA by forming aggregated and condensed structures that can trigger a robust IFN-α induction via TLR9 activation.[13] LL-37 can also form complexes with RNA and activate pDCs through TLR7. In parallel, LL-37/RNA can alert myeloid DCs through their TLR8, driving T-cell activation and production of cytokines found in psoriasis.[14] This finding suggests a fundamental role for LL-37 in alerting resident skin pDCs of tissue damage associated with cell death and the release of self-DNA. pDCs are typically absent in unperturbed skin and peripheral tissues under homeostatic conditions but can enter secondary lymphoid organs through the expression of CD62L and chemokine receptors (CXCR4, CXCR3, CCR5, and ChemR23). pDCs can also infiltrate inflamed tissue of immune-mediated skin diseases, and, in particular, accumulate in the skin of patients with psoriasis early during disease development.[9,10] Many studies have shown an evident IFN-α signature (*e.g.,* increased expression of IRF7 and the presence of MxA, markers for IFN-α activity) in primary psoriatic plaques in the absence of detectable levels of the IFN-α cytokine. Indeed, IFN-α expression was detected early and transiently during the development of the psoriatic phenotype, and its effect persisted until lesions became chronic. Paralleling IFN-α expression, BDCA-2$^+$ pDCs were detected only during the early developmental stages of psoriasis.[10] In fact, pDC infiltration in psoriatic skin correlates with the expression of markers typical of early phases of psoriasis (CD15$^+$ neutrophils and c-kit$^+$ mast cells localized in the mid- and papillary dermis, and few CD8 T lymphocytes or ICAM-1$^+$ keratinocytes), whereas they are almost absent in long-lasting lesions.[9] Importantly, pDC recruitment in psoriatic skin is strictly associated with the expression of the chemokine chemerin, which is temporally produced by dermal fibroblasts and active during psoriatic plaque development.[9] pDC migration toward fibroblast-derived chemerin is completely dependent on the expression of ChemR23 receptor on pDC. Compared with other chemokines potentially active on pDC (CXCL10 and CXCL12), chemerin is the main, if not the only, protein responsible for the pDC chemotactic activity released by fibroblasts in psoriatic skin.[9]

DC Driving of T-Cell Responses in Psoriatic Skin

Although pDCs are responsible for triggering psoriasis, mDCs are the main amplifiers of local inflammation. Dermal mDCs are dramatically increased in psoriasis, and targeted immunotherapy reduces their quantity in patients with psoriasis, supporting the concept that mDCs have a key pathogenetic role.[15] Dermal mDCs are found at the dermal–epidermal junction as well as throughout the whole dermis. mDCs are able to capture extracellular antigens for presentation to T cells and also intracellular antigens from adjacent cell types via cross-presentation (Chapter 6). In addition, mDCs within psoriatic lesions are intrinsically stronger stimulators of T-cell proliferation compared with DCs derived from peripheral blood or from the skin of healthy patients. mDCs uniformly express CD11c, and they can be further subdivided on the basis of expression of CD1c (BDCA-1). Steady-state skin has a predominance of CD11c$^+$ CD1c$^+$ resident DCs, whereas CD11c$^+$ CD1c$^-$ mDCs predominate in psoriatic inflammation.[15] A small fraction of CD11c$^+$ CD1c$^+$ DC bears “maturation” markers, such as DC-LAMP, CD83, and endocytic receptor DEC-205/CD205, suggesting that they could function as conventional DCs and present antigens to T cells to trigger acquired immune responses.[15] These rare, phenotypically mature cells, often aggregating in dermal clusters, could be required for rapid antigen presentation to local T cells or for ongoing “micro-” immune responses. During psoriasis development, dermal CD11c$^+$ DC mature and acquire a CD1c$^-$ HLA-DR$^+$ CD45$^+$ CD14$^-$ DC-specific ICAM-3–grabbing nonintegrin (DC-SIGN)$^+$ phenotype.[15] These inflammatory mDCs are CCR7$^+$ and respond to the chemokine CCL19, suggesting that they may migrate to draining lymph nodes for antigen presentation. CD11c$^+$ CD1c$^-$ inflammatory DC express very high levels of tumor necrosis factor (TNF)-α and the enzyme inducible nitric oxide synthase (iNOS) and can be considered the human equivalent of TIP-DC (TNF-α and iNOS-producing DCs), which have been shown in mice to have effector functions in clearing some bacterial infections.[15] The proinflammatory nature of TNF-α in psoriasis and other inflammatory diseases is well established, and the receptors TNFR1 and TNFRII are expressed on a wide range of cells in psoriatic skin, including keratinocytes and endothelial cells. TNF-α induces expression of ICAM-1 on keratinocytes, facilitating the adhesion of circulating leukocytes. Moreover, TNF-α can stimulate keratinocytes and dermal fibroblasts to produce the potent neutrophil chemoattractant CXCL8, as well as the proinflammatory cytokines IL-6 and IL-1, which help generate and maintain Th17 cells (Chapters 10 and 16). The role of TNF-α in psoriasis is underlined by the therapeutic success of anti–TNF-α therapies in psoriasis.[15] In addition, polymorphisms of the TNF-α promoter region have been associated with psoriasis. However, iNOS production by inflammatory DCs leads to nitric oxide (NO) release, inducing vasodilation, inflammation, and antimicrobial effects in psoriatic skin. Interestingly, NO inhibitors (*e.g.,* statins) can have a beneficial effect on psoriasis, although this has not been studied in a randomized prospective manner. Inflammatory DCs also produce other cytokines (Chapter 9) (*e.g.,* IL-23 and -12), which are linked to psoriasis. IL-12 mainly induces IFN-γ production, whereas IL-23 also stimulates IL-17 and IL-22 release by T cells, as shown in mice.[16] Other evidence for a role of IL-23 in psoriasis includes the clinical efficacy of an anti-p40 monoclonal antibody (mAb) against psoriasis and the association of a single nucleotide polymorphism in the *IL-23R* gene in psoriasis patients. mDCs of psoriatic lesions also release the proinflammatory cytokine IL-15, which induces T-cell proliferation and monocyte activation, as well as skin hyperplasia by protecting keratinocytes from apoptosis.

Another population of inflammatory mDCs, defined by the selective expression of the 6-sulfo LacNAc residue on the P-selectin glycoprotein ligand 1 membrane molecule, has been identified in psoriatic skin.[17] 6-Sulfo LacNAc$^+$ DCs (slanDCs) have a well-defined phenotype (CD1c$^-$, CD11c$^+$, CD16$^+$, CD14$^-$) that clearly distinguishes them from classic CD1c$^+$ blood DC (CD1c$^+$, CD11c$^+$) or pDC (BDCA-2, BDCA-4). SlanDCs produce more TNF-α, IL-23, IL-12, IL-1β, and IL-6 and can thus induce Th1/Th17 cells. SlanDCs also reinforce innate immunity in psoriasis by interacting with and potentiating the activity of neutrophils and NK cells.[17]

The function of another DC subset, the Langerhans cell, is still controversial. Langerhans cells are only found in the epidermal compartment where they are similar in number and phenotype in lesional and nonlesional skin, but they fail to migrate in response to proinflammatory stimuli[18] (Chapter 19). These findings and data from Langerhans cell ablation models suggest that Langerhans cells may help sustain immune tolerance in psoriasis. In psoriatic skin, the epidermis contains an additional DC subset, known as *inflammatory dendritic epidermal cells* and are distinguishable from Langerhans cells by the expression of the macrophage mannose receptor CD206.

Activation of T Lymphocytes and Establishment of the Cytokine Milieu Influencing Keratinocyte Proliferation and Immune Functions

Psoriasis lesional skin shows many inflammatory T cells in both the papillary dermis and the epidermis. Immunophenotyping of T cells shows that these are mainly activated memory T cells expressing HLA-DR, CD25, CD27, and cutaneous lymphocyte antigen (CLA). Although there is differential T-cell receptor usage in T cells from psoriatic skin, the causative antigens responsible for T-cell activation in psoriasis remain unknown. Exposure of altered autoantigens from keratinocytes could be responsible for the activation and expansion of distinct T-cell subpopulations in psoriatic skin. These autoantigens may include keratin 17 (patients with active psoriasis have an increased frequency of circulating Th1 cells reacting to peptides from keratin 17) and corneodesmosin, an attractive candidate for psoriasis susceptibility based on its putative biological function in keratinocyte adhesion.[19] Keratinocytes could also be responsible for the activation of pathogenetic T cells by viral or bacterial products. For example, human papillomavirus 5 (HPV-5) DNA and antibodies to HPV-5 virus-like particles have been found in psoriasis. Streptococcal infections are also frequently associated with psoriasis, and streptococcal superantigens could be presented to T cells by binding to MHC class II molecules expressed by lesional keratinocytes. Putative psoriatic antigens are assumed to be keratinocyte proteins that might share structural homology with streptococcal proteins and might thereby induce cross-reactive T-cell responses against skin components.[20] Recently, it has been found that two-thirds of patients with moderate-to-severe plaque psoriasis harbor CD4 and/or CD8 T cells specific for LL-37.[21] LL37-specific T cells produce IFN-γ, and CD4 T cells also produce Th17 cytokines. LL37-specific T cells can infiltrate lesional skin and can be tracked in patients' blood. The presence of circulating LL37-specific T cells correlates significantly with disease activity, suggesting a contribution to disease pathogenesis.

T-cell migration from the dermis into the epidermis is a key event in psoriasis. It is controlled by the interaction of $\alpha_1\beta_1$ integrin (very late antigen 1) on T cells with collagen IV in the basement membrane of the epidermis. Blockade of this interaction inhibits the development of psoriasis in clinically relevant models. Based on the analysis of infiltrating cell types, their secreted products, and genetic signatures present in lesional skin, psoriasis has been considered for many years as a type-1 (*i.e.,* Th1)–mediated reaction, with IFN-γ playing a prominent role.[22] Consistent with a Th1 pattern of response, CCR10 is preferentially expressed by skin homing CLA$^+$ memory T cells, which secrete TNF-α and IFN-γ, but minimal amounts of IL-10 and IL-4, upon activation. However, other cytokines and T-cell subsets have also been identified during inflammatory responses in psoriasis. These include Th17 and Th22 cells, which produce large amounts of IL-17 and IL-22, cytokines that have relevant effects on epithelial cells.[23] Keratinocytes are strongly influenced by IL-17 and upregulate chemokines and immunomodulatory molecules in response to this cytokine.[24] A functional role of Th17 cells, and also Tc17 cells, in psoriasis is suggested by their reduction during successful anti–TNF-α treatment or via blockade with neutralizing mAb in a clinically relevant xenotransplantation mouse model.[25] IL-22 also acts pathogenetically in psoriatic skin by inducing proliferation and de-differentiation of keratinocytes, as well as promoting their production of antimicrobial peptides and chemokines, including CXCL8 and CXCL1.[26] Binding of IL-22 to its receptor, whose expression in the skin is confined to keratinocytes, mediates epidermal acanthosis through the activation of STAT3. These observations may explain the increased STAT3 expression in the epidermal compartment and the pathogenicity of STAT3 overexpression in the epidermis of transgenic mice (see below).[27] The demonstration that T cells are the primary regulators of keratinocyte proliferation and differentiation in psoriasis came from studies showing that supernatants from lesional skin-derived T cells transformed β-integrin$^+$ keratin 1/keratin 10$^-$ PCNA$^-$ stem cells of patients with psoriasis, but not stem cells of healthy subjects, into PCNA$^+$ active cycling cells. T cell–derived supernatants contained high levels of granulocyte macrophage–colony-stimulating factor (GM-CSF) and IFN-γ, and low levels of IL-3 and TNF-α.[28] However, among these cytokines, only IFN-γ affects the proliferation of psoriatic stem cells. *In vivo,* IFN-γ injection into prelesional psoriatic skin triggers keratinocyte proliferation and plaque development. Considering that IFN-γ is an antiproliferative cytokine and an inducer of squamous differentiation, these latter findings are paradoxical. This discrepancy may reflect an intrinsic defect in the response of psoriatic keratinocytes to IFN-γ, and/or altered localization and expression of the IFN-γ receptor complex in the epidermis of psoriatic skin.

Another T cell–derived cytokine that has been shown to regulate keratinocyte proliferation in psoriatic skin is IL-21, which is mainly released by CD4 T cells and natural killer T cells (NKT cells). IL-21 contributes to epidermal hyperplasia, and neutralization of IL-21 reduces both skin thickening and expression of inflammatory molecules. Interestingly, IFN-γ is necessary for IL-21–induced epidermal hyperplasia, while abrogation of IL-21 signals reduces IFN-γ expression in psoriatic T cells.[22,24]

Finally, the importance of T regulatory (Treg) lymphocytes (Chapter 18) in psoriasis has been examined in the peripheral blood and the inflamed skin of patients. The number of Treg cells (defined by expression of the transcription factor FOXP3) is increased in the peripheral blood of individuals with psoriasis, and this increase is positively correlated with the disease activity index. CD4$^+$CD25$^+$FOXP3$^+$ Treg cells are also present in psoriatic lesions, with more in lesional skin biopsy specimens than those from control or uninvolved skin. However, these Treg cells may be less functional in that Treg cells from both the peripheral blood and psoriatic skin lesions showed reduced ability to suppress effector T cells. This impairment may be dependent on IL-6 as blockade of IL-6 reversed the impairment in suppression observed in cocultures of Treg cells and effector T cells from patients with psoriasis.

Intrinsic Defects of Keratinocytes Are Fundamental for the Amplification of Psoriatic Processes

Endogenous defects in keratinocytes may be pathogenically relevant for psoriasis, as shown in mice with engineered epidermal phenotypes. Transgenic animals that overexpress the transcription factor STAT3 or that lack the inhibitor of NF-κB kinase-2 (IKK-2) in their epidermis develop skin lesions that closely resemble human psoriasis.[27] Similarly, the abrogation of JunB in keratinocytes triggers a skin phenotype with the histological features of psoriasis, including marked hyperplasia of the epidermis and dense dermal inflammatory cell infiltrates. The hyperplasia observed in these models may, in part, depend on overexpression of S100A8 and S100A9, two antimicrobial peptides with chemotactic activity and a recognized role in keratinocyte maturation and proliferation. The development of psoriatic lesions in mice with an epidermal deletion of STAT3 depends on the presence of activated T cells, whereas the inflammatory responses occurring in the skin of IKK2-transgenic mice are mediated by TNF-α. This implicates an intrinsically dysregulated interrelation between keratinocytes and cells of both the innate and acquired immune response in the pathogenesis of psoriasis. Within psoriatic lesions, alterations are observed in the levels of expression of several growth factors, such as insulin-like growth factor, keratinocyte growth factor (KGF), transforming growth factor (TGF)-α, and amphiregulin, all of which stimulate basal cell proliferation in an autocrine fashion.[22] Other cytokines aberrantly elevated in psoriasis include members of the inhibitory TGF-β family, and cytokines that stimulate keratinocyte proliferation and inflammation, such as IL-19 and IL-20.[22,24] An important pathogenic role has also been uncovered for IL-36γ, a cytokine abundantly induced by IL-17 in keratinocytes, whose overexpression in mouse skin leads to a disease quite similar to human plaque psoriasis, whereas inhibition in human psoriatic skin ameliorates the inflammation.[29]

Finally, two anti-inflammatory molecules, suppressors of cytokine signaling (SOCS)1 and SOCS3, are dysregulated in psoriatic keratinocytes.[30] These efficiently suppress the IFN-γ– and TNF-α–dependent molecular cascades in keratinocytes, and it has been hypothesized that strengthening of the action of SOCS1 in keratinocytes could be a valid therapeutic approach for treatment of IFN-γ- and TNF-α-dependent skin diseases, including psoriasis.

ON THE HORIZON

- There have been significant advances in therapies for psoriasis during the past 15 years that strongly reduce both symptoms and relapse rates. New therapeutic approaches include the targeting of interleukin (IL)-17A.
- Personalized therapies based on the employment of antagonists aligned with elements of genetic risk of the patients will be likely more successful.
- Newer strategies will also need to focus on treatments that do not require continuous, long-term immune suppression (*i.e.,* strategies to restore immune regulation or tolerance).
- Future work to identify and clarify risk factors and antigenic triggers for psoriasis may lead to strategies for preventing the disease.

CONCLUSIONS

A complex interplay between environmental and genetic factors triggers a cascade of events that leads to the expression of psoriasis. Early upstream events occurring in the disease include activation of DCs and the generation of effector T cells that migrate into the psoriatic skin lesions and expand there. Cross-talk between keratinocytes and immune cells amplifies inflammation and is responsible for chronicity. Recent research has implicated many immunological mechanisms in psoriasis progression, and this has led to the development of new, pathogenesis-based therapies. Although this progress is remarkable, much remains unknown, especially regarding prevention of the condition and how to develop drugs with appropriate risk-benefit and long-term profiles. Future work must take into account these aspects to establish therapeutic and preventive approaches that lead to improved patient outcomes.

MULTIPLE-CHOICE QUESTIONS

1. The age of onset of psoriasis is most commonly:
   - **A.** First three decades of life
   - **B.** Before age 7 years
   - **C.** Middle age
   - **D.** Fifth and sixth decades of life

2. Development of psoriatic lesions at sites of skin trauma is known as:
   - **A.** Koebner phenomenon
   - **B.** Nikolsky sign
   - **C.** Auspitz sign
   - **D.** Dennie-Morgan lines
   - **E.** Triple response of Lewis

3. Early pathogenic events of psoriasis includes which one of the following:
   - **A.** Signal transducer and activator of transcription 3 (STAT3) activation in hyperproliferating keratinocytes
   - **B.** Recruitment of myeloid dendritic cells
   - **C.** Targeting of keratinocytes by proinflammatory cytokines
   - **D.** A cascade of events including formation of complexes formed by keratinocyte-derived nucleic acid and the cathelicidin LL-37

Myasthenia Gravis

Arnold I. Levinson

Myasthenia gravis (MG) is a disease characterized by weakness of striated muscles. The weakness is caused by impaired neuromuscular transmission resulting from a reduction in the number of receptors for the neurotransmitter acetylcholine (ACh) at the postsynaptic myoneural junction. In most cases, this reduction is the result of the action of anti–acetylcholine receptor (anti-AChR) antibodies. The disease occurs with a reported prevalence of 0.5–5/100 000 and an incidence of 0.4/100 000/year. Although MG can occur at any age, it typically presents in the second and third decades of life, with a later peak occurring after age 50 years (late-onset disease). A female preponderance (3:1–4:1) has been reported in the first 40 years of life; thereafter, the incidence is comparable between the sexes.

CLASSIFICATION

Patients with MG have traditionally been divided into two categories: those with generalized disease and those presenting with disease limited to the ocular muscles.[1] Within these two groups, patients can be further subdivided on the basis of age of onset. Neonatal MG affects 10–20% of offspring born to mothers with myasthenia. Disease manifestations are those of generalized MG (see below) but are transient, dissipating with the metabolism of maternal anti-AChR antibodies that had been transmitted across the placenta during the third trimester of pregnancy. Several congenital myasthenic syndromes have been described. For the most part, these manifest during the neonatal period, persist into adulthood, and are not considered to have an autoimmune basis.[2] Juvenile MG is said to occur in those patients who present with disease between 1 year of age and puberty. Apart from the age of onset, juvenile myasthenia behaves like adult MG.

Adult patients may present with ocular involvement or signs of more generalized disease. The ocular involvement is characterized by impaired ocular muscle motility and lid weakness, manifesting as diplopia and ptosis, respectively. The vast majority of patients with MG will experience ocular involvement, with roughly 50% of patients presenting with ocular signs at the time of diagnosis. Those generally at risk of disease progression are *(i)* patients with evidence of subclinical disease on electrophysiological testing of limb muscles; and *(ii)* patients who have markedly elevated titers of anti-AChR antibodies. Typically, patients with ocular symptoms for >2 years will not progress to a more generalized form of disease.

In the generalized disease group, patients can be classified into those with mild, moderate, or severe disease on the basis of clinical activity. Any skeletal muscle group can be affected, but typically the palatal, pharyngeal, and upper esophageal muscles are involved. This results in dysarthria, dysphagia, and difficulty handling secretions. Involvement of the diaphragm and intercostal muscles produces dyspnea and may lead to respiratory failure. Involvement of the muscles of the extremities and trunk occurs in 20–30% of patients at initial presentation and causes difficulties with activities of daily living. The hallmark of all muscle involvement in MG is its variability over time, with weakness usually exacerbated by repetitive use.

Furthermore, within the group of patients with generalized disease, patients are further subdivided into subtypes on the basis of age of onset, for example, early-onset MG (EOMG) and late-onset MG (LOMG) with onset before and after age 50 years, respectively. Moreover, patients can be additionally distinguished by their profiles of serum autoantibodies (see discussion of serum autoantibodies) and the presence/absence of thymic pathology (see discussion of thymic pathology).

CLINICAL PEARLS

Telltale Signs of Myasthenia Gravis

- Variable muscle weakness
- Weakness in cranial nerve distribution
- Normal reflexes and sensation

DIAGNOSIS

The differential diagnosis is extremely broad, encompassing neuropathies, primary and secondary myopathies, muscular dystrophy, demyelinating disorders, degenerative diseases, cerebrovascular accidents, mass lesions, and infectious diseases. The clinical features that point to a diagnosis of MG include the variable nature of the muscle weakness, normal sensation, and normal deep tendon reflexes. The diagnosis can usually be confirmed by pharmacological and electrophysiological testing. A decremental pattern is characteristically seen following repetitive nerve stimulation (Fig. 65.1), and this pattern is normalized following treatment with the anticholinesterase agent tensilon. Further confirmation rests on detecting anti-AChR antibodies, which are found in 85–90% of patients with generalized disease. In the standard assay, sera are reacted with a nicotinic AChR preparation labeled with ^{125}I-α-bungarotoxin, a snake venom polypeptide that binds irreversibly to the receptor. Bound antibodies are immunoprecipitated by an antiimmunoglobulin reagent or staphylococcal protein A, and the quantity of antibodies detected is expressed in terms of the amount of α-bungarotoxin bound.

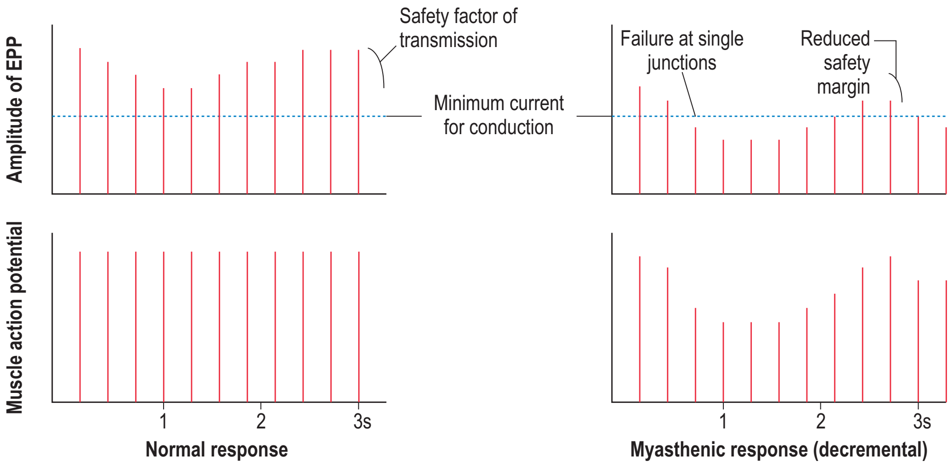

FIG 65.1 Neuromuscular Transmission in Normal and Myasthenic Subjects. With repetitive stimulation there is a reduction in the efficiency of acetylcholine (ACh) release, with a subsequent recovery in efficiency as the train of stimuli continues. Although the endplate potential (EPP) fluctuates at the normal junction, sufficient current is generated to stimulate an action potential of constant magnitude. At the myasthenic junction, however, the amplitude of the EPP in response to a given amount of ACh is reduced. Under conditions of inefficient ACh release, for example, repetitive stimulation, the minimum current for conduction is not generated, resulting in a profile of action potentials that shows a progressive decline or "decrement" with subsequent recovery.

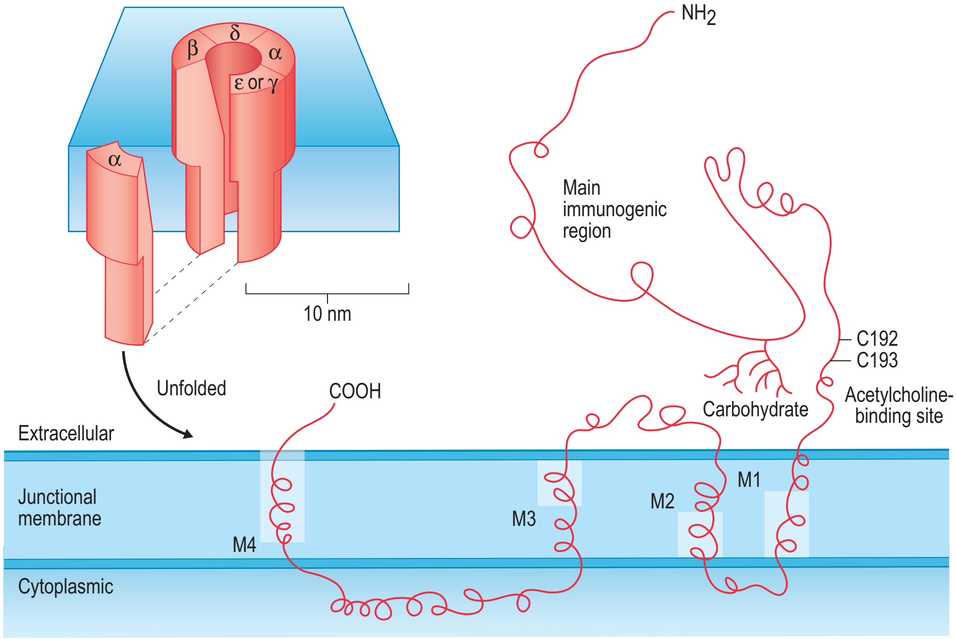

FIG 65.2 The Acetylcholine Receptor. The subunits of the acetylcholine receptor—α, β, δ, and γ or ε—are arranged like barrel staves around the central ion pore. Each subunit winds through the junctional membrane four times (sites M1, M2, M3, and M4). In the unfolded view of the α subunit, the amino-terminal end of the α subunit is extracellular, where it is accessible to acetylcholine, which binds at the site shown (amino acids 192 and 193). In myasthenia gravis, autoantibodies may bind to various epitopes of all subunits, but a high proportion of autoantibodies bind to the main immunogenic region of the α subunit.

ACHR STRUCTURE

The nicotinic acetylcholine receptor (nAChR) is a member of a larger family of ligand-gated ion channels. The muscle-type receptor, which is involved in myasthenia, can be subclassified further into mature junctional receptors and immature, extrajunctional, or denervated receptors. The nAChR at a mature myoneural junction is composed of four subunits, labeled α, β, δ, and ε (Fig. 65.2). In fetal muscle and adult denervated muscle or nonjunctional membrane, a γ subunit replaces the ε subunit found in mature innervated muscle endplates. This form of the receptor differs from the mature junctional form by its lower density (500 receptors/μm^2) and its distribution over most of the surface of the sarcolemma. The immature receptor also has a lower conductance, a longer open time, a more rapid turnover, and a decreased half-life.

The genes for the α, δ, and γ subunits are located on chromosome 2 in humans, and subunits β and ε on chromosome 17. The subunits of the AChR are homologous to each other and to their counterparts across species, with the greatest conservation of sequence being in the α subunit. Two α subunits and one of each of the other subunits are assembled to form an asymmetrical hourglass channel spanning the membrane. Each subunit has a large amino-terminus located extracellularly, four transmembrane regions, and a short cytoplasmic tail formed by a loop between the third and fourth transmembrane domains. The receptor appears as a dimer as a result of disulfide bonding between the δ subunits of two receptors. The two α subunits are not contiguous in each receptor but are separated by another subunit. One ACh-binding site is found on each of the α subunits around the pair of cysteines at amino acids 192 and 193. The binding of ACh to the α subunits is believed to engender a conformational change, possibly resulting in rearrangement of charged groups. The binding of ACh to both α subunits increases the probability of transition of the channel to an open conformation. Binding of curare or α-bungarotoxin to the α subunits blocks this channel.

In normal innervated neuromuscular junctions, there are two forms of the AChR, the predominant form having a long half-life, and a small subset that is rapidly turned over. The rapidly turned-over receptors are the precursors of the stable receptors. It is not clear how these two types differ or how they are regulated. The receptors are concentrated at the top of the folds in the muscle endplate, adjacent to the nerve terminus, at a density of 10 000/μm^2. This localization reflects the action of agrin, a nerve-derived synaptic organizing molecule. The AChRs are organized into clusters by rapsyn, a 43-kilodalton (kDa) cytoplasmic protein. The clustered AChRs are linked to the cytoskeleton by connections between rapsyn and a dystrophin–glycoprotein complex.

NEUROMUSCULAR TRANSMISSION

When an impulse is transmitted along an axon terminal, it results in the release of the neurotransmitter ACh across its presynaptic membrane (Fig. 65.3). ACh diffuses across a 50-nm synaptic cleft, where it interacts with AChRs, which are displayed in greatest density at the tops of the junctional folds of the postsynaptic muscle membrane or endplate. This interaction leads to a local depolarization or endplate potential caused by increased membrane permeability to sodium and potassium. The endplate potential is terminated by acetylcholinesterases, which are present in highest concentrations in the synaptic cleft around the junctional folds. If the summation of endplate potentials attains a prescribed threshold, it produces an action potential that depolarizes the surrounding sarcolemma and causes muscle contraction. In a healthy individual, the arrival of an impulse at the presynaptic membrane of a motor nerve releases considerably more ACh than is required to generate an action potential. This reserve, roughly four times the current needed for propagation of the impulse, is referred to as the *safety factor of neuromuscular transmission.* Because of the severe reduction in receptor number in MG, the electrical threshold for propagation of an action potential cannot be attained and muscle contraction is prevented. With a less severe reduction in receptor numbers neuromuscular transmission may proceed normally unless the efficiency of presynaptic vesicle release is compromised, as occurs with repetitive use of muscles. The combination of decreasing availability of ACh and the reduced number of receptors accounts for the characteristic decremental nerve conduction pattern seen on electromyograms of patients with MG following repetitive nerve stimulation (see Fig. 65.1).

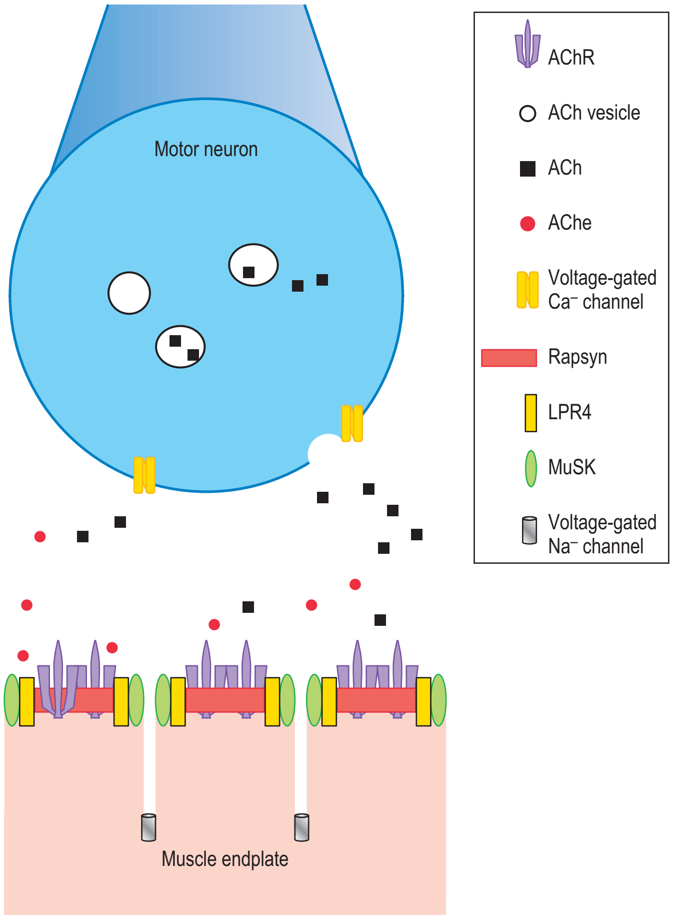

FIG 65.3 **Schematic Representation of the Myoneural Junction.** Vesicles of acetylcholine (ACh) release their contents at active zones across from acetylcholine receptors (AChRs) in response to impulses conducted down nerve axons. ACh diffuses across synaptic cleft and binds to AChRs, with opening of the ion channel and the generation of endplate potential. Action potential is propagated to muscle when sufficient amplitude of summated endplate potentials is attained. MuSK, muscle-specific tyrosine kinase.

IMMUNOPATHOGENESIS OF MG

KEY CONCEPTS

Involvement of Anti–Acetylcholine Receptor (AChR) Antibodies in the Pathogenesis of Myasthenia Gravis (MG)

- AChR antibodies are found in the serum of 85–90% of patients with MG.
- Infants born to mothers with myasthenia sometimes develop MG.
- Immunoglobulin G (IgG) and complement are deposited at the postsynaptic junction.
- Transfer of serum IgG from patients with MG to mice induces neuromuscular blockade.

Anti-AChR antibodies are detected in 85–90% of MG patients and are responsible for the impaired neuromuscular transmission.[3] There are several lines of evidence to support this contention. Immunoglobulin G (IgG), along with C3 and the terminal attack complex (C5–C9), is deposited at AChR-containing areas of the postsynaptic membrane, and anti-AChR/AChR complexes can be extracted from the muscles of patients with MG. Transfer of myasthenic serum from mother to fetus, or from human to mouse, results in symptoms or signs of myasthenia in the recipient. Plasmapheresis, which decreases anti-AChR antibody levels, is associated with clinical improvement.

Properties of Anti-AChR Antibodies and Characterization of B-Cell Epitopes

Anti-AChR antibodies are produced by a small subset of B cells in affected people. The frequency of IgG-producing AChR-specific peripheral blood mononuclear cells is estimated to be 1 in 15 000–70 000. IgG anti-AChR–secreting cells are also found in the peripheral blood of healthy volunteers, albeit in much lower numbers. The proportion of immunoglobulin producing AChR-specific B cells or plasma cells is greater in the germinal centers of hyperplastic thymuses, but still only 1 in 1000–10 000 antibodies produced is AChR specific. Anti-AChR antibodies are predominantly IgG1 and IgG3, but IgG2 and IgG4 isotypes have also been found. IgA and IgM anti-AChR antibodies are present in some patients, but never in the absence of IgG anti-AChR antibodies. The IgA and IgM anti-AChR antibodies tend to appear in patients whose disease is of longer duration and greater severity and in association with high IgG anti-AChR titers.

The pathogenic anti-AChR antibodies in MG are thought to be directed to conformationally dependent structures. Immunization of animals with irreversibly denatured AChR leads to the formation of anti-AChR antibodies capable of binding to native AChR, but the antibodies are not capable of causing disease. This observation indicates that conformationally dependent epitope(s) are important in the induction of disease. Many of the anti-AChR antibodies are directed against the α subunit, particularly to a small region on the extracellular portion referred to as the *main immunogenic region*[4] (see Fig. 65.2). Approximately 60% of the anti-AChR antibodies are directed against this region, which encompasses a set of overlapping epitopes clustered around amino acids 67–76 of the α subunit.[5] The reason for the predominant role of the α chain in the antibody response in myasthenia is not known. Not all disease-producing antibodies in humans or rats appear to be directed to this region. Many patients also have antibodies recognizing the γ-containing embryonic form of AChR. This observation has spawned speculation about a nonmuscle source of sensitization.

Anti-AChR Antibody Levels and Relationship to Disease Activity

The relationship of anti-AChR antibody and disease activity in MG is complicated. In general, serum levels of anti-AChR antibody or anti-AChR/AChR complexes correlate poorly with disease severity. Among patients within one clinical grade, anti-AChR antibody levels can vary by several orders of magnitude. In addition, approximately 10–15% of patients with clinical MG have no anti-AChR antibody by standard assays. Anti-AChR antibodies are more likely to be present if the disease is generalized or severe. In addition, in an individual patient an increase or decrease in anti-AChR antibody levels often accompanies deterioration or improvement, respectively, in clinical activity.

As the quantity of anti-AChR antibodies produced does not fully explain disease severity, studies have also focused on qualitative differences in these antibodies among different patients. These studies, however, have not been able to distinguish properties of anti-AChR antibodies that lead to greater pathogenicity. Differences in specificity and avidity of binding to AChR have not been associated with particular functional effects or disease severity. Anti-AChR antibodies that bind or compete for the same region of AChR can have different functional effects (see anti-AChR blocking antibody discussion). Anti-AChR antibodies show extensive heterogeneity by isoelectric focusing, but this characteristic also does not correlate with pathogenic potential.

Patients previously classified as seronegative have been found to have low-affinity AChR-specific IgG antibodies when their sera were tested with very sensitive assays that rely on tissue substrates on which the receptors are aggregated.[6,7] Antibody binding was facilitated by the high concentrations of AChRs, which compensate for the low affinity of the autoantibodies. Like the anti-AChR antibodies in classic anti-AChR antibody-positive MG, these antibodies belong largely to the IgG1 subclass. Like the conventional antibodies, the low-affinity antibodies also bind complement.

As noted above, 10–15% of MG patients are persistently antibody negative. Approximately 50% of these patients have been discovered to have serum IgG antibodies specific for *mu*scle-*s*pecific tyrosine *k*inase (MuSK).[7,8] This skeletal muscle receptor tyrosine kinase is activated by agrin and is critical for formation of the neuromuscular junction. Originally, anti-MuSK antibodies were found in patients with marked facial and bulbar weakness, including tongue weakness and respiratory involvement with relative sparing of upper- and lower-extremity muscles. Ophthalmoparesis was also seen but was not a first symptom in at least one series of patients. Subsequently, it has become apparent that patients with anti-MuSK antibodies can also have a more traditional clinical phenotype similar to that seen with anti-AChR patients. Patients often respond poorly to anticholinesterase agents and benefit greatly from plasmapheresis but only modestly from intravenous immunoglobulin (IVIG). They typically lack thymus pathology and, not surprisingly, thymectomy is not typically beneficial. Most anti-MuSK antibodies are of the non–complement-fixing IgG4 isotype. Anti-MuSK antibodies do not cause destruction of the muscle endplate, as might be expected because of their inability to activate the classical complement pathway and reduced capacity to bind activating Fcγ receptors on monocytes and macrophages. However, they have been shown to affect AChR clustering on cultured myotubes. The clinical relevance of these autoantibodies is underscored by the appearance of a myasthenic illness in animals either immunized with MuSK or infused with serum antibodies from patients with anti-MuSK antibody–associated MG.

IgG antibodies specific for lipoprotein-related protein 4 (LRP4) have also recently been discovered in the sera of patients with anti-AChR antibody–negative MG.[7,9] LRP4 is an important component of the neuromuscular junction, which serves as a receptor for agrin and which is required for agrin-induced activation of MuSK and AChR clustering. The prevalence of reactivity to LRP4 varied from 2–50% of patients who are negative for anti-AChR and MuSK antibodies (double seronegative), with the differences possibly being related to geography or ethnicity.

Anti-LRP4 antibodies were found in the sera of 3% of patients with anti-MuSK antibodies in one study but otherwise were limited to double-seronegative (anti-AChR$^-$/anti-MUSK$^-$) patients. Anti-LRP4 antibodies were not present in the sera of a large number of patients with other neurological diseases with the exception of neuromyelitis optica spectrum disorder, where 12.5% of patients had anti-LRP4 antibodies. If larger studies demonstrate that anti-LRP4 antibodies are found in patients with MG but without anti-AChR or MuSK antibodies and are rare in other neurological disorders, this test could become important in the diagnosis of MG.

MG sera also contain antibodies reacting with the ryanodine receptor.[7] These receptors, which are critically involved in muscle contraction, are Ca^{2+} release channels located in the sarcoplasmic reticulum of striated muscles. Antibodies to ryanodine receptors are found in 50% of patients with MG who have thymoma, and patients with high levels have a worse prognosis than do antibody-negative patients with MG who have thymoma. *In vitro* studies have suggested a pathogenic role for these autoantibodies in MG.

Antirapsyn antibodies have been detected in a small subset of patients with MG.[7] Seropositive patients with MG are indistinguishable from seronegative patients with regard to clinical and laboratory features of disease. The presence of antirapsyn is not specific for MG, having been detected in the sera of an occasional patient with MS and a majority of the patients with lupus tested.

Antiagrin antibodies have recently been reported, often in MG patients with anti-AChR or anti-MuSK antibodies and occasionally in patients with MG who are “triple seronegative” (AChR$^-$ MuSK$^-$ LRP4$^-$).[7] Studies of larger numbers of patients will be necessary to determine the prevalence of antiagrin antibodies in triple seronegative MG patients and their degree of specificity for MG.

Patients with MG associated with thymoma show distinct patterns of antibody production. Almost all patients with thymoma are anti-AChR antibody positive, and most produce antistriational antibodies.[9] These latter antibodies react with titin, a giant filamentous protein of striated muscle. Titin filaments are involved in muscle assembly and contribute to the muscle’s ability to recoil following stimulation. Such antistriational antibodies are also found in approximately 50% of the sera of older patients with MG who have thymic atrophy but not thymoma; however, they are not frequently detected in patients with early-onset disease and thymic hyperplasia. The finding of antistriational antibodies in a patient with MG who is less than 40 years old strongly suggests the presence of thymoma. There is no evidence that antistriational antibodies are involved in muscle weakness.

Pathogenic Effects of Anti-AChR Antibodies

KEY CONCEPTS

- Effects of anti–acetylcholine receptor (AChR) antibodies in myasthenia gravis pathology
  - Reduced number of receptors
  - Widening of the synaptic cleft
  - Distorted geometry of the synaptic membrane
- Mechanism of damage
  - Complement-dependent damage to muscle endplate
  - Enhanced rate of AChR degradation
  - Block cholinergic binding sites

Complement-Mediated Damage

The critical problem in MG is the anti-AChR antibody–mediated reduction in the number of nAChRs at the myoneural junction. There are several possible mechanisms by which the anti-AChR antibodies could lead to impaired neuromuscular transmission.[10] Ultramicroscopic studies show marked destructive changes in some endplates, particularly at the peaks of the postsynaptic folds, where AChR is usually present in the greatest concentration. The architecture of the muscle endplate is simplified, with loss of junctional folds and widening of the synaptic cleft that contains membrane debris. C3, C9, and the membrane attack complex are deposited at the muscle endplate, suggesting a role for complement in membrane destruction.[11] Indeed, in many patients, anti-AChR antibodies can fix complement *in vitro* when bound to skeletal muscle and can damage cultured rat myotubes with a resultant decrease in AChR content.

Although antibody-directed, complement-mediated destruction is important in the pathophysiology of MG, it is not the entire story. The rapid clinical improvement in MG following certain therapeutic interventions and the lack of destructive changes in many neuromuscular junctions of symptomatic areas despite prominent immunoglobulin deposition suggest that a more readily reversible process is also likely to be involved in the neuromuscular block.

Acceleration of AChR Degradation

In vitro and *in vivo* studies have shown that anti-AChR antibodies can accelerate the rate of degradation of extrajunctional and junctional receptors, respectively.[12] This reaction is complement independent and results from the endocytosis of AChRs via shallow depressions, presumably clathrin-coated pits. Other membrane receptors are not affected. Both stable and rapidly turned-over receptors appear to be affected, thereby explaining the greater than expected antibody-mediated loss of AChRs observed at neuromuscular junctions. The reaction requires cross-linking of adjacent AChRs, as it can be mediated by $F(ab')_2$ fragments, but not Fab fragments, of anti-AChR antibodies. The effect of antibody on the synthesis of new AChR is controversial.

Receptor Blockade

The inhibition of ACh binding has been assessed by studying the effects of MG serum on the binding of the neurotoxin α-bungarotoxin to AChRs. Such blocking antibodies are found in a variable number of MG sera. Blockade has been generally attributed to steric hindrance of the ligand-binding site, rather direct binding to the ACh-binding site.[13] The importance of these antibodies in the pathophysiology of MG remains unclear. However, in one study the functional ability of an individual serum to accelerate degradation and cause blockade of AChRs paralleled most closely the clinical status of the patient. The *in vivo* significance of such antibodies has also been demonstrated by passive transfer of certain rat monoclonal anti-AChR antibodies into chicks. Complete paralysis was observed within 1 hour of the transfer, presumably before there was time for complement-mediated damage. It has been reasoned that in patients with MG, such blocking antibodies could further diminish synaptic function already decreased owing to complement-mediated damage or accelerated receptor degradation. This could result in acute clinical deterioration or a rapid clinical improvement after plasmapheresis, before the repair of damaged membrane and regeneration of new AChRs.

Role of T Cells

An overwhelming body of data indicates that anti-AChR antibody production in patients with MG and rodents with experimental autoimmune myasthenia gravis (EAMG) is dependent on the activity of CD4 T cells. Researchers have used freshly isolated CD4 T cells, T-cell lines and T-cell clones stimulated with AChR purified from the electric organs of *Torpedo californica* (T-AChR), recombinant human AChR, human AChR concentrated on immunomagnetic beads, and synthetic AChR peptides. Most of the T cells derived from patients with MG have responded to the complete AChR or the α subunit, but responses to the δ, ε, and γ subunits have also been demonstrated.[14] Unlike EAMG, a T cell–immunodominant epitope has not been found in humans. However, T cells from most patients recognize a limited number of AChR sequences. In an individual patient, T cells reactive with a particular AChR epitope can show limited T-cell receptor Vβ (TCR Vβ) usage, but the same TCR Vβ usage has not been observed for different patients. A range of major histocompatibility complex (MHC) class II molecules can present AChR epitopes. This is not surprising, given the degenerate binding capabilities of MHC molecules needed to present an extremely large and diverse group of peptides to the immune system. T cells from normal controls respond to some of the same epitopes to which MG patients' T cells respond, albeit in smaller numbers and less vigorously.

EXPERIMENTAL AUTOIMMUNE MYASTHENIA GRAVIS

The serendipitous discovery that rabbits injected with purified AChR developed not only anti-AChR antibodies but signs of MG provided the evidence for the pivotal role of antibodies in this disease and paved the way for the development of an experimental model of human MG.[15] EAMG has been studied in a number of different animal species.[16] It is generally induced by immunizing animals with AChR purified from the electric organs of *T. californica* emulsified in adjuvant. Disease can also be passively transferred by immunoglobulin from affected animals or from patients with myasthenia. Animals suffer from fatigue, hypoactivity, weight loss, paralysis, difficulty breathing, and dysphagia; these signs are reversible with anticholinesterases. There is a decremental response to repetitive nerve stimulation on electromyography in EAMG as in MG. Anti-AChR antibodies are present, and most are directed against the main immunogenic region (see Fig. 65.2). They are deposited along with complement at the muscle endplate. Similar to the pathology in humans, there is simplification of the muscle endplate and a loss of AChR content of muscles in the experimental disease. A major difference between the induced rodent models of EAMG and spontaneous human MG is the absence of thymic pathology in the former.

In murine models, there are disease-resistant and disease-susceptible strains. The MHC determines this susceptibility, in part, with specific H-2 alleles being associated with susceptibility or resistance. However, even in the high-responder strains, only 50–70% of immunized animals manifest disease. This lack of concordance remains to be fully explained. Differences in the level of complement activation and the physiological safety factor of neuromuscular transmission may partly account for the variability in disease expression.

Most immunized animals demonstrate anti-AChR antibodies, whether or not they develop EAMG. Induction of pathogenic antibody production requires the integrity of the three-dimensional structure of the receptor, as immunization with denatured AChR elicits antibody production but not disease, even in susceptible animals. Anti-AChR antibody levels correlate with anti-AChR/AChR complexes and with the AChR content of the muscle, but not with clinical disease severity. No characteristic feature distinguishing disease-producing and nonpathogenic autoantibodies has been defined. Antibodies in rats with and without disease are predominantly of the same immunoglobulin isotope and subclass, express similar clonotypic heterogeneity, and show similar avidities. The percentage of antibodies that recognize the native receptor (as opposed to the foreign eel receptor immunogen) is low (0.2–2%) but similar between the symptomatic and the asymptomatic mice. The percentage of antibody directed against the main immunogenic region of AChR is also similar. The antibodies that develop in asymptomatic animals can bind and cause a decrease in receptor half-life, as well as those that develop in paralyzed animals. In fact, EMG abnormalities can be demonstrated in mice that appear disease free. An analogous situation in humans may be the high frequency of single fiber EMG abnormalities in asymptomatic family members of patients with MG. Importantly, antibodies from affected animals will cause disease in resistant strains, indicating that disease differences between strains is not caused by differences in the AChR receptor itself.

Although EAMG is mediated by autoantibodies, it is a T cell–dependent process. Examination of T-cell responses in rats and mice has shown that EAMG requires the action of CD4 T cells. These cells recognize immunodominant T-cell epitopes located on the α subunit. The T-cell responses to the immunodominant epitope in rats involve a variety of TCRVβ and Jβ gene segments (Chapter 4). However, in susceptible C57BL/6 mice, there is a predominant use of the TCRVβ6 family in the CD4 T-cell response. CD4 T cells in susceptible and resistant strains recognize different immunodominant AChR α-chain epitopes.[17]

Early reports suggested that AChR-reactive T-cell clones did not fit neatly into T-helper-1 (Th1) and Th2 subsets. However, later studies suggested that interferon-γ production by Th1 cells is essential for the development of disease and that IL-4 may subserve a protective role.[16,18] In addition to interferon-γ, tumor necrosis factor (TNF)-α, interleukin (IL)-6, IL-12, IL-18, IL-1, IL-5, and IL-10 have been reported to promote the development of EAMG. However, a more recent publication indicated that C57BL/6 mice genetically deficient in IL-12/IL-23 and IFN-γ are susceptible to experimental EAMG, suggesting a pathogenic role of non-Th1 cells. This result led the authors to suggest that AChR-specific Th17 cells may also contribute to the pathogenesis of this experimental autoimmune disease.[19] Subsequently, Th17 cells were, indeed, shown to be important in the pathogenesis of EAMG.[20]

The roles of a number of costimulatory factors have also been investigated in EAMG. CD28/B7 and CD40/CD40L appear to be required for the development of the primary immune response to AChR. An interaction between ICOS and B7RP-1 may play an important role in the secondary response and/or in the maintenance of the immune response to this autoantigen.

THE THYMUS IN MYASTHENIA GRAVIS

Several lines of evidence have suggested that the thymus is directly linked to the pathogenesis of MG.

KEY CONCEPTS

Pathogenic Roles of the Thymus in Myasthenia Gravis (MG)

- Pathological
  - 65–75% of patients with MG have follicular hyperplasia with germinal centers
  - 10% have thymoma
- Clinical
  - Improvement following thymectomy
- Immunological
  - Acetylcholine receptor (AChR) subunits expressed on myoid cells and thymic epithelial cells
  - AChR-reactive T and B cells localized in the thymus
  - Increased thymic AChRα expression
  - Anti-AChR antibody secreted by thymic B-lineage cells
  - Decreased thymic T regulatory cell (Treg) function
  - Interleukin (IL)1-β, IL-6, CXCL13, CCL21, and B cell–activating factor (BAFF) overexpressed in thymus

Thymic Pathology

Interest in a primary role for the thymus in the pathogenesis of MG has been fueled by pathological, clinical, and immunological lines of evidence, although the nature of its involvement remains to be elucidated.[21-24] The thymus is pathologically abnormal in 80–90% of patients with MG. The majority of patients (65–75%) have thymic follicular hyperplasia with germinal center formation. The architecture of the hyperplastic thymi is generally preserved, with well-demarcated cortical and medullary regions. However, the medulla is crowded by numerous germinal centers that display the architectural features and cellular constituents of germinal centers in the secondary follicles of peripheral lymph nodes from normal individuals. Although these germinal centers in patients are generally thought to occupy an intraparenchymal position, some observers feel that they may actually lie extraparenchymally in the perivascular space.

Thymomas are seen in approximately 10% of patients with MG who tend to be older than those with hyperplastic thymi.[21-24] The thymomas are characterized by a loss of cortico-medullary demarcation and consist largely of neoplastic epithelial cells admixed with thymocytes. The affected epithelial cells belong to the cortical epithelial compartment, and the thymocytes have the immunophenotypic properties of normal immature cortical thymocytes.

Further evidence for a pathogenic role of the thymus comes from the results of empiric trials of thymectomy. Despite the absence of controlled clinical trials until recently,[25] there was general agreement in the past that removal of the thymus, particularly in young patients with follicular hyperplasia, leads to clinical improvement. The underlying basis of this improvement remains unknown.

Intrathymic Factors Possibly Contributing to Local Anti-AChR Antibody Response

The MG thymus, particularly hyperplastic thymus, is characterized by several unique features that strongly suggest its primary role in the immunopathogenesis of MG.[21-24] The thymus contains important constituents necessary for and indicative of an immune response directed against nAChRs. There is considerable evidence that resident cells in the thymus, including myoid cells and medullary epithelial cells, express various subunits of AChR including the α subunit. Additional factors found uniquely in hyperplastic MG thymus include increased expression of chemokines that attract immigrant CD4 T and B cells (CXCL13, CCL21); the presence of nAChR-reactive B and CD4 T cells; cytokines that can facilitate B-cell activation, differentiation, and survival (IL1β, IL6, APRIL, BAFF); anti-AChR antibody–secreting plasma cells; and possibly decreased $CD4^+CD25^+$ T regulatory cell function.[21-24]

As yet, it is not known whether or how such perturbations of the thymus lead to a breach in self-tolerance and the induction of anti-AChR antibodies, although there is mounting evidence that an antecedent inflammatory reaction in the thymic medulla may serve as the initiating trigger. An understanding of this enduring mystery likely holds the key to unlocking the immunopathogenesis of this disease. The reader is referred to other works for an in-depth discussion of this topic.[22,24,26]

ETIOLOGICAL FACTORS

Genetic Factors

As in most autoimmune diseases, the MHC represents an important genetic susceptibility locus for the development of MG. Studies indicate that the extended human leukocyte antigen (HLA)-A1-B8-DR3 haplotype is associated with EOMG and hyperplastic thymus in Caucasian individuals. This haplotype has been associated with the development of other autoimmune disorders. An association with HLA-B7-DR2, although weaker, has also been described in patients with onset of MG occurring after the age of 40 years and associated with atrophic thymic histology. However, the strongest association, focused on a Norwegian population of patients with late-onset MG, was recently shown to be the DRB1*15:01 allele. A recent study found a strong association between the HLA-DQ5 allele and patients with anti-MuSK antibody–positive MG. Interestingly, the MuSK-positive T-cell repertoire appears to be skewed to the usage of this HLA MHC class II allele. In murine studies, the MHC class II molecules I-A^b and I-E^k have been associated with susceptibility to EAMG.[16] In EAMG, the permissive MHC class II molecules are capable of binding AChR peptides that are recognized by antigen-specific CD4 T cells.

Studies have also addressed the potential genetic contributions of other immune system–related genes in the pathogenesis of MG. An association has been reported for a particular IL-1β allele and MG and increased serum levels of this cytokine have been reported. This was most pronounced in patients who lacked disease-susceptible HLA genes. Several groups have reported an association between MG and the presence of particular TNF-α polymorphisms. The expression of a high-transcription TNF-α allotype, TNF-α-308 allele 2, correlated with EOMG. In this regard, patients with MG demonstrate increased serum levels of TNF-α and their peripheral blood mononuclear cells display increased expression of TNF-α messenger RNA (mRNA). Polymorphisms in the IL-10 promoter region have been reported to be associated with distinct patterns of thymic histology. No correlations have been made between IL-4 alleles and MG. Allotypic markers on IgG and FcγRIIA receptors have been associated with the coexistence of MG and thymoma. A single nucleotide polymorphism in the gene encoding the intracellular tyrosine phosphatase PTPN22, which has been associated with the risk of developing other autoimmune diseases, has also been identified in both a subgroup of patients with anti-titin antibody–positive nonthymomatous MG and patients with thymomatous

MG.[27,28] The risk of developing MG has also been linked to a polymorphism in the promoter region of *CHRNA1,* the previously mentioned gene that encodes the α subunit of AChR and *CHRND,* the gene that encodes the δ subunit.[22] It has been proposed that such polymorphisms in genes encoding autoantigens cause reduced expression of AChRα on thymic medullary epithelial cells, thereby impairing central deletion of autoantigen-specific thymocytes. Additional MG-associated risk factors include polymorphisms in *CTLA4*, type II, *IFNII*, *IL12*, *CD86, AKAP12, VAV1, BAFF, TCF19,* and *TNIP* genes.[22,23]

Exogenous Factors

Whether or not sensitization to AChR occurs in the thymus or the periphery, the stimulus for this autoimmune response remains a conundrum. Moreover, it remains to be determined whether the stimulus is a self-antigen (AChR) or a foreign antigen that mimics the receptor's molecular structure. In this regard, several examples of molecular mimicry between AChRα chain and other molecules have been reported. Studies carried out with certain monoclonal anti-AChR antibodies demonstrated epitope sharing between the receptor and several bacteria, including *Klebsiella pneumoniae, Escherichia coli, Proteus vulgaris,* and *Yersinia enterocolitica.*[29] However, for the most part, no difference was observed in the binding of polypeptides from these organisms by either sera from patients with MG or control sera. A computer search of protein banks revealed a sequence homology between AChRα chain and a short peptide in herpes simplex glycoprotein D,[30] although the significance of this finding is unknown. Finally, similarities were reported between idiotypic determinants on anti-AChR antibodies and antibodies reactive with α1,3-dextran. Interestingly, antidextran antibodies were detected in approximately 13% of patients with MG but rarely in normal controls.[31] α1,3-Dextran is found in the cell walls of several common enteric pathogens and thus represents a potential ubiquitous source of immunogen. This type of idiotypic network connectivity led the investigators to postulate that an unregulated antiidiotypic response to anti-α1,3-dextran antibodies might lead, in certain individuals, to an anti-AChR antibody response. Unfortunately, there has been no follow-up to these observations.

A striking association has been reported between the development of MG and treatment with the drug penicillamine,[32,33] particularly in individuals with HLA-DR1. MG developed in patients with rheumatoid arthritis and patients with Wilson disease treated with this agent. After discontinuation of penicillamine, resolution of MG symptoms was reported in some patients but not others. Penicillamine treatment was associated with the development of anti-AChR antibodies that appeared to have the same type of specificity profile as found in idiopathic myasthenia. Additional evidence suggests that penicillamine may directly interfere with neuromuscular transmission. Although penicillamine has been shown to have diverse effects on the immune response in the normal host and has reactive sulfhydryl groups capable of modifying self-antigens, its role in the development of MG remains to be determined.

Currently, considerable attention is being focused on the role of epigenetic mechanisms to explain how environmental factors may promote the development of autoimmune diseases. Although some key epigenomic mechanisms, such as DNA methylation, histone acetylation, and microRNAs, have been demonstrated to possibly play a pathogenic role in several autoimmune disorders, the analysis of these factors is at a rudimentary stage in MG. To date, there is evidence to support an association between miR155 and the development of EOMG and human MG. An interesting story has emerged concerning miR150-P. Increased levels of this miRNA were found in the serum of patients with MG, and these levels fell in association with the clinical improvement that followed thymectomy.[34] A decrease in miR320a was observed in the peripheral blood mononuclear cells of a cohort of Chinese patients.[22] This finding was associated with increased levels of a number of proinflammatory cytokines. Further studies of the role of miRNAs will need to be conducted to elucidate whether they contribute to the immunoregulatory abnormalities seen in MG.

TREATMENT OF MYASTHENIA GRAVIS

THERAPEUTIC PRINCIPLES

- Anticholinesterase agents
- Corticosteroids
- Thymectomy
- Plasmapheresis
- Immunosuppressive agents
- Intravenous immunoglobulin

Therapeutic intervention in MG usually proceeds in a stepwise manner, beginning with anticholinesterase agents.[35] Most of the experience dealing with therapeutic modalities is based on treating patients with anti-AChR-associated MG.

Anticholinesterases

Anticholinesterases are the mainstay of treatment. These agents protect acetylcholine from hydrolysis by cholinesterase, thereby increasing the amount of neutrotransmitter and the number of contacts with the reduced number of receptors at the postsynaptic junction. This, in turn, raises the probability of attaining the necessary threshold for neuromuscular transmission. In addition, some of the anticholinesterase agents have a direct agonist effect at the postsynaptic junction. The three most popular agents in this group are neostigmine bromide (Prostigmin), pyridostigmine bromide (Mestinon), and ambenonium chloride (Mytelase). Although there are only slight differences between these agents, Mestinon remains the most commonly used. It has an onset of action of 30–60 minutes, peak action at about 2 hours, and loss of activity after 4 hours. Adverse effects of these agents are caused by excessive stimulation of nicotinic and muscarinic receptors. Auxiliary drugs that have been purported to have a salutary effect on neuromuscular transmission are ephedrine and xanthine derivatives (theophylline), which are thought to increase the presynaptic release of ACh. The minimal effect of their added benefit has not warranted their common usage. As mentioned previously, anticholinesterase agents often are not beneficial in patients with anti-MuSK-antibody–associated MG and may even exacerbate weakness. These agents neither induce sustained remission of symptoms nor impede disease progression.

Thymectomy

Another mainstay in the therapy of the adult with generalized MG is thymectomy.[36,37] The benefit is greatest in younger patients and those with thymic hyperplasia, although many centers include older patients as well. Over many years, despite the absence of a controlled study, there was general agreement that removal of the thymus leads to clinical improvement, particularly in young patients with follicular hyperplasia. In one study, 90% of patients were asymptomatic or in complete remission within a few years of thymectomy, and 46% were off all medications. An international multicenter controlled trial completed recently compared clinical outcome in patients with MG treated with corticosteroid versus those treated with corticosteroid plus thymectomy and those receiving thymectomy demonstrated a more favorable clinical outcome.[25] With improvements in preoperative care, anesthesia, surgical technique, and postoperative care, thymectomy has become a safe procedure, but its value and safety in children and older patients is less well established. There is still some controversy over what represents the best surgical procedure. The mechanism responsible for the salutary effect of thymectomy remains to be elucidated. No obvious effects on immunoregulatory mechanisms have been demonstrated, although anti-AChR titers tend to fall months after the procedure. Thymectomy is also the recommended treatment for patients of all ages suspected of having thymoma.

Corticosteroids

Corticosteroids are used in patients with generalized MG who fail to respond to anticholinesterase agents or thymectomy and in patients needing optimization of their clinical condition in preparation for thymectomy.[38] They are generally not used as first-line agents to replace thymectomy but are used in patients with ocular myasthenia who fail to respond to anticholinesterases. Corticosteroids are initially given on a daily basis, with therapy initiated in a hospital. This cautious approach is followed because of the fear of clinical deterioration that may occur in some patients during the introduction of corticosteroids. This concern resulted in some groups advocating initiation of alternate-day therapy, which is not typically associated with clinical deterioration and can be carried out on an outpatient basis. Daily corticosteroids are usually started in patients with generalized MG at a dose >1 mg/kg prednisone. Patients should be continued on this dose until clinical improvement is maintained for several days, then gradually weaned off, and switched to alternate-day therapy. With improvement sustained over several months, an effort should be made to reduce the dose (usually in 5-mg decrements) administered on alternate days. Although a Cochrane review underscored the dearth of controlled trials, the improvement rate is generally estimated to be 60–90%.[39] Complete remission is rare, and most patients will require some dose of steroids indefinitely. The physician should be alert to the possibility that anticholinesterase requirements may decrease as the patient responds to corticosteroids.

Plasmapheresis

Plasmapheresis has enjoyed popularity since its introduction as an auxiliary treatment modality in patients with generalized MG in 1976, particularly as a temporizing measure.[40] It appears to be most beneficial in patients in myasthenic crisis and in those experiencing progressive deterioration despite treatment with anticholinesterases and corticosteroids. Plasmapheresis has also proved to be useful in preparing patients for thymectomy when their course is complicated by involvement of the bulbar and respiratory musculature. Such patients may also require short-term plasmapheresis during the postoperative period. Plasmapheresis also appears to be particularly efficacious in anti-MuSK antibody–associated disease. There is no long-term benefit of plasmapheresis when added to prednisone.

Although there are no hard and fast rules, the average exchange is 1–2 L/day for 7–14 days. Improvement is usually observed within a few days of concluding the treatment course, although patients in crisis often benefit more quickly. The mechanism of action most likely involves the removal of the pathogenic autoantibody, as a reduction in titer of anti-AChR antibody correlates with clinical improvement. However, it is also possible that the removal of other phlogistic humoral factors contributes to clinical efficacy.

Intravenous Immunoglobulin

The efficacy of IVIG in the treatment for MG was suggested by several uncontrolled clinical trials. Interest in the use of this biological grew out of its demonstrated efficacy in other autoimmune diseases, most notably autoimmune thrombocytopenia. Subsequent randomized double-blind placebo-controlled trials provided proof of clinical efficacy. Conventional dosing is infusion of 2 g/kg divided over 5 days, although some practitioners prefer to administer this dose over 2 days. In a randomized, controlled trial a total dose of 1 g/kg was found to be as efficacious as a dose of 2 g/kg. IVIG therapy is generally associated with rapid clinical improvement in responsive patients, independent of whether they had undergone thymectomy or were being treated concurrently with corticosteroids or immunosuppressive agents. In some patients, improvement was sustained over a period of several weeks. Improvement has not always been accompanied by a consistent reduction in anti-AChR antibody titers. In general, IVIG and plasmapheresis appear to be equivalent in efficacy.[41] However, there is a general impression that IVIG is preferable because of better tolerance and less cost. The mechanism(s) of this apparent salutary effect is unknown, although there is evidence IVIG contains antibodies directed against the idiotypes of anti-AChR antibodies.

Immunosuppressive Agents

Immunosuppressive drugs have been tried primarily in patients who have failed treatment with anticholinesterases, thymectomy, plasmapheresis, and corticosteroids.[42] Most of the experience has been obtained with azathioprine, which has strong antiinflammatory effects as well as immunosuppressive activity. The dose of azathioprine has varied between 1 and 3 mg/kg/day, with improvement seen between 5 and 20 weeks. The drug is usually started at a lower dose and escalated weekly to achieve the maintenance dose. The patient should be followed with complete blood counts, particularly during the initiation of therapy, as azathioprine has a suppressive effect on the bone marrow. A white blood cell count below 2500 or a neutrophil count below 1500 should prompt a reduction or termination of the dosage. The results of a randomized double-blind placebo-controlled trial indicated that the addition of azathioprine (2.5 mg/kg) to alternate-day prednisolone was associated with a reduction of the prednisolone dose, fewer treatment failures, longer remissions, and fewer side effects.[43]

There is considerably less experience in the treatment of steroid-unresponsive patients with cyclophosphamide, another powerful immunosuppressive agent. It is associated with more adverse effects and does not appear to offer any significant advantage over azathioprine when used in standard dosing regimens. High-dose intravenous cyclophosphamide therapy for patients with MG refractory to conventional immunosuppressive agents has been investigated as an approach to immunoablate bone marrow and allow for subsequent repopulation by endogenous stem cells. Although durable responses were seen in some patients in an early trial, this regimen is not readily available and should only be utilized in refractory patients under treatment in specialized centers.

Methotrexate has been used in some uncontrolled studies, but there is no information to indicate that it is more efficacious or safer than azathioprine and its onset of action may take as long as several months. As is true for corticosteroid therapy, it is the rare patient who enjoys a permanent remission following institution of immunosuppressive therapy, and those who show some improvement often require treatment indefinitely.

Cyclosporine, a potent immunosuppressive agent, has been investigated because it interferes with IL-2–mediated T-cell proliferation and thus would be expected to interfere with the generation of T cells that would "help" the anti-AChR antibody response. A retrospective study suggested that cyclosporine provided benefit in patients whose disease was refractory to corticosteroids and azathioprine. Serious renal toxicity and treatment withdrawal, which plagued earlier studies, were reduced by careful selection of patients. In a 12-month European trial, cyclosporine appeared to be as efficacious as azathioprine in producing clinical improvement. Tacrolimus has a similar mechanism of action to cyclosporine. When used in low dosage, it has proved as effective as cyclosporine as a corticosteroid-sparing agent with fewer side effects. Nevertheless, most practitioners reserve these agents for use in patients whose disease is refractory to the combination of azathioprine and prednisone.

Mycophenolate mofetil (MMF), another immunosuppressive agent that affects both T and B cells, was widely touted following the completion of early trials as a steroid-sparing agent in patients with MG. That experience suggested that it was effective 70–75% of the time, although probably less so in refractory MG. It has an acceptable safety profile with adverse effects largely related to gastrointestinal intolerance. Benefit may require many weeks of administration. However, two randomized, placebo-controlled trials have challenged the early optimism. In one, the addition of MMF treatment at the initiation of a 36-week schedule of prednisone tapering was not found to be superior to placebo in maintaining myasthenia control.[44] In the second, the coadministration of MMF and prednisone provided no better control of myasthenic weakness than prednisone alone in the initial management of generalized MG.[45] However, none of the patients included in these two studies was known to be steroid resistant. Thus whether MMF has long-term benefits with respect to myasthenic weakness or steroid-sparing effects in the population of steroid-resistant patients remains an open question.

POSSIBLE FUTURE THERAPEUTIC OPTIONS

Many possible experimental avenues of investigation that have been opened by studies in EAMG. These are aimed at interrupting the sensitization process of helper CD4 T cells, interrupting their effector function, or interdicting the action of downstream proinflammatory molecules. Studies directed at CD4 T cells include impeding their activation by inhibitors of the costimulatory molecules CD28 and ICOS and the induction of anergy or apoptosis of AChR-reactive T cells.[34] In addition, inhibition of factors that contribute to AChR antibody production, and against which monoclonal antibodies (mAbs) are now available for human use, make this approach possible and, in some cases, are now under clinical trials. This includes agents that abrogate the action of IL-6, IL-17, and BAFF. Additional studies directed at AChR-specific B cells include the use of AChR/Fcγ fusion proteins to induce apoptosis of AChR-specific B cells by cross-linking their B-cell AChR receptors and inhibitory FcγRIIb receptors. In addition, non–cross-linking IgG4 anti-AChR antibodies have been used to inhibit pathogenic IgG autoantibody-induced antigenic modulation. Bortezomib, a proteosome inhibitor approved for usage in multiple myeloma and mantle cell lymphoma, has been found to reduce anti-AChR antibody titers, inhibit damage to the postsynaptic muscle membrane, and lead to clinical improvement. Moreover, this agent was shown to suppress anti-AChR antibody production and deplete plasma cells from cultures of cell suspensions obtained from thymus specimens of patients with MG.[34]

The induction of antigen-specific immune tolerance, the therapeutic holy grail in autoimmune diseases, has received considerable attention in EAMG. Early studies utilized extracellular domain sequences that form epitopes for pathological autoantibodies to induce tolerance to AChR. However, this approach risks provoking autoimmunity rather than suppressing it. To avoid this risk, one group has recently developed a novel vaccine consisting of bacterially expressed human AChR cytoplasmic domains.[46] To date, this group has used this vaccine to prevent development of chronic EAMG when administered immediately after the acute phase of EAMG and to rapidly reverse established chronic EAMG when started during the chronic phase of EAMG. Treatment effects are robust and long-lasting. Although the mechanisms of action of this novel approach have yet to be fully elucidated, they may involve a combination of antibody-mediated feedback suppression and regulatory T cell–mediated active suppression.

Complement inhibition has shown efficacy in the treatment of EAMG and represents a target in patients with MG now that complement inhibitors have demonstrated benefit in the treatment of a number of human disorders. A phase II placebo-controlled cross-over study with a fully humanized monoclonal anti-C5 antibody was initiated only to be terminated because of inadequate recruitment.[34] Nevertheless, given the importance of the terminal complement pathway in the pathogenesis of cases of MG and the continued development of a number of complement inhibitors, it is likely that this strategy will be revisited.

A B-cell targeting agent that has gotten much attention in patients with MG is rituximab, a mAb specific for CD20, a protein expressed on B lymphocytes. Anecdotal reports and small uncontrolled case series using rituximab have shown improvement of MG. Interestingly, responsive patients do not demonstrate a reduction in anti-AChR antibodies, suggesting an effect on nonantibody functions, such as antigen presentation and proinflammatory cytokine secretion. Although most treated patients have been anti-AChR antibody positive, benefit has also been observed in anti-MuSK-positive/anti-AChR antibody–negative patients, in whom longstanding remission has been seen in association with reduction of anti-MuSK antibody titers. A controlled clinical trial of rituximab in anti-AChR–associated MG is currently underway. A number of other mAbs directed at CD20, including fully humanized ones, are under study in other autoimmune diseases and will likely attract attention with regard to MG.

CONCLUSIONS

MG is a prototypic autoimmune disease in which the autoantigen/s are well defined as are the mechanisms that mediate dysfunction of the target tissue, skeletal muscle. EAMG, in which many of the features of MG are faithfully recapitulated, has provided a useful vehicle for elucidating the immunoregulatory abnormalities that underlie the pathogenesis of the human disease, and the

ON THE HORIZON

Development of Immunomodulatory Therapies

- Newly developed B-cell lineage inhibitors, including anti–plasma cell monoclonal antibodies
- Acetylcholine receptor (AChR)–Fc fusion molecules
- Inhibitors that target key immunopathogenic cytokines
- AChR-specific immunosuppression

development of novel therapies for use in the humans. MG occupies a unique position in the pantheon of autoimmune diseases because of its strong association with thymic pathology. In MG-associated thymic hyperplasia, thymic events, particularly those leading to antecedent inflammation within the medulla, likely serve as a driving force behind the development of the autoimmune process. Indeed, the overarching idea that tolerance is breached in the thymus may be viewed as antithetical, given the established and critical role this organ plays in T-cell central tolerance. Unravelling the link between the thymus and MG will require further study. However, in the meantime, we can expect that continued exploration of immune perturbations and their underlying molecular mechanisms in animals with EAMG and in patients with MG will lead to safer and more robust therapeutic interventions.

MULTIPLE-CHOICE QUESTIONS

1. The most frequent pathogenic autoantibodies found in patients with myasthenia gravis (MG) are specific for a conformational epitope on which subunit of the neuromuscular acetylcholine receptor?
   A. α
   B. β
   C. δ
   D. ε

2. Patients with MG whose serum is positive for anti- *mu*scle-*s*pecific tyrosine *k*inase (MuSK) antibodies are most resistant to treatment with which one of the following modalities?
   A. Corticosteroid
   B. Intravenous immunoglobulin
   C. Plasmapheresis
   D. Pyridostigmine bromide

3. A 35-year-old man presented with diplopia, difficulty swallowing, and weakness in his upper and lower extremities. On laboratory testing of his serum, he was found to have elevated titers of anti–acetylcholine receptor antibodies and antistriational antibodies. He underwent thymectomy, which very likely showed which of the following pathologies?
   A. Germinal center hyperplasia
   B. Thymic atrophy
   C. Cortical thymoma
   D. Medullary lymphoma

4. An inflammatory process in which of the following anatomical locales is considered to initiate the development of MG?
   A. Skeletal muscle
   B. Thymic cortex
   C. Cervical lymph node
   D. Thymic medulla

Multiple Sclerosis

Benjamin M. Segal

Multiple sclerosis (MS), a chronic inflammatory demyelinating disorder of the central nervous system (CNS), is the most frequent cause of nontraumatic neurological disability among young adults in the Western Hemisphere. Although MS is widely considered a disease of North America and Europe, there is increasing evidence that it is more common in other regions of the world, including Asia and the Middle East, than previously appreciated. The median age at presentation is 28–31 years, which is, in part, responsible for the disproportionately high social and economic tolls of the disease. Furthermore, the incidence of MS is increasing for unknown reasons. Fortunately there have been dramatic advances in the treatment of relapsing forms of MS over the past 20 years, spurred by the introduction of 14 disease-modifying agents (DMAs); and more are actively under development. These drugs significantly decrease the risk of relapse and lesion formation. Consequently, the implications of being diagnosed with relapsing-remitting MS have changed considerably in the span of a generation. Despite this success, significant challenges persist. There is a dire need for treatments that slow, or even halt, disability accumulation in patients with progressive forms of MS, and for interventions that restore lost neurological functions across MS subsets.

CLINICAL SUBSETS AND PHENOMENOLOGY

Relapsing-Remitting MS (RRMS)

In the majority of cases (85–90%), MS presents with a relapsing-remitting course, characterized by discrete episodes of neurological dysfunction (relapses or exacerbations) separated by clinically quiescent periods (remissions). The frequency of relapses can vary widely among patients as well as during different periods in an individual patient's disease course. At present no clinical features or biomarkers that are predictive of relapse rate have been identified. The signs and symptoms that occur during relapses are also diverse and unpredictable, since lesions can form at literally any site in the CNS, spanning the cerebrum, brainstem, cerebellum, optic nerves, and spinal cord. By definition, the peripheral nervous system is spared.

MS lesions are readily visualized in CNS white matter via magnetic resonance imaging (MRI) (Fig. 66.1). Symptomatic lesions generally occur in locations where nerve fibers converge to subserve a common function. Hence, typical presentations of RRMS include optic neuritis with monocular visual deficits (secondary to lesions in the optic nerve), myelitis with weakness and numbness in the extremities, sometimes accompanied by incontinence (caused by spinal cord lesions), and brainstem syndromes manifesting as slurred speech, swallowing difficulties, imbalance, tremor, and/or double vision. Serial MRI studies have demonstrated that the majority of MS lesions are actually clinically silent. This is not surprising considering the abundance of redundant nerve fiber tracts in the CNS and the commitment of large areas of cerebral white matter to subtle personality traits and cognitive skills. Consequently, CNS tissue damage may be inflicted surreptitiously during clinical remissions, making MRI a more sensitive indicator of disease activity compared with the history or the results of neurological examination (see Fig. 66.1).

Patients with MS often recover function following a clinical relapse, either partially or fully, particularly during the early clinical course. However, old symptoms can temporarily reemerge when the core body temperature is elevated as a result of infection or strenuous exercise. This unmasking of latent deficits, referred to as the *Uhthoff phenomenon,* is a consequence of the physiological slowing of axon signal propagation that normally occurs at high core body temperatures. In healthy individuals, the degree of slowing has no clinical consequence, but in MS patients, it may precipitate the decompensation of white matter tracts already compromised by demyelination and axonal drop-out.

Secondary Progressive MS (SPMS)

During the course of RRMS, relapses decrease in frequency over time and sometimes disappear completely. However, in the vast majority of cases, they are replaced by an insidious, gradual accumulation of disability, referred to as the *secondary progressive (SP) stage.* The symptoms and signs that characterize neurological decline during SPMS are diverse. Progressive myelopathy, hemiparesis, and/or gait imbalance are common. Subcortical dementia is increasingly recognized as a feature of the disease. Longitudinal natural history studies conducted before DMAs were widely available found that the majority of patients with RRMS transitioned to the SP stage within 10–20 years of the initial presentation of disease. An epidemiological study of MS patients in British Columbia, published in 2010, found that the median time to SPMS onset was 21.4 years.[1] A number of factors, including male gender, the presence of motor symptoms at clinical onset, and a history of poor recovery from relapses, are associated with both a shorter time to, and younger age at, evolution to SPMS. It has not been definitively determined whether optimal management of RRMS with the use of DMAs can delay, or even prevent, the onset of SPMS. Previous longitudinal observational and retrospective cohort studies that investigated whether treatment with first-generation DMAs alters the time to reach SPMS yielded conflicting results. However, a recent prospective study of 517 actively treated patients found that rates of worsening and evolution to SPMS were substantially

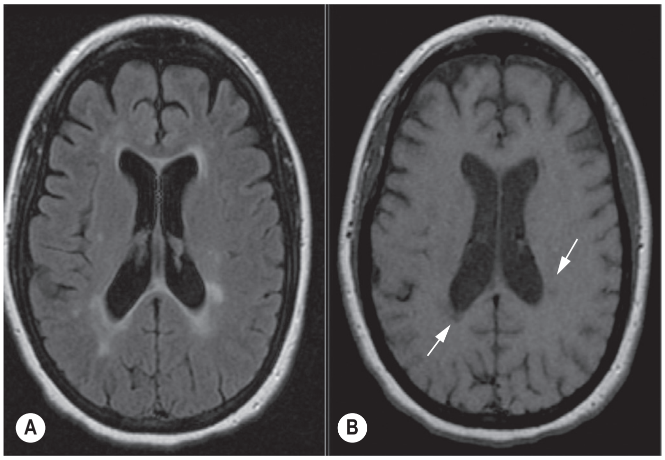

FIG 66.1 (A) T2-weighted fluid-attenuated inversion recovery (FLAIR) magnetic resonance imaging (MRI) scan of the brain of a patient with multiple sclerosis (MS) showing hyperintense lesions located in the periventricular and subcortical white matter. (B) T1-weighted MRI scan showing T1-black holes (arrows), indicative of profound axonal loss, and generalized atrophy with enlarged ventricles.

lower when compared with the findings of earlier natural history studies of untreated patients.[2]

The cellular and molecular mechanisms underlying the conversion from the RR stage to the SP stage are poorly understood. Some investigators have questioned the relevance of neuroinflammation during the SP stage and have posited neurodegeneration as being primarily responsible for the clinical deterioration that ensues (in the form of neuronal death, mitochondrial dysfunction in axons, Wallerian degeneration, and gliosis).[3] Conversely, there is evidence of persistent immune dysregulation in SPMS, although it may differ from RRMS with regard to the cytokine networks and leukocyte subsets involved, as well as the distribution of infiltrating cells within the CNS.[4-6] Nonetheless, DMAs that are therapeutically beneficial in RRMS have generally not been found to be effective in slowing disability accumulation in SPMS.[7] At present, the management of SPMS involves alleviation of symptoms, optimization of residual functions, and prevention of complications.

Primary Progressive MS (PPMS)

PPMS is distinguished from SPMS by the absence of an antecedent RR phase. Otherwise, the clinical features of SPMS and PPMS can be indistinguishable. The most common clinical phenotype is spastic paraparesis, followed by cerebellar dysfunction and hemiplegia. However, there are striking demographic differences between PPMS and RRMS/SPMS. PPMS tends to present at an older age (peaking in the fifth and sixth decades) compared with RRMS (which peaks in the third and fourth decades). Furthermore, RRMS occurs 2–3 times more frequently in females than in males, whereas in PPMS the gender ratio is closer to 50 : 50. Some investigators have noted that the neuropathological and radiological features of PPMS overlap extensively with those of SPMS, leading them to conclude that PPMS and SPMS belong to the same disease spectrum. In support of that viewpoint, familial clusters of MS that include some members with PPMS and others with RR/SPMS have been described. It is possible that, analogous to SPMS, acute inflammatory lesions form during early stages of PPMS, prior to overt clinical progression, but happen to arise exclusively in clinically silent areas. Conversely, some investigators have argued that PPMS is a distinct disease entity driven primarily by neurodegenerative processes from its inception.[3] This viewpoint is supported by the general failure of immunomodulatory agents to attenuate the course of PPMS.[8] Conversely, in a randomized double-blind placebo-controlled trial, treatment with a B cell–depleting monoclonal antibody (mAb) delayed disability progression in a subset of patients with PPMS who were younger and/or had inflammatory lesions.[9] Collectively, these findings suggest that the pathogenesis of PPMS is multifaceted and heterogeneous and that the relative contribution of inflammation and neurodegeneration to clinical outcomes varies among patients.

CLINICAL PEARLS

Clinical Features of MS

In the majority of cases (80–85%), multiple sclerosis (MS) presents with a relapsing-remitting course.

- The symptoms and signs experienced by patients with MS are diverse because lesions can form at any site in the central nervous system (CNS), including the optic nerves, cerebrum, brainstem, and spinal cord.
- The rate, severity, and symptoms of relapses are highly variable and unpredictable.
- Most MS lesions form silently; magnetic resonance imaging (MRI) is a more sensitive tool to gauge disease activity compared with history or neurological examination.
- Acute relapses tend to decrease in frequency over time and are typically replaced by a gradual accumulation of disability. This later phase of disease is referred to as *secondary progressive MS* (SPMS).

DIAGNOSIS

The most widely used guideline for diagnosing MS is the *McDonald criteria*, originally proposed by the International Panel on Diagnosis of Multiple Sclerosis in 2001 and subsequently revised in 2005 and 2010[10] (Table 66.1). RRMS is, by definition, a dynamic multifocal inflammatory demyelinating disease of the CNS. Therefore the demonstration of lesion dissemination in time and space is crucial for its diagnosis. The criteria for dissemination in time can be satisfied by ≥2 distinct clinical exacerbations, by one exacerbation followed by the interval appearance of a new lesion on serial MRI scans, or by the simultaneous presence of asymptomatic gadolinium-enhancing (*i.e.*, acute inflammatory) and nonenhancing MRI lesions at any time. Dissemination in space can be demonstrated by objective clinical evidence of involvement of ≥2 sites in the CNS (based on the neurological examination and/or delayed latencies on evoked potential testing) or by the presence of T2-weighted MRI lesions in at least two of the following areas: periventricular, juxtacortical, and infratentorial, cerebral white matter or spinal cord. In the latest iteration of the McDonald criteria, an MS exacerbation is defined as "patient-reported symptoms or objectively observed signs typical of an acute inflammatory demyelinating event in the CNS, current or historical, with duration of at least 24 hours, in the absence of fever or infection." There are no clinical features or biomarkers that are pathognomonic for MS. Therefore it is essential to rule out competing diagnoses. The presence of unique oligoclonal bands and/or elevated immunoglobulin G (IgG) index in the cerebrospinal fluid (CSF), indicative of

TABLE 66.1 McDonald 2010 Criteria for the Diagnosis of Multiple Sclerosis

Clinical Presentation	Additional Data Needed for an MS Diagnosis
≥ 2 attacks; objective clinical evidence of ≥ 2 lesions or objective clinical evidence of 1 lesion with reasonable historical evidence of a prior attack	None
≥ 2 attacks; objective clinical evidence of 1 lesion	Dissemination in space demonstrated by ≥ 1 T2 lesion in at least 2 or 4 MS-typical regions (periventricular, juxtacortical, infratentorial, or spinal cord)
1 attack; objective clinical evidence of ≥ 2 lesions	Simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time; or a new T2 and/or gadolinium-enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan; or Await a second clinical attack
1 attack; objective clinical evidence of 1 lesion (clinically isolated syndrome)	Dissemination in space and time, demonstrated by: *For DIS:* ≥ 1 T2 lesion in at least 2 of 4 MS-typical regions of the CNS (periventricular, juxtacortical, infratentorial, or spinal cord); or Await a second clinical attack implicating a different CNS site; and For DIT: Simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time; or A new T2 and/or gadolinium-enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan; or Await a second clinical attack
Insidious neurological progression suggestive of MS (PPMS)	1 year of disease progression (retrospectively or prospectively determined) plus 2 of 3 of the following criteria: 1. Evidence for DIS in the brain based on ≥ 1 T2 lesions in the MS-characteristic (periventricular, juxtacortical, or infratentorial) regions 2. Evidence for DIS in the spinal cord based on ≥ 2 T2 lesions in the cord 3. Positive CSF (isoelectric focusing evidence of oligoclonal bands and/or elevated IgGindex)

From Polman CH, Reingold SC, Banwell B, et al. Diagnostic criteria for multiple sclerosis: 2010 revisions to the McDonald criteria. Ann Neurol 2011; 69(2): 292–302.

primary antibody production in the CNS, supports a diagnosis of MS, but those findings are observed in a wide range of neuroinflammatory conditions, including subacute sclerosing panencephalitis, neurosarcoidosis, Lyme disease, and systemic lupus erythematosus (SLE) with CNS involvement. A diagnosis of PPMS requires 1 year of disease progression plus two of the three following criteria: *(i)* at least one T2 lesion in the periventricular, juxtacortical, or infratentorial cerebral white matter; *(ii)* at least two T2 spinal cord lesions; and *(iii)* positive CSF findings, defined as the presence of oligoclonal bands or elevated IgG index.

RISK FACTORS

Genetic Risk Factors

A monozygotic twin whose cotwin has MS has a 20–30% risk of developing the disease, whereas the corresponding risk for a dizygotic twin is 2–5%.[11] In contrast, the incidence of MS in the general population is approximately 0.1%. Hence, the risk of MS drops with increasing genetic distance, suggesting that genes play a significant role in determining MS susceptibility. The human leukocyte antigen (HLA) region represents the strongest MS susceptibility locus, genome wide, and has been implicated in all ethnic populations thus far studied. It accounts for up to 10.5% of genetic variance underlying risk.[12] The primary signal maps to the *HLA-DRB1* gene in the class II segment of the locus, implicating a role of CD4 T-cell responses in MS pathogenesis. Genome-wide association studies (GWAS) have revealed over 100 non-HLA susceptibility loci, each of which contributes a small amount to MS risk. Strikingly, most of these map to regions containing genes implicated in immunological, rather than neuronal or glial, pathways. Genes involved in T-helper (Th)–cell differentiation are overrepresented, including the interleukin-2 (IL-2) receptor α chain and the IL-7 α chain, which modulate T-cell proliferation and survival. Over one-third of the MS susceptibility loci overlap with regions previously identified in GWAS of other autoimmune diseases, including celiac disease, type 1 diabetes, rheumatoid arthritis, and/or inflammatory bowel disease. Together these data provide support for a primary immunological, as opposed to neurodegenerative, etiology of MS. An unresolved question is whether genetic variants affect the clinical course of RRMS, including such features as relapse rate or severity and time to conversion to the SP stage. Genetic variants that are predictive of responsiveness to DMAs have yet to be identified. A growing area of interest that warrants further investigation is the potential impact of epigenetic modifications in different cell types on MS susceptibility, clinical course, and/or therapeutic responsiveness.

Environmental Risk Factors

As mentioned above, twin concordance rates in MS have been used to highlight the importance of heredity in MS susceptibility. Paradoxically, the same data can be used to argue for the importance of environmental influences. Hence, over 70% of monozygotic twins of individuals with MS do not develop the disease. Despite arduous attempts, no convincing evidence has been produced for genetic, epigenetic, or transcriptome differences that explain MS discordance among monozygotic twin pairs.[13] The risk of MS appears to be predicated on a complex interplay between genetic and environmental factors.

Geographic Prevalence Patterns

One of the most convincing illustrations of the impact of the environment on the development of MS is its geographical distribution. The prevalence of MS is highest in the Scandinavian countries, Canada, and Scotland and lowest in the equatorial regions. Kurtzke et al. were the first to notice a latitudinal gradient in the prevalence of MS across the United States, with the disease being most common in the Northern states and gradually declining toward the South.[14] Similar latitudinal gradients have been observed in Europe, Australasia, and Japan. Population migration studies indicate that the geographical risk of MS is established prior to adolescence. Prepubescent children who migrate assume the risk of their adopted country, whereas adults carry forward the risk of the location where they spent their childhood. An environmental agent that is encountered in childhood and acts as predisposing factor for the development of MS later in life must be responsible, but this agent has yet to be definitely identified.

Vitamin D

The discovery of the protective role of vitamin D in MS may explain, in part, its geographical distribution. Ultraviolet light catalyzes the conversion of vitamin D to its bioactive form, and the prevalence of MS is highest in regions with relatively low annual sunlight exposure. In a large prospective study, the risk of MS decreased with increasing serum levels of 25-hydroxyvitamin D.[15] Therefore interventions that raise the level of 25-hydroxyvitamin D levels might have a prophylactic protective effect on healthy individuals who are predisposed to develop MS, such as the first-degree relatives of patients with MS. Indeed, numerous independent prospective studies have found an inverse relationship between dietary or supplemental vitamin D intake in adults and future risk of MS. Furthermore, there is accumulating evidence that low serum 25-hydroxyvitamin D levels and low dietary vitamin D intake during pregnancy increase the risk of MS in the offspring.[16] Whether vitamin D levels influence the clinical course of individuals with established MS is more controversial. A randomized controlled trial of vitamin D supplementation in patients with MS is currently underway in 16 academic centers (ClinicalTrials.gov identifier: NCT01490502). The results of that trial should bring clarity to the issue.

Infection

In addition to low levels of vitamin D, another prognostic factor for development of MS is primary infection with Epstein-Barr virus (EBV) in adulthood, as indicated by the emergence of EBV-specific IgM antibodies in serum. Analysis of serial serum samples stored in the US Department of Defense Serum Repository revealed that MS risk was extremely low among individuals not infected with EBV but increased sharply in the same individuals following seroconversion to positivity for antibodies against EBV.[17] The odds of MS were recently estimated to be >10 times higher among EBV-positive persons than among EBV-negative persons.[18] One way in which EBV infection could promote MS pathogenesis is via "molecular mimicry," which occurs when a microbial epitope shares sequence similarities with a self peptide, in this case a myelin peptide (Chapter 50). T-cell receptors (TCRs) that cross-react with structurally homologous EBV and myelin antigens have been discovered in the peripheral CD4 TCR repertoire of individuals with MS.[19] Peripheral CD4 T cells that express such cross-reactive TCRs could be activated during EBV infection, enabling them to cross the blood–brain barrier (BBB), encounter their cognate myelin antigen within CNS white matter, and initiate MS lesion formation. An alternative theory involves infiltration of the CNS by EBV-infected B cells. B cells expressing EBV small RNA and proteins have been detected in meningeal follicle–like structures and inflamed cortical lesions in SPMS brain tissue.[20] EBV-driven expansion and activation of meningeal B cells could potentially contribute to the formation of the follicle-like structures, which have been associated with large subpial cortical lesions and a more aggressive clinical course.[6]

Although infectious agents, such as EBV, have been implicated in MS pathogenesis, other pathogens may have a therapeutic effect. It has been suggested that in addition to high levels of sunlight exposure, endemic helminth infection is one of the factors responsible for the low prevalence of MS in tropical regions. Infection with helminths, including *Heligmosomoides polygyrus, Fasciola hepatica, Schistosoma mansoni,* and *Trichinella,* has been shown to be protective in animal models of MS.[21] Several small prospective studies showed that patients with MS naturally infected with different species of parasitic worms had a milder disease course and lower MRI inflammatory activity compared with uninfected patients.[22] Antiparasite treatment was associated with exacerbation of MS. Mechanistic substudies have suggested that parasites modulate MS disease activity by boosting the frequency of IL-10 and transforming growth factor-beta (TGF-β)–producing regulatory T and/or B cells. A phase I safety study of orally administered *Trichuris suis* ova (TSO) has been conducted in RRMS, and a number of clinical trials of TSO or dermally administrated hookworm *Necator americanus* as disease-modifying therapy in MS are planned or underway.

Obesity

Observational studies have found that individuals who are obese in early adulthood, as measured by elevated body mass index (BMI), have an approximately twofold increased risk of MS.[23] Obesity in girls is associated with an increased risk of pediatric MS or clinically isolated syndrome.[24] Furthermore, higher weight in adolescence and young adulthood is associated with an earlier age at onset of MS. A mendelian randomization analysis of large GWAS for MS and BMI, respectively, found that one standard deviation (SD) increase in genetically determined BMI conferred a 41% increase in the odds of MS.[25] A number of theories have been proposed for a mechanistic link between obesity and MS risk. First, obesity is known to cause a systemic proinflammatory state, possibly mediated by an adipose-derived hormone that could create a milieu conducive to the differentiation and/or activation of autoimmune effector cells. Alternatively, there is some evidence that genetically elevated BMI decreases 25-hydroxyvitamin D levels.

Modifiable Habits

A substantial body of literature indicates that cigarette smoking increases the risk of MS. A recent meta-analysis revealed a dose–response relationship between cigarette pack-years and MS risk.[26] On the basis of data collected from the Swedish National MS Registry, it was estimated that each additional year of smoking after diagnosis accelerates the time to conversion to SPMS by 4.7%.[27] There is growing evidence that exposure to passive smoking is also a risk factor for MS. Acrolein, a component of cigarette smoke, was found to exacerbate the clinical course of an animal model of MS, in association with enhanced microglial activation.[28]

Another behavior that has come under scrutiny in relationship to MS is dietary sodium intake. In one study, exacerbation rates were found to be 2.75–3.95-fold higher in patients with RRMS with medium or high sodium intakes, respectively, compared with the low-intake group.[29] In contrast, high salt intake was not associated with decreased time to relapse in pediatric-onset MS.[30] High-salt conditions promote the induction of highly pathogenic myelin-reactive T cells *in vitro* and in animal models *in vivo.*[31]

Sex Hormones

MS relapse rates decline during pregnancy, particularly in the third trimester, and rebound in the first 3 months post partum before returning to the prepregnancy rate. This has led to the hypothesis that certain female sex hormones may play a protective role in RRMS. Estriol is an estrogen unique to pregnancy. It is synthesized by the fetoplacental unit and reaches its highest levels in the last trimester. A randomized, double-blinded, placebo-controlled phase II trial of estriol in combination with glatiramer acetate (GA) versus placebo plus GA showed a reduction in the annualized relapse rate at 2 years in the estriol-treated group.[32] Animal model studies have indicated that estrogens, including estriol, have antiinflammatory and neuroprotective effects through engagement of the estrogen receptors expressed on leukocytes and CNS resident cells, respectively.

Testosterone has neuroprotective effects in animal models of MS, and decreased testosterone levels in males with MS were reported to be associated with disability.[33] In a small, open-label, phase II clinical trial, testosterone treatment appeared to arrest loss of gray matter (and even to reverse atrophy of gray matter in the right frontal cortex), as quantified by using voxel-based morphology, in 10 male patients with MS.[34]

KEY CONCEPTS

Risk Factors

The risk of multiple sclerosis (MS) is determined by a combination of genetic and environmental factors.

- The majority of MS susceptibility loci map to regions containing genes implicated in immunological pathways, including human leukocyte antigen (HLA) class II molecules, the interleukin-2 (IL-2) receptor, and the IL-17 receptor.
- Relapse rates decline during the third trimester of pregnancy, in association with high serum levels of estriol.
- Environmental risk factors include low vitamin D levels, exposure to the Epstein-Barr virus (EBV) in adulthood, cigarette smoking, and childhood obesity.

PATHOLOGICAL FEATURES OF MS

White Matter Lesions

The hallmark of MS pathology is the focal demyelinated lesion, or "plaque," present in the white matter of the optic nerves, brain, and spinal cord. Acute lesions are invariably associated with focal breakdown of the BBB and perivascular inflammatory infiltrates. MS infiltrates are dominated by T cells (with a relatively high CD8/CD4 ratio) and myeloid cells (blood-derived monocytes/macrophages and activated microglia). Macrophages/monocytes and activated microglia are spatially associated with disintegrating myelin sheaths, and they actively take up myelin debris. Apoptosis and loss of oligodendrocytes vary widely among lesions. Frequent sites of lesion formation include subcortical and periventricular cerebral white matter, middle cerebellar peduncles, and the posterior columns of the cervicothoracic spinal cord. In the brain, infiltrates frequently follow the course of pericallosal venules, resulting in "Dawson fingers," which are oblong lesions oriented perpendicular to the long axes of the lateral ventricles (Fig. 66.2).

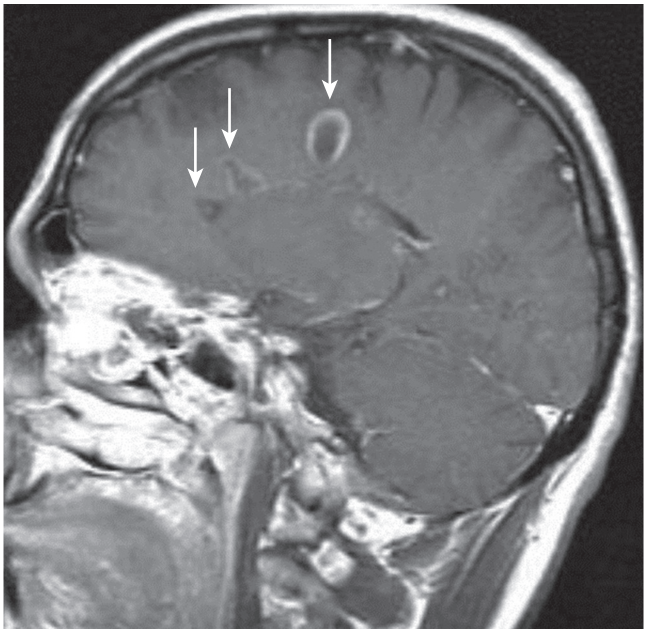

FIG 66.2 A post-gadolinium T1-weighed magnetic resonance imaging (MRI) scan of the brain showing Dawson fingers (arrows).

Classic actively demyelinating plaques are primarily seen during the RR stage of disease and generally decrease in frequency with increasing disease duration. Lesions more typical of progressive forms of MS have been termed "chronic active," or smoldering, and "chronic silent," or inactive. Chronic active plaques are distinguished by a rim of activated microglia and deposits of complement at the lesion edge, surrounding a hypocellular and gliotic core. They are slowly expansive as a consequence of active demyelination at the lesion edge. In contrast, chronic silent plaques have a sharp border. Other characteristics of silent plaques include prominent loss of oligodendrocytes and axons, pronounced astrogliosis, and a paucity of macrophages and activated microglia. Immunopathological changes in the so-called normal-appearing white matter (NAWM), outside of plaques, are pervasive in progressive MS but have also been observed in RRMS. These changes consist of diffuse axonal injury and microglial activation, as well as scattered lymphocytes.

MS is widely classified as a demyelinating disorder. The reason is that a large number of the nerve fiber segments traversing plaques demonstrate myelin loss with relative axonal sparing. However, it is now recognized that axonopathy also occurs and is, in fact, an early and prominent feature of acute MS lesions. Axonal damage results in dysmorphic mitochondria, focal swellings, fragmentation, and frank transections with terminal bulbs at the stumps. Mitochondrial abnormalities and focal swelling have been observed in fully myelinated axons within MS lesions, suggesting that they can occur independent of demyelination.[35] In animal models of MS, axons with abnormal mitochondria are restricted to areas of immune infiltration, and progressive axonal changes correlate with the density of infiltrates.[35] Hence, it is likely that the axonal damage is directly mediated by direct contact with inflammatory cells. Although demyelination can be reversed to some extent by remyelination, axonal transection is irreversible. Clinicopathological investigations have found that permanent motor disability in MS correlates with loss of corticospinal tract axons more so than with degree of demyelination.

Gray Matter Lesions

MS was traditionally considered a white matter disease. It is now established that the gray matter is affected as well. Three types of cortical lesions have been described: leukocortical (which span gray and white matter), intracortical, and subpial. All of these lesions show demyelination and oligodendrocyte loss, microglial activation, neuritic transections, neuronal death, and reduced presynaptic terminals. Subpial lesions are the most common. They can cover long distances of the cortical ribbon and usually extend to the cortical layer III or IV. Cortical lesions are not visible on conventional MRI scans and require special staining to be appreciated in CNS tissue sections. This explains why they were not recognized as common features of MS until recently. In fact, cortical demyelination and gray matter atrophy are evident from the earliest stages of disease, even before a clinically definite diagnosis can be made, and continue to advance at an increasing rate throughout the disease course. Extensive cortical demyelination is evident in the forebrain and cerebellum during progressive MS. Gray matter atrophy in individuals with MS correlates strongly with cognitive deficits and clinical disability.[36]

Meningeal Inflammation

White blood cell (WBC) counts tend to be within normal limits or only slightly elevated in the CSF of most patients with MS. Nonetheless, there is growing recognition that low-grade diffuse meningeal inflammation and focal perivascular meningeal inflammation are common. Meningeal inflammation is most prominent in progressive forms of MS but is prevalent in early MS as well. The meningeal infiltrates are topographically associated with cortical lesions. Lymphoid follicle–like structures, composed of proliferating B cells, T cells, and follicular dendritic cells (FDCs), have been observed in the meninges of up to 40% of autopsied brains from individuals with SPMS.[6] In almost every case, the follicles were found to reside in deep sulci and abut an underlying subpial lesion, suggesting that toxic factors are released by inflammatory cells in the follicles and diffuse into the brain parenchyma. The presence of lymphoid follicles has been associated with a more severe clinical course, shorter disease duration, and younger age at death.

KEY CONCEPTS

Pathology

- The hallmark of multiple sclerosis (MS) pathology is the focal demyelinated lesion, or "plaque," with perivascular inflammatory infiltration and focal blood–brain barrier (BBB) breakdown.
- Axonopathy is an early and prominent feature of acute MS lesions.
- Central nervous system (CNS) damage includes demyelination, apoptosis and loss of oligodendrocytes, and axonal swellings and transections.
- Both gray matter and white matter are affected.
- The pathological features of MS are heterogeneous and evolve over time.

IMMUNOPATHOGENESIS

Animal Models of MS

According to the current dogma, MS is an autoimmune disease mediated by CD4 T cells reactive against myelin antigens. The identification of HLA class II, IL-2Rα, and IL-7Rα as MS susceptibility loci is consistent with a role of CD4 T cells in MS pathogenesis. An autoimmune etiology is further supported by the animal model experimental autoimmune encephalomyelitis (EAE). EAE is a multifocal inflammatory demyelinating disease of the CNS that has striking histological and clinical similarities to MS (Fig. 66.3 and Fig. 66.4). It has been induced in a wide variety of mammalian species (including nonhuman primates, but most commonly in rodents) by vaccination against major histocompatibility complex (MHC) class II–restricted myelin epitopes. EAE can be transferred from myelin-vaccinated mice to syngeneic naïve hosts with purified CD4 T-cell lines or clones. These encephalitogenic myelin-specific CD4 T cells invariably fall within the Th1 or Th17 lineage and produce the proinflammatory cytokines interferon-γ (IFN-γ) and IL-17, respectively, in response to antigenic stimulation[37](Chapter 16). Both Th1 and Th17 cells produce granulocyte macrophage–colony-stimulating factor (GM-CSF), a monocyte mobilizing and growth factor that plays a critical role in many models of EAE. Upon activation in the periphery, myelin-reactive CD4 T cells upregulate adhesion molecules and chemokine receptors, thereby acquiring the ability to cross the BBB. Once having infiltrated the CNS, they are reactivated by local antigen-presenting cells (APCs), such as perivascular macrophages or microglia, which constitutively express MHC class II molecules bound to myelin peptides on their surface. GM-CSF, as well as other Th1 and/or Th17 cytokines, are subsequently released *in situ* and initiate an inflammatory cascade, resulting in the production of chemokines, mobilizing factors and vasoactive substances, upregulation of adhesion molecules on the cerebrovascular endothelium, and thus the recruitment of myeloid cells and lymphocytes from the circulation to the nascent plaque. GM-CSF may drive the differentiation of infiltrating monocytes and CNS-resident microglia into CD11c$^+$ DCs, which are among the most potent APCs. Adoptive transfer studies with labeled donor T cells have demonstrated that the myelin-specific T cells remain clustered in the perivascular space throughout lesion development. A secondary wave of myeloid cells infiltrate deep into the CNS

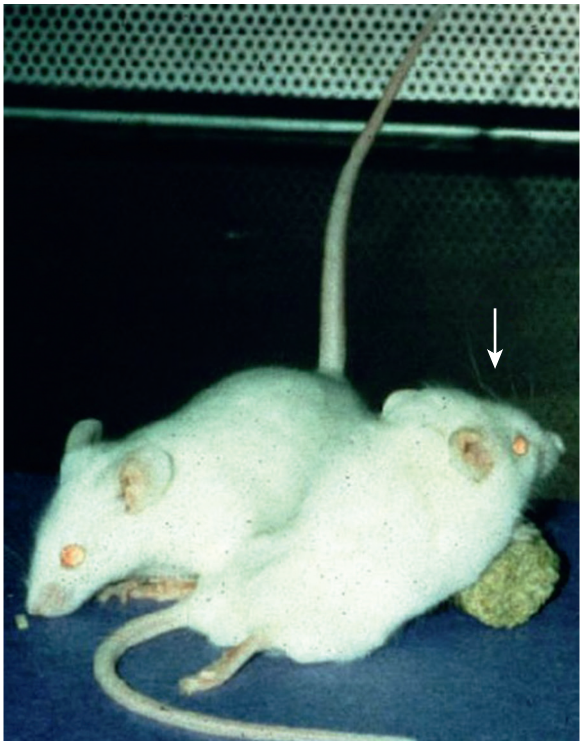

FIG 66.3 A mouse with experimental autoimmune encephalitis (EAE) (arrow) and a healthy littermate. The mouse with EAE has a limp tail and hindlimb weakness.

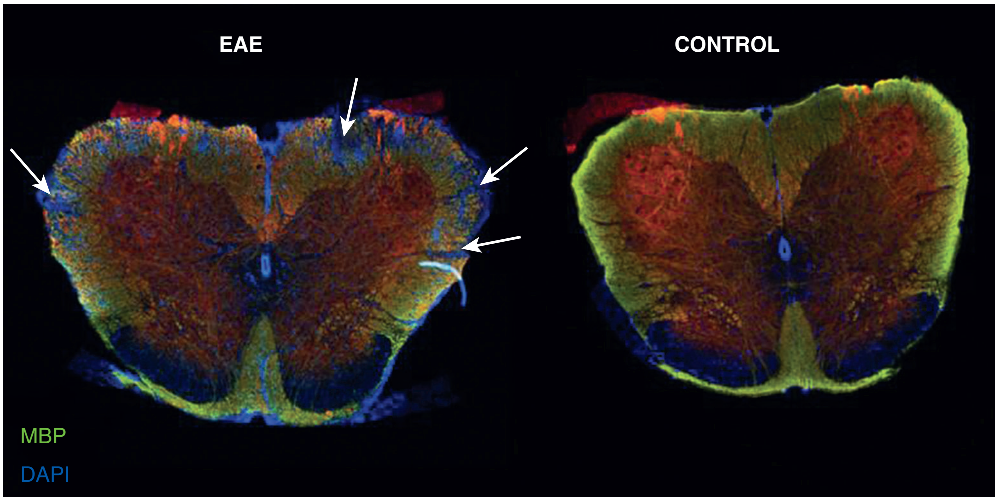

FIG 66.4 Immunofluorescent histology of spinal cord sections from a mouse with experimental autoimmune encephalitis (EAE) (left) and a healthy control (right). White matter tracks were stained with a monoclonal antibody (mAb) specific for myelin basic protein (green). The nuclei of inflammatory cells are stained with DAPI (4′,6-diamidino-2-phenylindole) (blue). The arrows point to areas of demyelination.

white matter, associate with nodes of Ranvier, and directly inflict damage to the myelin sheath and axons[35] (see Figs. 66.3 and Fig. 66.4).

Immune Dysregulation in Patients With MS

Studies on the frequency of myelin-reactive T cells in patients with MS have reported conflicting results; some investigators found a significantly higher incidence of myelin-specific peripheral blood mononuclear cells (PBMCs) in individuals with MS compared with age- and gender-matched healthy controls (HCs), whereas others found no significant difference.[5] Many of the earlier studies that found no differences between patients and HCs used proliferation as a measure of T-cell reactivity and nonhuman myelin proteins for antigenic stimulation. In contrast, several laboratories have found that untreated patients with RRMS have increased frequencies of PBMCs that produce IFN-γ or IL-17 in response to *ex vivo* challenge with human myelin basic protein (MBP), human proteolipid protein (PLP), or their constituent peptides.[4,38,39] IFN-γ responses to PLP peptides were shown to correlate with level of clinical disability.[38] T cells that coexpress IL-17 and IFN-γ were identified in the brain tissue of patients with MS, and circulating lymphocytes obtained from patients with MS were found to have an increased propensity to differentiate into IL-17/IFN-γ double producers.[40] T cells coexpressing IL-17/IFN-γ, and IL-17–producing T cells that convert into IFN-γ producers (the so-called ex-Th17 cells), have been implicated in the pathogenesis of some EAE models. In a recent study, untreated patients with RRMS had a higher frequency of peripheral blood T cells that expressed intracellular GM-CSF in response to stimulation with phorbol myristate acetate and ionomycin, compared with HCs or IFN-β–treated RRMS patients.[41] Approximately 15–20% of both CD4 and CD8 T cells in active MS lesions expressed GM-CSF and the majority coexpressed IL-17 and/or IFN-γ.

There is an increasing appreciation that the cytokine dysregulation that occurs during EAE and MS is heterogeneous. Hence, clinically identical forms of EAE can be induced with stable murine Th1 or Th17 cells independently.[42] Subsets of patients with MS who consistently mounted either IFN-γ– or IL-17–skewed responses to human MBP over the course of a year were recently identified, while others exhibited mixed or oscillating responses.[37] Diversity in the immune pathways that drive MS pathology holds important implications for the development of a more personalized approach to the management of patients in the future. Indeed, Th1- and Th17-mediated forms of EAE show different patterns of responsiveness to the same immunomodulatory drug.[42]

Perhaps the strongest evidence of an autoimmune basis of inflammatory demyelination in humans comes from clinical trials of immunomodulatory agents. Patients with RRMS were treated with an altered peptide ligand (APL) of MBP with the intention of tolerizing MBP-reactive T cells or deflecting their differentiation toward an immunosuppressive, regulatory, or innocuous Th2 phenotype. Unexpectedly, administration of the APL was temporally associated with expansion of circulating MBP-reactive Th1 cells and clinical worsening in a subgroup of patients.[43] In contrast, as will be discussed in detail below, drugs that impede lymphocyte trafficking to the CNS,[44,45] block growth factor signaling into T lymphocytes,[46] or deplete lymphocytes from the periphery[47] suppress MS relapse rates and the accumulation of MRI lesions.

DISEASE-MODIFYING THERAPIES

The approval of IFN-β-1b (Betaseron) by the US Food and Drug Administration (FDA) in 1993 for the management of RRMS marked the beginning of a new era in MS therapeutics. In the intervening 23 years, an additional 13 disease-modifying therapies have been approved, all of which have significantly reduced the annualized relapse rate (in a range from 25% to almost 70%) and the frequency of gadolinium enhancing (acutely inflamed) MRI lesions. Prior to 1993, corticosteroids were the only class of drugs routinely used to treat MS. Although corticosteroids accelerate the rate of recovery from acute exacerbations, there is little evidence that they alter the ultimate clinical outcome or prevent subsequent disease activity. Therefore the introduction of disease-modifying therapies has represented a major advance in the treatment of individuals with RRMS and has had a profound impact by mitigating morbidity and enhancing quality of life.

Recombinant IFN-β

IFN-β is a type I IFN with potent antiviral properties. It has pleiotropic effects on the innate immune system. Recombinant IFN-β was first tested in MS on the basis of the contemporaneous theory that the disease was caused by an active viral infection of the CNS. Although MS is now believed to be an autoimmune disease, recombinant IFN-β therapy was serendipitously found to significantly reduce annualized MS relapse rates. It is manufactured as four different commercial products, all of which are self-administered via either subcutaneous or intramuscular injection. There are two distinct structural forms. IFN-β-1a is produced in mammalian cells and has the same sequence as the naturally occurring compound, while IFN-β-1b is produced in modified *Escherichia coli* and has a Met-1 deletion and a Cys-17 to Ser mutation. IFN-β-1a is glycosylated, and IFN-β-1b is nonglycosylated. Studies of the efficacy of IFN-β in RRMS have yielded remarkably consistent results across different formulations of the drug. In multiple randomized, double-blinded placebo-controlled trials, IFN-β therapy reduced annual relapse rates by 20–35%.[48] However, approximately 30% of patients with MS do not respond to the drug. The mechanism of action of IFN-β in MS has not been definitively elucidated. Proposed mechanisms include induction of the immunosuppressive cytokine IL-10, inhibition of pathogenic Th17 cells, and stabilization of the BBB via direct effects on the cerebrovascular endothelium.

Glatiramer Acetate

GA comprises a mixture of polypeptides of different lengths and sequences, synthesized by the randomized polymerization of four amino acids, namely, glutamic acid, lysine, alanine, and tyrosine. These are the most prevalent amino acids in MBP, a candidate autoantigen in MS. It was originally thought that GA would act as a competitive antagonist of MBP peptides for binding to MHC class II molecules on APCs. Subsequent mechanistic studies did not support that theory. The mechanism of action of GA in MS is currently unknown, but alternative hypotheses that have been proposed include immune deviation of myelin-reactive T cells from a destructive Th1 to an innocuous Th2 phenotype, increase in frequency and function of FoxP3$^+$ regulatory CD4 T cells or regulatory CD8 T cells, and induction of antiinflammatory type II monocytes. A pivotal trial of GA versus placebo in 1995 demonstrated a mean reduction in the relapse rate of approximately 30%.[49] In contrast, a multinational, multicenter, double-blind, placebo-controlled phase III trial of GA in PPMS was stopped after an interim analysis by an independent data safety monitoring board indicated no discernible treatment effect on the primary outcome measure.[8] GA, administered by subcutaneous injection, was approved by the FDA in 1996 for reducing the frequency of relapses, but not for reducing the progression of disability.

Teriflunomide

Teriflunomide, an oral pyrimidine synthesis inhibitor, was approved by the FDA in 2012 for relapsing forms of MS. It has broad immunosuppressive effects, including a cytostatic effect on proliferating T and B lymphocytes. In a pivotal phase III trial, teriflunomide reduced annualized relapse rate by 31% compared with placebo.[50] In an independent phase III rater-blinded comparator trial, teriflunomide was found to have a similar efficacy to IFN-β-1a in reducing the proportion of participants with at least one relapse over 1 year.[51] Teriflunomide is teratogenic in rats and rabbits and is therefore contraindicated in pregnant women and women of childbearing potential not using reliable contraception.

Dimethyl Fumarate

Dimethyl fumarate (DMF) is the methyl ester of fumaric acid. Prior to being tested as a DMA in MS, DMF was used as a biocide in furniture and shoes to prevent the growth of molds during storage or transport. A combination of DMF and three other fumaric acid esters was marketed in Germany as a treatment for psoriasis. In two phase III trials conducted in 2012, oral DMF was demonstrated to decrease the annualized relapse rate of adults with RRMS by approximately 34–50% compared with placebo.[52,53] An additional cohort of subjects treated with GA was included as a reference comparator in one of the trials.[53] There was no significant difference in the effect of twice-daily oral DMF versus daily subcutaneous GA on relapse rate, but significantly fewer new or enlarging hyperintense lesions were noted on T2-weighted MRI images in participants treated with DMF. These results led to FDA approval in 2013. DMF therapy is often associated with lymphopenia. Therapeutic efficacy does not appear to be inversely related to lymphocyte counts. As with IFN-β and GA, the mechanism by which DMF suppresses MS disease activity remains unclear. The most common side effects of DMF are flushing and gastrointestinal upset. In the postmarketing setting, several cases of progressive multifocal leukoencephalopathy (PML), a rare viral infection of the brain, were reported in patients who were taking DMF and had persistent lymphopenia. PML has also been reported as a complication of other DMAs, including fingolimod and, most notably, natalizumab.

Fingolimod

During homeostasis, sphingosine 1 phosphate receptor 1 (S1P1) signaling into lymphocytes drives their egress from lymph nodes into the bloodstream. Fingolimod is an orally administered S1P1 receptor modulator that effectively traps myelin-specific T cells in lymph nodes so that they cannot reenter the circulation and gain access to the CNS. In a 24-month randomized, double-blinded, placebo-controlled trial, fingolimod was shown to reduce annualized relapse rates by 50%.[54] Furthermore, the probability of disease progression at the 24-month follow-up was lower in the fingolimod-treated subjects. In an independent 12-month, double-blind, double-dummy phase III comparator study, fingolimod reduced the annualized relapse rate to a range of 0.16–0.20, as compared with 0.33 for IFN-β-1a, corresponding to a relative reduction of 38–52%.[45] In 2010, fingolimod became the first oral DMA approved by the FDA to reduce relapses and delay disability progression in patients with relapsing forms of MS. However, in a phase III randomized, double-blind, placebo-controlled trial, fingolimod did not slow disease progression in patients with PPMS.[11,12] Fingolimod does not distinguish between pathogenic and protective lymphocytes, and a number of opportunistic infections have emerged as complications of the treatment. Patients taking fingolimod are susceptible herpes virus infections, particularly shingles. In the phase III comparator study with IFN-β-1a, two fatal infections occurred among the fingolimod-treated subjects: disseminated primary varicella zoster and herpes simplex encephalitis.[45] Consequently, patients are screened for immunity to varicella zoster before commencing treatment. In the postmarketing setting, there have been at least three cases of PML in fingolimod-treated patients with no or only distant prior exposure to immunosuppressant drugs. Other potential side effects of fingolimod include macular edema, bradycardia, and atrioventricular block.

Natalizumab

Natalizumab is a humanized mAb reactive against the cell adhesion molecule α_4 integrin, which is widely expressed on lymphocytes and monocytes. Natalizumab is believed to mediate its ameliorative effects in RRMS by blocking interactions between the very late antigen-4 (VLA-4; a heterodimer composed of the α_4 and β_1 integrin chains) on leukocytes with its cognate ligand, vascular cell adhesion molecule (VCAM)-1, on cerebrovascular endothelial cells. VLA-4–VCAM-1 interactions are required for the passage of lymphocytes and monocytes past the BBB. Natalizumab was approved by the FDA for relapsing MS in 2004 following a 2-year phase III trial. Natalizumab reduced the relapse rate at 1 year by 68% and the number of gadolinium-enhancing MRI lesions at both 1 year and 2 years by over 90%, compared with placebo.[44] Natalizumab also reduced the risk of sustained progression of disability by 42% over 2 years. In an independent placebo-controlled trial, the addition of natalizumab to IFN-β-1a suppressed break through disease activity and reduced the risk of sustained disability in patients who were refractory to IFN-β alone.[55] The effects of natalizumab on leukocyte trafficking are not specific to the CNS. In fact, in 2008, the FDA approved natalizumab for the treatment of refractory Crohn disease. The most serious complication of natalizumab treatment is PML; there have been over 400 reported cases. Factors that increase the risk of natalizumab-associated PML include John Cunningham (JC) virus seropositivity, duration of treatment >2 years, and prior exposure to immunosuppressant drugs.

Alemtuzumab

Alemtuzumab is a humanized anti-CD52 mAb that globally depletes circulating T and B lymphocytes via antibody-dependent cell-mediated cytotoxicity, complement-dependent cytolysis, and induction of apoptosis. CD52 is primarily expressed on the cell surface of T and B lymphocytes, but it is also expressed at lower levels on macrophages, eosinophils, and natural killer (NK) cells. The function of CD52 is unknown, although there is some evidence that it is involved in T-cell activation. Hematopoietic stem cells (HSCs) do not express CD52, allowing the subsequent repopulation of circulating lymphocyte pools following alemtuzumab treatment, which occurs at variable rates between lymphocyte subsets. Reconstituted circulating T-cell pools have been found to be enriched in $CD4^{+}CD25^{high}CD127^{low}FOXP3^{+}$ regulatory T cells (Tregs) that might be responsible, in part, for the long-lasting therapeutic effect of alemtuzumab, that has been observed in some individuals.[56] In a 2-year, rater-masked, randomized controlled phase III trial, previously untreated patients with RRMS were randomly allocated to receive intravenous alemtuzumab or subcutaneous IFN-β-1a.[57] Alemtuzumab was given once per day for 5 days at baseline and once per day for 3 days at 12 months. Relapse rates were reduced by 54.9% in the alemtuzumab group compared with the IFN-β-1a group. In an independent study, alemtuzumab reduced relapse rates and the risk of sustained accumulation of disability in patients with RRMS refractory to first-line DMAs.[47] Although alemtuzumab suppressed new MRI lesion formation and superimposed relapses in patients with SPMS, it did not prevent clinical progression or progressive cerebral atrophy.[7]

Despite causing a profound lymphopenia, alemtuzumab therapy has only rarely been associated with opportunistic infections and has not been associated an increased incidence of malignancy. Surprisingly, the principal adverse effect of alemtuzumab in MS is antibody-mediated autoimmune disease, most commonly Graves disease. Idiopathic thrombocytopenic purpura, Goodpasture syndrome, and antiglomerular basement membrane disease have been reported less frequently. The underlying mechanism is not fully understood but may be a consequence of homeostatic T-cell proliferation following lymphoablation, leading to the generation of chronically activated oligoclonal CD4 and CD8 T cells capable of producing proinflammatory cytokines.[58]

Daclizumab

Daclizumab is a humanized mAb reactive to CD25, the α subunit of the IL-2 receptor. Daclizumab was originally proposed as a treatment for RRMS based on the hypothesis that it would block IL-2–dependent expansion of effector T cells. However, mechanistic studies have shown that daclizumab does not inhibit T-cell survival, proliferation, or cytokine production. Some patients treated with daclizumab exhibit an expansion of circulating $CD56^{bright}$ NK cells, which correlates with treatment response.[59] $CD56^{bright}$ NK cells have been shown to possess immunoregulatory properties and to kill activated autologous T cells *in vitro.* Daclizumab might also modulate lymphoid tissue inducer cells in patients with MS and thereby suppress the development of meningeal lymphoid follicles.[60] In a phase III randomized placebo-controlled clinical trial in RRMS, subcutaneous administration of daclizumab reduced the annualized relapse rate by 45%, the proportion of patients who relapsed by 41%, and new or newly enlarged T2-weighted MRI lesions by 54%, compared with intramuscular IFN-β-1a over 144 weeks.[61] It was approved by the FDA in 2016 for the treatment of relapsing MS in adults. Side effects include an increased risk of infections, hepatotoxicity, noninfectious colitis, lymphadenopathy, and cutaneous events, such as rash and eczema. On the basis of its safety profile, daclizumab is generally reserved for patients who have an inadequate response to ≥2 other disease modifying agents.

B Cell–Depleting Monoclonal Antibodies

A role of B cells in the pathogenesis of MS has been suspected since the discovery of unique oligoclonal bands in the CSF of the majority of individuals with MS, indicative of intrathecal antibody synthesis. Nonetheless, B cells are not a prominent component of the perivascular infiltrates in MS lesions. This apparent paradox has been resolved, at least in part, by the discovery of lymphoid follicle–like structures, composed of proliferating B cells, antibody-producing plasma cells, Th cells, and FDCs, in the meninges of some individuals with MS.[6] Although meningeal lymphoid follicles have primarily been detected in autopsy specimens from persons with progressive MS, it is possible that nascent immune cell aggregates develop in the RR stage but are disrupted during the dissection and processing of CNS tissues. The most direct evidence for a role of B cells as effector cells in MS pathogenesis comes from trials of mAbs directed against CD20, a B cell–specific surface molecule. CD20 is expressed on preB cells and mature B cells. It is not expressed on antibody-secreting plasma cells. Rituximab, a genetically engineered chimeric anti-CD20 mAb, induces a rapid depletion of circulating B cells that lasts approximately 6–9 months. In a phase II clinical trial of rituximab in RRMS, subjects in the active treatment arm experienced a significant reduction in clinical relapses and in the formation of new or enhancing MRI lesions compared with subjects in the placebo arm.[62] Ocrelizumab is a next-generation fully human recombinant anti-CD20 mAb that binds to a different epitope from rituximab and with higher affinity. In two large phase III studies, ocrelizumab reduced the annualized relapse rate in subjects with RRMS by nearly 50% compared with IFN-β-1a over a 2-year period.[63] Additionally, ocrelizumab delayed confirmed disability progression by approximately 40% and the total number of gadolinium-enhancing lesions by >90% compared with IFNβ-1a.

Interestingly, some patients with progressive MS might also benefit from the depletion of $CD20^+$ cells, particularly if there is evidence of ongoing activity at the time of treatment initiation. Hawker et al. found that rituximab significantly delayed the time to confirmed disease progression in a subset of patients with primary progressive MS who had gadolinium enhancing lesions on baseline MRI scans of the brain.[9] The benefit was most dramatic in subjects aged <51 years. In a recently completed trial of ocrelizumab in PPMS, the risk of progression of clinical disability was reportedly reduced by 24%.[63] As a result, in early 2016, the FDA granted ocrelizumab "breakthrough therapy designation" for PPMS.

The mechanism by which B cell–depleting therapy alleviates MS does not appear to be reduction in antibody titers. Rituximab depletes B cells from the CSF of patients with RRMS with little effect on CSF IgG levels.[64] B cells are professional APCs, and there is some evidence that they are important for sustaining myelin-specific Th17 responses in MS. The frequency of GM-CSF–producing B cells was found to be elevated in RRMS.[65] Hence, ocrelizumab and rituximab may eliminate an important cellular source of GM-CSF, a monocyte/macrophage–mobilizing cytokine that has been implicated in the pathogenesis of autoimmune demyelinating disease. Disruption of meningeal follicle–like structures is yet another putative mechanism of action that might be particularly relevant to progressive forms of MS.

THERAPEUTIC PRINCIPLES

Pharmaceutical Management of MS

- Corticosteroids accelerate the rate of recovery from multiple sclerosis (MS) relapses, but there is little evidence that they impact the ultimate degree of recovery or the future clinical course.
- The US Food and Drug Administration (FDA) has approved 14 disease-modifying agents (DMAs) that reduce annualized relapse rates in patients with RRMS by approximately 20–70%.
- Newer generation DMAs either deplete lymphocytes, inhibit their expansion, or block their migration to the central nervous system (CNS).
- DMAs differ in efficacy and safety profiles. Opportunistic infection, in particular progressive multifocal leukoencephalopathy, has been observed in association with several DMAs.
- The choice of DMAs must be customized on an individual basis, taking into account disease activity and risk tolerance.

FUTURE DIRECTIONS

Dramatic advances have been made in the management of RRMS, but much remains to be done. The DMAs currently in use have global effects on lymphocytes, as opposed to specifically targeting autoreactive Th1 and Th17 cells. Consequently, protective as well as pathogenic immune responses may be undermined, increasing the risk of infection. Furthermore, DMAs are generally ineffective in progressive forms of disease. Critical goals of the MS research community at present are to better define the cellular and molecular mechanisms that link neuroinflammation to end-organ injury (namely, demyelination and axonopathy) and to elucidate the pathogenic pathways that underlie clinical progression. It is also imperative to develop a deeper understanding of obstacles to endogenous repair pathways in the CNS. This knowledge could ultimately lead to the discovery of laboratory-based surrogate biomarkers of both acute and chronic disease activity, as well as drugs that block, or even slow, disability accumulation in progressive MS and promote remyelination and axonal regeneration across clinical subtypes.

ON THE HORIZON

- The introduction of disease-modifying therapies has represented a major advance in the treatment of individuals with relapsing–remitting multiple sclerosis (RRMS). However, these drugs have global effects on lymphocytes, thereby increasing the risk of infection. A future goal will be to develop drugs that specifically target pathogenic leukocytes and/or autoreactive lymphocytes.
- Disease-modifying therapy is currently focused on the modulation of lymphocytes. Drugs that target innate immune cells may enhance MS therapy in the future.
- Recent studies suggest that B cell–depleting therapy may be beneficial for some patients with primary progressive MS (PPMS). There is a dire need for drugs that slow, or even halt, disability accumulation in progressive forms of MS and that are effective in older patients without evidence of recent neuroinflammatory activity.
- An increased understanding of the mechanisms by which inflammatory cells cause central nervous system (CNS) damage and of the obstacles to endogenous repair pathways in MS may inform the development of neuroprotective and neuroregenerative agents.

MULTIPLE-CHOICE QUESTIONS

1. The etiology of multiple sclerosis is believed to be:
   - **a.** a viral infection of the central nervous system
   - **b.** an autoimmune disorder mediated by myelin-reactive lymphocytes
   - **c.** a primary neurodegenerative disorder
   - **d.** a toxic encephalopathy

2. The mechanism of action of disease modifying therapies currently used to reduce MS relapse rates is:
   - **a.** Blockade of lymphocyte trafficking to the central nervous system
   - **b.** Depletion of lymphocytes
   - **c.** Inhibition of T cell proliferation
   - **d.** Inhibition of pyrimidine synthesis
   - **e.** All of the above

3. To make a diagnosis of relapsing remitting MS it is critical to demonstrate:
   - **a.** Dissemination of lesions in time
   - **b.** Dissemination of lesions in space
   - **c.** Immunoglobulin synthesis in the central nervous system
   - **d.** Worsening of symptoms with increases in core body temperature
   - **e.** a and b

Autoimmune Peripheral Neuropathies

Marinos C. Dalakas

Autoimmune peripheral neuropathies (APNs) occur when immunological tolerance to peripheral nerve components (myelin, Schwann cell, axon, and motor or ganglionic neurons) is lost. In some of these neuropathies, there is direct evidence for autoimmune reactivity mediated by specific antibodies or autoreactive T lymphocytes against peripheral nerve. In others, the underlying immune-mediated mechanism is secondary or indirect, and an autoimmune cause is suspected when the neuropathy coexists with another systemic autoimmune disease or viral infection.

This chapter reviews the most common autoimmune neuropathies (Table 67.1), their clinical features and diagnostic criteria, the prevailing autoimmune phenomena that govern each neuropathy, and the most effective therapeutic approach.

ACUTE INFLAMMATORY POLYNEUROPATHY: GUILLAIN-BARRÉ SYNDROME(S)

Guillain-Barré syndrome (GBS) is an acute demyelinating polyneuropathy characterized by acute (within 1 week) or subacute (within 4 weeks) ascending motor weakness, mild or moderate sensory abnormalities, occasional cranial nerve involvement, and muscle or radicular pain.[1-5] Tendon reflexes are reduced but can be normal, especially in axonal GBS. It is a disease of all ages, with an incidence of 0.8–1.9 (median 1.1) per 100 000,[4] and occurs sporadically, although occasional outbreaks have been noted. In typical cases, the maximum deficit is reached by the fourth week, a sign conventionally used to separate GBS from chronic inflammatory demyelinating polyneuropathy (CIDP), in which the disease begins slowly and usually reaches a nadir after at least 2 months. There are, however, patients with CIDP (perhaps up to 16%) with subacute onset and monophasic course and fall between the two time-frames and still others with an even more acute onset, reaching a nadir within 6–8 weeks and resembling GBS.[1-4] Distinguishing GBS from acute-onset CIDP is challenging because the distinction, in most cases, becomes evident in retrospect, although proposed criteria may help separate the two early in the disease course.[1-5]

After reaching the clinical peak, there is a recovery period that varies from weeks to years according to disease subtype or severity at onset; rapid initial progression over <7 days, severity at onset requiring mechanical ventilation, age >60 years, and preceding diarrheal illness are signs associated with incomplete recovery or worse outcome. GBS is not one syndrome, but several syndromes, reflecting the varying degree of involvement of the motor or sensory nerve fibers and the myelin sheath or the axon. The GBS subtypes, or GBS variants,[1-5] include:

- *Acute inflammatory demyelinating polyneuropathy* (*AIDP*), which accounts for the majority (probably 80%) of patients. In classic cases, the weakness starts from the legs and spreads up to the arms, intercostal and diaphragmatic muscles, and facial or bulbar muscles, causing dysphagia and dysarthria. At times the weakness may be limited to one or two limbs or to cranial nerves. Patients need to be monitored for impending respiratory failure, hence the need for early admission to intensive care units (ICUs). Autonomic dysfunction occurs in varying degrees in up to 65% of patients; if severe, it can be life-threatening as a result of cardiac arrhythmias or hemodynamic changes, such as hypertension, orthostatic hypotension, and reduced peripheral vascular tone.[1-5]
- *Acute motor axonal neuropathy* (*AMAN*), which exhibits primary axonal damage caused by massive acute demyelination and inflammation, as occurs in experimental allergic neuritis (EAN) when the animals are immunized with a high dose of myelin antigen,[1-5] or by a primary axonal event mediated by macrophages. These patients have a fulminant course with severe paralysis and complete electrical inexcitability of motor nerves as early as 3–5 days after onset.[1-5] In contrast to AIDP, involvement of cranial nerves is infrequent, and reflexes are normal or increased, especially early in the disease. AMAN is common in Asia and Central South America, accounting for 30–65% of all GBS cases in these regions.[5] Recovery of motor function is variable; some patients recover within days as a result of resolution of conduction block, but others have slow and poor recovery because of excessive axonal degeneration at the root level.[1-5] Infection with *Campylobacter jejuni* appears to be responsible for many of these cases.[1-7] A number of patients also have high levels of antiganglioside GM1 antibodies.[1-7]
- *Acute motor–sensory axonal neuropathy* (*AMSAN*) is similar to AMAN, but with concurrent involvement of the sensory axons, and has a pathomechanism similar to that of AMAN, including frequent antibodies against GM1 and GD1a gangliosides following *C. jejuni* infection.
- *Miller Fisher syndrome* (MFS) is characterized by acute onset of ophthalmoplegia, gait ataxia, normal sensation, and areflexia.[1-7] In a third of patients, there is muscle weakness with pharyngeal, facial, trunk, and respiratory muscle involvement; rarely it can present as an isolated ocular nerve palsy.[1-7] MFS is a variant that is distinct because of the presence of a unique immunoglobulin G (IgG) antibody against GQ1b ganglioside.[1-7]

TABLE 67.1 Common Autoimmune Neuropathies

- Guillain-Barré syndrome(s) (GBS)
- Chronic inflammatory demyelinating polyneuropathy (CIDP) and its variants
- Polyneuropathy associated with paraproteinemias
- Immunoglobulin M (IgM) monoclonal gammopathies
- IgG and IgA monoclonal gammopathy
- Polyneuropathy, organomegaly, endocrinopathy, myeloma, and skin changes (POEMS) syndrome
- Cryoglobulinemic polyneuropathy
- Multifocal motor neuropathy with conduction block
- Paraneoplastic neuropathies associated with anti-Hu antibodies
- Autoimmune autonomic neuropathies
- Vasculitic neuropathies
- Infectious neuropathies (human immunodeficiency virus [HIV], cytomegalovirus [CMV], Epstein-Barr virus [EBV], and herpes virus infections; Lyme disease; leprosy; Chagas disease; diphtheria; others)

- *Sensory ataxic GBS* results from the involvement of roots and ganglionic neurons. Some of these patients have antibodies to GD1b ganglioside, probably forming a continuum with MFS because they share autoantibodies with the same sialic groups.[1-7]
- *Acute pandysautonomic neuropathy,* where the target antigen is seemingly in the ganglionic neurons, although never identified. Autonomic symptoms, however, can coexist in all forms of GBS during the acute, stable, or even the recovery phase.[1-5]

Diagnosis

The diagnosis is often suspected on clinical grounds, but it is confirmed with elevated levels of cerebrospinal fluid (CSF) protein and abnormal results of electrophysiological studies consistent with active demyelination or nerve inexcitability.

CSF protein may be normal in the early phase of the disease, but it can be as high as 1000 mg/dL by the sixth week. The elevation of CSF protein levels may result from the involvement of the roots related to inflammation, but, as the blood–nerve barrier becomes impaired, serum albumin and IgG may enter freely into CSF, contributing further to protein elevation. CSF cell count is normal (or slightly increased <50 cells per microliter); there is, however, lymphocytosis when GBS occurs in conjunction with viral infections, such as human immunodeficiency virus (HIV), cytomegalovirus (CMV), Epstein-Barr virus (EBV), or Lyme disease. When CSF protein is very high, papilledema can develop because of impaired reabsorption of CSF and raised intracranial pressure. Oligoclonal IgG bands can be also seen. Results of nerve conduction studies can be normal early in the disease; they are, however, often helpful to distinguish AIDP from AMAN or AMSAN, although sometimes serial studies are needed in the ensuing weeks. Nerve conduction studies may also have prognostic value because features of demyelination suggest higher chances of needing mechanical ventilation, whereas the presence of low compound muscle axon potentials from the outset (indicative of axonal loss) predicts poor outcome.[4,5] Differential diagnosis of GBS should include other forms of acute flaccid paralysis, such as brainstem stroke; brainstem encephalitis; acute motor neuron involvement caused by poliomyelitis or West Nile virus infection; acute myelopathy; disorders of neuromuscular transmissions, such as myasthenia gravis or botulism; disorders of muscles, such as hypokalemia, inflammatory myopathy (especially the necrotizing autoimmune subtype), acute rhabdomyolysis, or periodic paralysis; and other rare causes of acute neuropathy, such as porphyria, toxins, vasculitis, or critical illness polyneuropathy.

Antecedent Illnesses or Events

Two-thirds of patients with GBS give a history of a flu-like illness or acute dysenteric episodes that precede the development of GBS by 1–3 weeks.[1-5] Among the implicated viruses are CMV, EBV, herpesvirus, hepatitis A, HIV, and now Zika virus. Among bacteria, infection with *Mycoplasma pneumoniae* and, most importantly, *C. jejuni* may be present in >25% of the patients and in some parts of the world up to 50%.[1-5] *Campylobacter* is of special interest because it contains glycoconjugates that share epitopes with the peripheral myelin, as discussed later. Two vaccines—one against rabies and the other against the swine flu A/New Jersey influenza strain that caused an outbreak of GBS in 1976[1-5]—have been convincingly associated with development of GBS. Administration of rabies vaccine that contains brain material is followed by GBS in about 1 in 1000 cases. Apart from these vaccines, however, despite anecdotal reports, there is no convincing evidence that the incidence of GBS is increased in association with other vaccines. Presently there is concern that Zika virus, an arbovirus in the family of Flaviviridae, is emerging in several countries and territories of South America as a cause of microcephaly and GBS. Although the information is still evolving, compelling data from French Polynesia provide evidence that Zika is associated with GBS in the form of AMAN with rapid disease evolution—within 4–6 days—and antiglycolipid antibodies in 31% of the patients.[8] On the basis of the total number of 42 reported cases from October 2013 to March 3014, the risk of GBS was estimated to be 0.24 per 1000 Zika virus infections.[8] Although this is clearly alarming, considering that Zika is a mosquito-borne virus, more data are needed. Surgery can precede the development of GBS in some patients[1-4]; surgical stress, the release of nerve autoantigens, and infections have been proposed as possible explanations for this association. Three drugs—gold, perhexiline, and suramin at high doses—have been causally associated with acute demyelinating neuropathy. GBS has occurred in patients who suffer from neoplasms, especially lymphoma, melanoma, and Hodgkin disease.[1-4] Interestingly, GBS is rarely seen as part of another connective tissue disorder.

Immunopathology of Guillain-Barré Syndrome

GBS is an inflammatory demyelinating polyneuropathy in which the peripheral myelin, the axon, the node of Ranvier, or the Schwann cell are the putative target antigens of an immune attack, possibly triggered by various antecedent events. Both the cellular and the humoral components of the immune system have been implicated.[1-5]

Cellular Factors

Two histopathological features are prominent in typical GBS: perivascular and endoneurial inflammatory infiltrates throughout the nerves, roots, or plexuses[1-4] and segmental demyelination in areas associated with the lymphoid infiltrates, especially macrophages. Macrophages, which are the most prominent cells in contact with nerve fibers, break through the basement membrane of healthy Schwann cells and make direct contact with the outermost myelin lamellae, leading finally to lysis of the superficial myelin sheath (macrophage-mediated demyelination).

Cytokines and chemokines released by the activated T cells or complement activation may increase capillary permeability and facilitate transmigration of additional macrophages or T cells. When the demyelination is extensive or chronic, it is followed by axonal degeneration.[1-5] The degree and effectiveness of remyelination and axonal regeneration dictate the degree of clinical recovery.

The role for a T cell–mediated process in GBS is mostly derived by analogy to the animal model of EAN, which resembles GBS in both its pathology and its clinical course.[1-5] Animals sensitized to whole human nerve or to various myelin proteins, such as P0, P2, and the neutral glycolipid galactocerebroside, develop segmental demyelination with mononuclear cell infiltrates consisting of macrophages and T cells. In EAN, T cells are sensitized against myelin and can passively transfer the disease to healthy animals. Increased levels of interleukin-2 (IL-2) and soluble IL-2 receptors are noted in serum during the acute phase of GBS, suggesting ongoing T-cell activation. Further, lymphocytes from patients with GBS exert myelinotoxic activity when applied to cultures of myelinated axons.

Humoral Factors and Antiganglioside Antibodies

There is much stronger evidence that circulating serum factors are responsible for GBS. On clinical grounds, this is supported by the beneficial effect of plasmapheresis, presumably by removing putative antibodies. On laboratory grounds, it is supported by the variety of autoantibodies detected in patients' sera. Serum from the acute phase of GBS can demyelinate rodent dorsal root ganglionic extracts in a complement-dependent manner. Furthermore, GBS serum injected into rat sciatic nerves causes demyelination and conduction block. Complement-fixing IgM antibodies against a human peripheral nerve myelin glycolipid that contains carbohydrate epitopes as well as high-titer antibodies against various sulfated or acidic glycosphingolipids are present in several patients with GBS.[1-7]

Gangliosides are present in all tissues but are especially abundant in the nervous system. Their lipid portion lies in the cell membrane, and their signature sugar residues are exposed at the extracellular surface bearing one or more sialic acid molecules, such as one sialic acid ganglioside (GM1), two (GD1a), three (GT1a), or four (GQ1b).[1-7] Although they do not form a common "GBS antigen," different gangliosides are involved in different GBS subtypes. They are of pathogenic relevance because immunization of rabbits with GM1 and GD1b induces acute neuropathy with histological features of AMAN.[1-7] Their pathogenicity was also confirmed by an inadvertent experiment in humans who had received ganglioside injections for various maladies and developed AMAN accompanied by anti-GM1 antibodies.[1-7] Additionally, antibodies to GQ1b or GD1a cause conduction block at the motor nerve terminals in a preparation of mouse phrenic nerve.[1-7] Similarly, antibodies to GalNAc-Gd1a from a patient with AMAN blocked neuromuscular transmission in a mouse spinal cord muscle coculture system.

IgG antibodies that react with GM1, GD1a, GalNAc-GD1a, and GM1b are found in 80% of cases with the motor axonal form of GBS (AMAN and AMSAN), but in the most common GBS subtype, AIDP, ganglioside-specific antibodies are uncommon. Among gangliosides, the one that clearly correlates with a specific clinical syndrome is the GQ1b, which is specifically associated with the MFS variant with IgG anti-GQ1b antibodies present in >90% of these patients [1-7] In contrast, anti-GQ1b antibodies of the IgM class can be found in patients with chronic IgM paraproteinemic polyneuropathies,[6] as discussed later. Anti-GQ1b IgG antibodies are also found in postinfectious ophthalmoplegias as well as in GBS with ophthalmoplegia, but not in those without ophthalmoplegia or other autoimmune conditions.[1-7] Of interest, anti-GQ1b antibody binds the paranodal regions of oculomotor nerves III, IV, and VI, suggesting that damage to these regions blocks impulse propagation at the nodes of Ranvier, resulting in a conduction block that is characteristic for GBS. Many patients with antibodies to GQ1b also have antibodies to GD1a.

The reasons for different clinical syndromes in connection with specific gangliosides remains unclear, but distribution, accessibility, and density or configuration of gangliosides at different sites may be critical factors. For example, there is more GM1 in ventral roots than in dorsal roots, hence the predominantly motor neuropathy seen with anti-GM1 antibodies; there is also more GQ1b in the ocular motor nerves, which may explain the involvement of eyes in MFS. How these antibodies induce disease, however, remains unclear. Current evidence suggests that antibodies against different acidic glycolipids or sulfatides may be related to different viral or bacterial antecedent factors, as discussed below.

Molecular Mimicry: Relationship Between *Campylobacter jejuni* and Gangliosides in Acute Motor Axonal Neuropathy

Antecedent infection with *C. jejuni* has been commonly associated with AMAN. The strain of *C. jejuni* associated with AMAN (Penner D: 19 serogroup) is, however, different from those causing common enteritis and is more likely to have the genes for enzymes that synthesize sialic acid in the bacterial wall mimicking ganglioside GM1, GD1a, or GQ1b.[1-5] These patients have a higher incidence of anti-GM1 antibodies, which suggests cross-reactivity between epitopes in the lipooligosaccharide in the bacterial wall and the ganglioside.[1-5] Further, injection of lipooligosaccharides extracted from *C. jejuni* into rabbits has been shown to induce acute neuropathy, with development of anti-GM1 antibodies identical to those found in AMAN.[1-7] In addition, immunization of mice with these lipooligosaccharides generates a monoclonal antibody (mAb) that reacts with GM1 and binds to human peripheral nerve. This GM1 mAb as well as the anti-GM1 IgG extracted from patients with GBS block muscle action potentials in muscle–spinal cord coculture. Carbohydrate mimicry between the bacterial lipooligosaccharide and human GM1 is therefore an important cause of AMAN. Because *C. jejuni* is a common cause of a diarrheal illness worldwide, and diarrhea has been an antecedent event in up to 50% of patients with GBS, *Campylobacter* appears to trigger the disease in many patients, especially in certain parts of the world. Isolation of *Campylobacter* from stools early in acute GBS varies from 44% to 88% of patients, and IgG or IgM *Campylobacter*-specific antibody titers are seen in a higher percentage (36%) of patients with GBS than in controls (10%).

Molecular mimicry may not be limited to *C. jejuni* because GM1 and GQ1b epitopes are also found in the bacteria wall of *Hemophilus influenzae,* which is also a triggering factor in GBS. GBS triggered by CMV infection has been also associated with the presence of IgM anti-GM2 antibodies. Another potential factor for molecular mimicry is *M. pneumoniae,* which precedes GBS in 5% of cases and is known to stimulate antibodies against human carbohydrate antigens, including galactocerebroside, the main glycolipid antigen in peripheral nerves.[1-7]

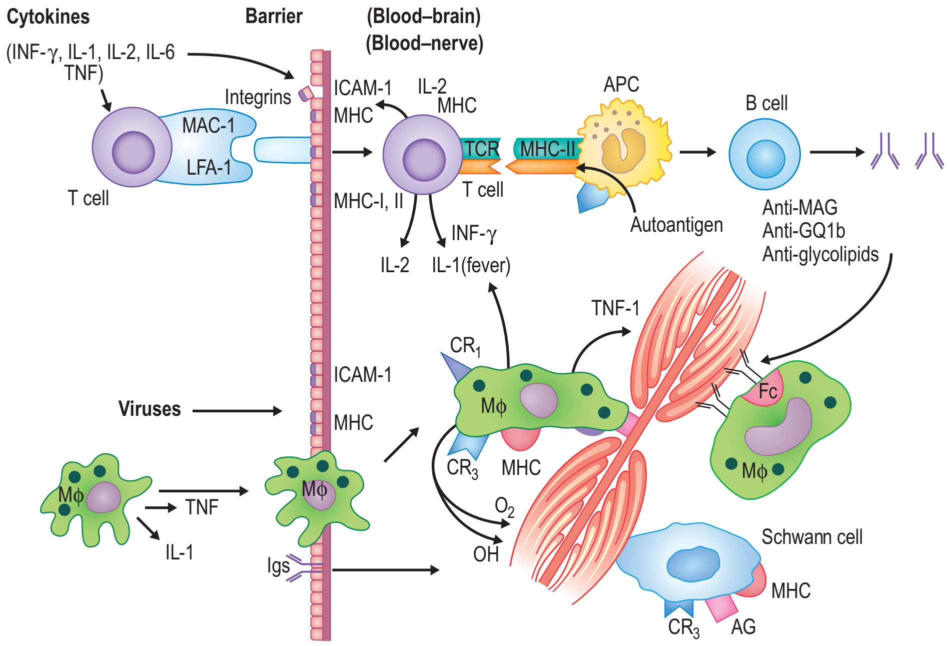

FIG 67.1 Sequence of events in the mechanisms of immune-mediated demyelinating polyneuropathy. Cytokines lead to increased expression of major histocompatibility complex (MHC) class I and intercellular adhesion molecules, allowing the sensitized T cells and macrophages to exit the endothelial cell wall and traffic to the peripheral nerve. There they recognize myelin antigen and induce a macrophage-mediated demyelination. The antigen-presenting cells (APCs; probably Schwann cells or macrophages), in concert with MHC class II expression, interact with CD4 T cells and lead to clonal expansion of B cells, producing antibodies against various peripheral nerve antigens.

Molecular mimicry may also play a role in the Zika virus–associated GBS as antiglycolipid antibodies were found in 31% of these patients.[8]

Molecular mimicry between epitopes of viral proteins (which trigger the disease) and myelin components may result in sensitization of cross-reactive T cells that may stimulate B cells to produce specific antibodies directed against myelin components or may recruit macrophages as effector cells. A combination of cellular and humoral factors therefore seems to participate in the cause of the disease.[1-8] Circulating cytokines triggered by the initiating event (viruses or bacteria) could also upregulate intercellular adhesion molecule (ICAM)-1 expression on the endothelial cells and facilitate the entrance of activated T cells or antibodies to the endoneurial parenchyma. It is relevant that ICAM-1 is increased in patients with GBS.[1-5] A scheme summarizing the immunopathogenic mechanism is shown in Fig. 67.1.

Nodal and Paranodal Alterations and Specific Antinodal Antibodies

Antibodies to nodal and paranodal antigens seen in CIDP subsets, as discussed later, have been also detected in a small number of patients with GBS in Europe. Antibodies against neurofascin, ankyrin G, and contactin could potentially explain the acute conduction block or the paranodal axonal degeneration and the rapid reversibility or slow and incomplete recovery seen in several patients with AMAN [1-5,9,10]

KEY CONCEPTS

Autoimmunity in Guillain-Barré Syndrome (GBS)

Cellular Factors

- The peripheral myelin or the Schwann cells are targets.
- Activated macrophages are the dominant endoneurial cells and lift the outermost myelin lamellae, lysing the superficial myelin sheaths.
- Peripheral blood lymphocytes exert myelinotoxic activity *in vitro.*
- Levels of interleukin-2 (IL-2) and soluble IL-2 receptors are increased during the acute phase of the disease and decline during recovery.

Humoral Factors

- Serum exerts a complement-dependent demyelination *in vitro.*
- Intraneural injections of serum from patients with acute GBS cause demyelination and conduction block.
- Immunoglobulin G (IgG), IgM, and membranolytic attack complex are detected immunocytochemically on the patients' nerves.
- High titers of IgG antibodies against peripheral nerve acidic glycolipids (GM1, GQ1b) are detected in the sera of patients with acute motor axonal neuropathy (AMAN) and Miller Fisher syndrome (MFS). The GQ1b ganglioside is a specific antigen for MFS.
- There is a high incidence of antibodies to *Campylobacter jejuni*, and GM1, with molecular mimicry between *Campylobacter* and nerve gangliosides.
- Injection of lipooligosaccharides extracted from *C. jejuni* cause AMAN and elicit GM1 antibodies in rabbits.
- Antiganglioside antibodies extracted from patients with GBS block muscle action potentials *in vitro.*

CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

CIDP is the most common form of chronic APN with prevalence as high as 9/100 000.[2,3,11,12] It is also the most gratifying chronic autoimmune neuropathy because it is treatable in the majority of the cases. It can be considered the chronic counterpart of GBS because of the various clinical, electrophysiological, histological, and laboratory similarities. CIDP differs from GBS predominantly by its tempo, mode of evolution, prognosis, and responsiveness to steroids. First described as a “steroid-responding relapsing polyneuropathy,” CIDP shares with GBS a variety of common autoimmune features.

Clinical Features and Disease Variants

The typical CIDP is characterized by a progressive, symmetrical, proximal and distal muscle weakness; paresthesias; sensory dysfunction; and impaired balance that evolve slowly over at least 2 months.[2,3,11,12] Tendon reflexes are absent or reduced. Cranial nerves rarely may be affected. The course is often monophasic, with stepwise progression; at times the disease has a relapsing course, with spontaneous remissions necessitating the need to periodically evaluate the usefulness of continuing immunotherapeutic interventions. Because the demyelination is multifocal, affecting spinal roots, plexuses, and proximal nerve trunks,[3,13] the clinicopathological picture may be variable, accounting for the different manifestation of symptoms and signs.[2,3,11,12] The most notable CIDP variants include the asymmetrical, unifocal or multifocal, motor–sensory form (Lewis-Sumner syndrome); the pure motor form; the pure sensory form; the sensory ataxic form; and the pure distal form.

Diagnosis

In CIDP, CSF protein is elevated, up to sixfold, without pleocytosis (except if an infection coexists). Nerve biopsy shows demyelination and remyelination, occasional epineurial or endoneurial T cells, and several macrophages that are either scattered or in small perivascular clusters in the endoneurium (Fig. 67.2).[2,3,11,12] Electrophysiological testing is fundamental for the diagnosis by demonstrating the following typical features of demyelination in motor and sensory fibers: *(i)* slow conduction velocity; *(ii)* prolonged distal motor or sensory latencies; *(iii)* prolonged F

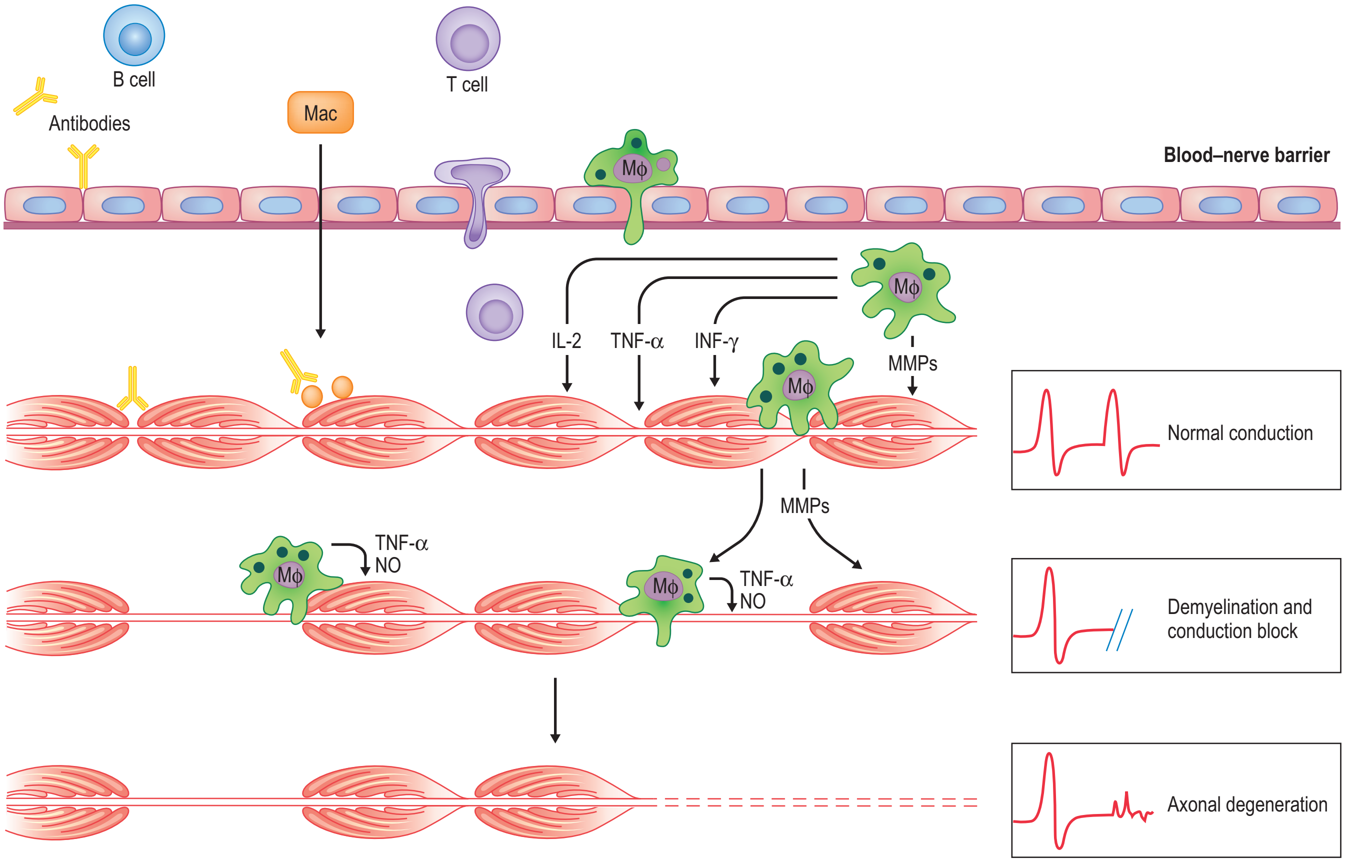

FIG 67.2 Diagrammatic scheme of the main cellular and humoral factors implicated in the demyelinating process of chronic inflammatory demyelinating polyneuropathy (CIDP) leading to axonal loss. Activated macrophages (Mϕ) and T cells cross the endothelial cell wall of the blood–nerve barrier and reach the myelinated fibers. Activated, TNF-α-positive Mϕ invade the myelin sheath, causing Mϕ-mediated segmental demyelination. Axonal loss secondary to demyelination, probably enhanced by TNF-α and metalloproteinases, may become prominent in the chronic phases of the disease. Other cytokines, T cells sensitized to unidentified antigens, and putative antibodies may participate. IL, interleukin; IFN, interferon; MMP, metalloproteinase; Mϕ, activated macrophage; TNF, tumor necrosis factor.

waves latencies; and *(iv)* conduction block with dispersion of the compound muscle action potentials. An associated axonal loss is not unusual in the majority of CIDP cases. A variety of diagnostic criteria have been proposed to capture the most pertinent of the aforementioned features; the revised European Federation of Neurological Societies/Peripheral Nerve Society (EFNS/PNS) guidelines seem the most appropriate because they offer 81% sensitivity and 96% specificity to capture patients more likely to respond to therapies.[2,3,11,12] Routine CSF testing and nerve biopsy are not mandatory for the diagnosis,[2,3,11,12] but they can be helpful when the results of electrophysiological testing are not convincing, or there is a need to exclude hereditary and vasculitic neuropathies. Other diseases causing neuropathy that should be excluded include severe diabetes (although CIDP seems more frequent in patients with diabetes), neoplasms, amyloidosis, IgM paraproteinemia (IgG or IgA monoclonal gammopathy of undetermined significance (MGUS) can be seen in CIDP), myelomas, vasculitis, alcoholism, exposures to neurotoxic drugs, or family history of neuropathy.

KEY CONCEPTS

Autoimmunity in Chronic Inflammatory Demyelinating Polyneuropathy (CIDP)

- Activated macrophages are the predominant endoneurial cell, displacing the Schwann cell cytoplasm, disrupting myelin, and lysing superficial myelin lamellae.
- Complement-fixing immunoglobulin G (IgG) and IgM antibodies are deposited on the myelin sheath.
- IgG antibodies to acidic glycolipids LM1, GM1, or GD1b and against the 28-kDa P0 myelin proteins are detected in the sera of some patients.
- There is upregulation of DR and B-7 costimulatory molecules in Schwann cells and macrophages.
- Serum IgG can induce conduction block when injected into rat nerves.
- Up to 25% of patients with CIDP harbor specific antibodies against antigens in the nodes of Ranvier; in 10% of them these antibodies have been identified as directed against neurofascin-155 and CASPR causing conduction block.

Immunopathogenesis

Because of immunopathological similarities to GBS and the relapsing–remitting EAN, in CIDP, activated T cells, macrophages, complement, and autoantibodies seem to work in concert with each other to induce an immune attack against peripheral nerve antigens[2,3,11,12] (as depicted in Fig. 67.1), but no triggering factors have been identified so far.

The predominant endoneurial mononuclear cells in CIDP are the macrophages that constitute the final effector cells associated with demyelination because they express activation markers probably induced by cytokines released by autoreactive T cells *in situ* or the circulation. These cells sequentially penetrate the basement membrane of the Schwann cell, displace the cytoplasm, and split the myelin lamellae, resulting in focal lysis of the myelin sheath.[2,3,11,12] Macrophages as well as Schwann cells may serve as antigen-presenting cells (APCs) because they express human leukocyte antigen (HLA)-DR and costimulatory molecules B7-1 (CD80) and B7-2 (CD86), whereas their counterreceptors cytotoxic T lymphocyte antigen-4 (CTLA-4) and CD28 are expressed on rare endoneurial CD4 T cells.[2,3,14] B7-2–deficient mice also develop CIDP.[15] Elevated soluble adhesion molecules, chemokines, cytokines, and metalloproteinases are detected in serum and CSF in CIDP, probably facilitating lymphoid-cell transmigration across the blood–nerve barrier. Although T cells are not prominent overall, the few CD8 and CD4 cells found endoneurially have monoclonal or oligoclonal restrictions in their T-cell receptor (TCR) repertoire, implying an antigen-driven T-cell response.[2,3,12,13]

Humoral factors seem to play a predominant role, especially with the recent identification of target antigens at the nodes of Ranvier in >10% of patients with CIDP, even though in the majority of the patients, the pathogenic antigens remain elusive. The beneficial effect of plasmapheresis provides indirect evidence that some circulatory factors are pathogenic. The concept that antibodies may be implicated dates back to >30 years when complement-fixing IgG and IgM were found deposited on a patient's myelin sheath.[16] Antibodies to glycolipids LM1, GM1, or GD1b also have been seen in some patients, but less frequently than in GBS and more frequently than in controls.[2,3,11,12] Overwhelming evidence accumulated in the last 5 years indicates that molecules associated with saltatory conduction at the nodes of Ranvier may be more meaningful targets[3,4,10,17-19] because functional blockade in these regions can best account for the rapid improvement noticeable within days after plasmapheresis or intravenous immunoglobulin (IVIG). Likely antigenic targets include neurofascin-186, moesin, and gliomedin (at the node); neurofascin-155 (NF155), contacting/Caspr 1 (CNTN1), and connexins (at the paranode); and transient–axonal–glycoprotein-1 or potassium channels (at the juxtaparanode).[3,4,10,17-19] Evidence from proteomics, transfected cell lines, teased-nerve fibers, immunocytochemistry, and enzyme-linked immunosorbent assay (ELISA) has shown that IgG4 antibodies against paranodal NF155 and CNTN1 antigens are the most relevant and seemingly pathogenic antibodies that are currently detected in at least 10% of patients.[17-19] Of interest, anti-NF155– and CNTN1-positive patients appear to have a distinct clinical phenotype with more severe disease, axonal involvement, tremors, sensory ataxia, and suboptimal response to IVIG[17-19]; these patients, however, respond better to anti–B cell therapies, such as rituximab.

Overall, the immunopathogenetic scheme proposed for GBS (see Fig. 67.1) is also appropriately applied to CIDP. Molecular mimicry can be implicated in rare cases of CIDP associated with melanoma because the carbohydrate myelin epitopes GM2, GM3, and GD3 are also expressed on melanoma cells, and antibodies against melanoma cells react with myelin glycoproteins.[20] The axonal involvement that accompanies demyelination in both CIDP and GBS, either acutely or after long-standing demyelination, is depicted in Fig. 67.2. The relevant nodal target antigens are presented in Fig. 67.3 separately[2,3,10] to highlight their recognized importance in the field of antibody-mediated peripheral demyelination.

MULTIFOCAL MOTOR NEUROPATHY WITH CONDUCTION BLOCK

MMN is a distinct disease that, although rare with prevalence of 0.6/100 000, should be recognized early because it is treatable. It affects males more than females and is more common in those <50 years of age. MMN presents with progressive weakness, atrophy, and areflexia that often begins in the hands and is prominent in distal muscle groups supplied by many individual peripheral nerves (multifocal).[2,3,21] It differs from vasculitic neuropathy because it is slow and is painless because it affects only the motor nerve fibers. It also differs from the motor variant of CIDP because it is multifocal and asymmetrical. Because some

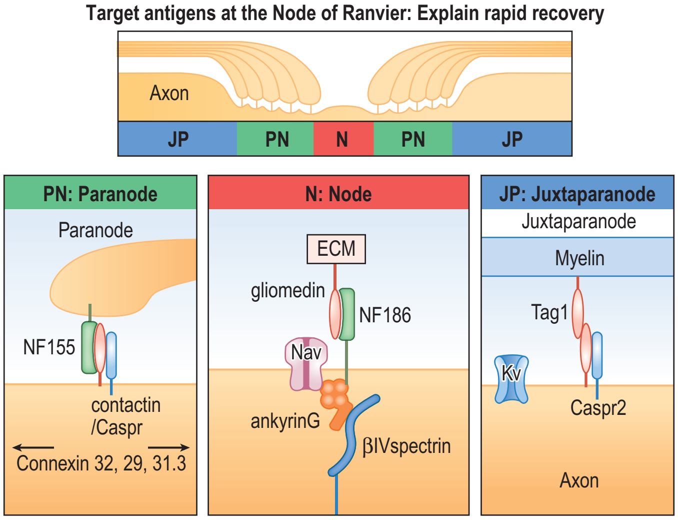

FIG 67.3 Main proteins in the nodal (N), paranodal (PN), and juxtaparanodal (JP) regions in the nodes of Ranvier implicated as antigens in acquired demyelinating neuropathies (Guillain-Barré syndrome [GBS] and predominantly chronic inflammatory demyelinating polyneuropathy [CIDP]). The two main antigenic targets in CIDP are neurofascin-155 and CASPR2 located in the paranodal regions; antibodies against these proteins are detected in the serum of 10% of patients with CIDP, resulting in conduction block and paranodal axonal changes that probably account for resistance to IVIG.[4,13]

patients with MMN can experience cramps and fasciculations, the disease is often erroneously diagnosed as lower motor neuron disease, and treatment is delayed. In contrast to lower motor neuron disease, however, MMN progresses very slowly, the weakness is within distributions of peripheral nerves and not multisegmental, and the cranial musculature is often spared. CSF protein level is normal, an important finding that distinguishes MMN from the motor variant of CIDP.

MMN has a distinct electrophysiological criterion, namely, multifocal conduction block in motor nerves. In contrast to CIDP, in which sensory conduction block is also present, in MMN the sensory conduction remains normal across the nerve segments that have motor block. The reason for a selective motor involvement is unclear. Differences in the antigenic specificities in the myelin components between motor and sensory fibers are suspected because the ceramide composition of gangliosides differs between sensory and motor fibers. Although the immunopathology of the disease remains unclear, patients with MMN respond remarkably well to immunotherapy, as discussed later. Up to 50% of the patients have high antibody titers to GM1 ganglioside, but the role of these antibodies is uncertain. IgM GM1 antibodies can be also seen in other autoimmune neuropathies and in even up to 25% of patients with amyotrophic lateral sclerosis (ALS) who do not have conduction block.

POLYNEUROPATHIES ASSOCIATED WITH MONOCLONAL GAMMOPATHIES OF UNDETERMINED SIGNIFICANCE

A distinct subset of acquired polyneuropathies has been associated with a circulating monoclonal protein (Chapter 80). Although neuropathy occurs in a setting of myeloma, plasmacytoma, or Waldenström macroglobulinemia, the majority of patients with paraproteinemic neuropathies do not have a lymphoproliferative disease, and the monoclonal gammopathy is of undetermined significance (MGUS). A benign monoclonal gammopathy may occur in up to 1% of normal people >50 years of age.[22] The incidence increases to 1.7% above age 70 years and reaches up to 6% above age 90 years. Monoclonal gammopathies, however, are 10 times more frequent in patients with polyneuropathy than in an age-matched control population, and almost 10% of patients with acquired polyneuropathy have MGUS.[23] If these gammopathies are categorized into subclasses, the incidence of polyneuropathy among patients with IgM monoclonal proteins can be as high as 50%,[23,24] implying that almost 50% of patients with IgM MGUS may have or will develop polyneuropathy. At present, polyneuropathies with MGUS comprise 10% of patients with acquired neuropathy,[23-25] and paraproteinemic polyneuropathy is a potentially treatable APN.[25]

Patients with demyelinating polyneuropathy associated with IgG or IgA MGUS are indistinguishable from those with CIDP; the paraprotein in such patients is coincidental and causally unrelated to neuropathy. In contrast, the demyelinating polyneuropathy associated with IgM MGUS is a distinct clinicopathologic entity, and the IgM is considered pathogenic because it is often directed against myelin glycoproteins or glycolipids.[2,3,6,24,25]

Some patients with paraprotein may have an associated amyloidosis derived from the variable region of the Ig light chain, primarily λ. When amyloidosis is present, the neuropathy is painful, and the sensorimotor deficits are accompanied by autonomic symptoms consisting of orthostatic hypotension, impotence, impaired gastric motility, or frequent diarrhea. Amyloid neuropathy is difficult to treat; apart from symptomatic therapy (mostly opiates), immunosuppressive therapies, especially with the various anti–B-cell agents, and bone marrow transplantation are largely applied.

ANTIBODIES TO MYELIN-ASSOCIATED GLYCOPROTEIN IN PATIENTS WITH IgM M MONOCLONAL GAMMOPATHIES OF UNDETERMINED SIGNIFICANCE POLYNEUROPATHY (ANTI-MAG NEUROPATHY)

Most of these patients present with a sensory, large-fiber, demyelinating polyneuropathy that manifests as sensory ataxia.[2,3,24,26] Other patients have a sensorimotor polyneuropathy with mixed features of demyelination and axonal loss. CSF protein is often elevated. Nerve conduction studies have demonstrated slow conduction velocity and a rather characteristic prolonged distal motor and sensory latency indicative of distal demyelination. Sural nerve biopsy demonstrates a diminished number of myelinated axons. On electron microscopy, there is splitting of the outer myelin lamellae, linked to the presence of IgM deposits in the same area of the split myelin sheath.

Sera from approximately 50% of these patients react with myelin-associated glycoprotein (MAG), a 100-kilodalton (kDa) glycoprotein of the central and peripheral nerve myelin, as well as other glycoproteins or glycolipids that share antigenic determinants with MAG.[2,3,24,27,28] The antigenic determinant for the anti-MAG IgM resides in the carbohydrate component of the MAG molecule.[3] The anti-MAG IgM paraproteins coreact with

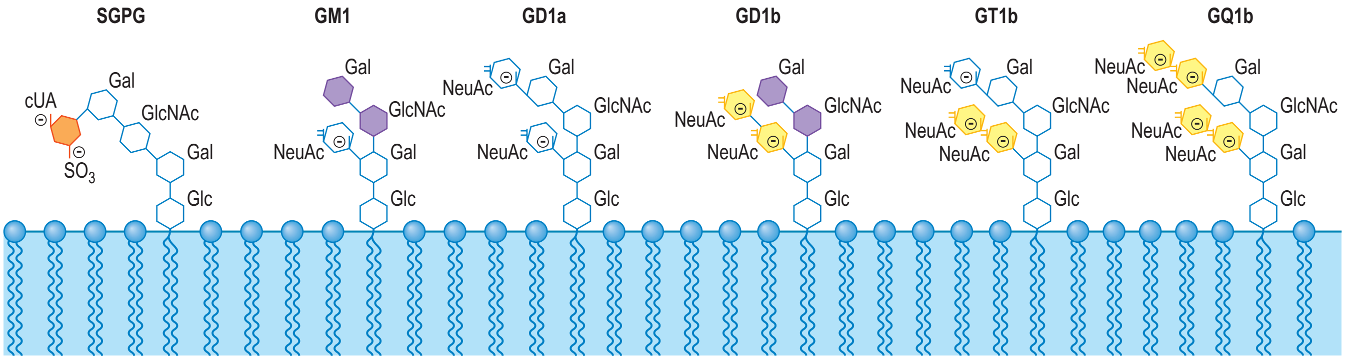

FIG 67.4 Glycolipids implicated as antigens in immune-mediated neuropathies. Sulfate-3-glucuronyl paragloboside (SGPG) is the glycolipid sharing a carbohydrate epitope with myelin-associated glycoprotein (MAG), and the terminal sulfated glucuronic acid is a key part of the epitope. GM1 is the ganglioside implicated in motor nerve disorders, and in most cases the terminal Gal (β1-3) GalNAc epitope, which is shared with GD1b, is involved. The disialosyl moiety implicated in sensory neuropathies consists of NeuAca2—8NeuAc—and is present in GD1b and GT1b gangliosides, as well as the simpler GD2 and GD3 gangliosides (not shown). GQ1b ganglioside, which is the target antigen in Miller Fisher syndrome (MFS), has two disialosyl moieties. Although GD1a ganglioside has two sialic acid residues they are not linked to each other, so antibodies to GD1a do not cross-react with anti-GD1b antibodies. The color-coded sugar moieties represent key aspects of the various epitopes, but carbohydrate sequences recognized by the antibodies may include additional sugar residues. GlcUA, glucuronic acid; Gal, galactose; G1cNAc, *N*-acetylglucosamine; Glc, glucose; GalNAc, *N*-acetylgalactosamine; NeuAc, *N*-acetylneuraminic acid (sialic acid).

an acidic glycolipid in the ganglioside fraction of human peripheral nerves, identified as a sulfoglucuronyl glycosphingolipid (SGPG).[28] In contrast to MAG, which is mostly present in the central nervous system, SGPG is found only in the peripheral nerves. The sera of some patients with IgM-MGUS with sensory ataxia may not react with MAG, but with various gangliosides, most commonly those that contain either a disialosyl moiety, such as GD1b, GQ1b, GT1b, GalNac-GM1b, and GalNAc-GD1a, or two gangliosides that share epitopes with GM2, or a combination of GM2 and GM1, GM1 and GD1b.[2,3,6,24,27,28] More than half of the IgM paraproteins recognize MAG and SGPG, and 75% of the rest recognize ganglioside antigens, indicating that acidic glycolipids are the most common antigenic epitopes.[2,3,6,24,27,28] The glycolipids implicated as antigens in immune-mediated neuropathies are depicted in Fig. 67.4.

Human anti-MAG antibodies can be detected readily in sera with ELISA or preferably with standard Western blot. Because anti-MAG–reacting sera always recognize the SGPG glycolipid, the assay is often performed by using SGPG as antigen instead of purified human MAG. It is preferable, however, to use MAG as the target antigen, rather than SGPG, because the IgM binds to MAG 10–100 times the affinity compared with SGPG—that is, low-affinity anti-MAG antibodies can be missed if SGPG is used as the antigen.

The following factors suggest that these antibodies are related to the cause of the neuropathy:

1. IgM and complement are deposited on the myelinated fibers on the patient's sural nerve biopsy,[2,3] suggesting that activated complement may be needed in the induction of demyelination.
2. IgM recognizes neural cell adhesion molecules and colocalizes with MAG on the areas of the split myelin lamellae, suggesting involvement in myelin disadhesion. Skin biopsies from these patients have also confirmed the presence of IgM, complement C3d, and MAG deposition on the dermal myelinated fibers and the concurrent loss of nerve fibers.[29]
3. Injection of serum from patients with IgM anti-MAG/SGPG paraprotein supplemented with fresh complement into feline peripheral nerve causes complement-dependent demyelination and conduction block within 2–9 days of the injection.[30] The IgM injected intraneurally localizes to the outer layer of the myelin sheath.

KEY CONCEPTS

Autoimmunity in Polyneuropathy With Immunoglobulin G (IgM) Monoclonal Gammopathy

- In more than 50% of patients IgM is an antibody against two antigens, myelin-associated glycoprotein (MAG) and sulfoglucuronyl glycosphingolipid (SGPG).
- In many patients with non-MAG–reacting monoclonal IgM, the IgM recognizes *(i)* gangliosides containing disialosyl moieties, including GM1, GM2, GD1b, GD1a, and LM1; *(ii)* sulfatides; and *(iii)* rarely, chondroitin sulfate.
- Overall, in at least 75% of patients the IgM recognizes gangliosides that appear to be the primary antigenic targets.
- IgM is deposited on the homologous myelin sheath and fixes complement.
- IgM, when deposited on the myelin sheath, results in disadhesion and separation of the myelin lamellae and disruption of normal myelin function.
- Intraneural injection of anti-MAG–reacting IgM or passive transfusion into experimental animals causes segmental demyelination, whereas complement-fixing IgM is immunolocalized to the myelin sheath, causing myelin separation.
- Immunization of cats with purified SGPG causes an ataxic neuropathy, similar to the one seen in humans, with involvement of the dorsal root ganglia.

4. Systemic transfusion of anti-MAG IgM paraproteins produces segmental demyelination in chickens,[31] with deposition of IgM on to the outer lamellae of the myelin along with splitting of the myelin lamellae, similar to that observed in the human neuropathy.
5. Immunization of cats with purified SGPG causes an ataxic neuropathy, similar to the one seen in humans, with involvement of the dorsal root ganglia including inflammation within the ganglionic neurons.[32]

POLYNEUROPATHY, ORGANOMEGALY, ENDOCRINOPATHY, MYELOMA, AND SKIN CHANGES

A subset of patients with malignant IgG or IgA monoclonal proteins have polyneuropathy with osteosclerotic myeloma. Most of them have POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M* protein, and *s*kin changes).[33] Not included in the acronym are several features, such as sclerotic bone lesions, giant lymph node hyperplasia (Castleman disease), papilledema, pleural effusion, edema, ascites, and thrombocytosis.[34] More than 50% of patients with osteosclerotic myeloma of the IgA or IgG type have a sensorimotor, symmetric polyneuropathy with mixed demyelinating and axonal features and high (usually 200 mg/dL) CSF protein. Pure axonal neuropathies can be also seen. In POEMS, the neuropathy tends to be associated with edema in the legs, with hyperpigmentation, sclerodermatous thickening, or papular angiomas of the skin, and hypertrichosis with dark hair. Endocrinopathy most often includes gonadal failure, amenorrhea, impotence, gynecomastia, hypothyroidism, diabetes, or elevated prolactin levels. The IgG class is slightly more common than the IgA class, with λ light chain present in the majority of the patients.[34] Bone lesions can be sclerotic, solitary, or multiple, sparing the skull and the extremities. Pathological changes in lymph nodes resemble those of Castleman disease, which can also be associated with polyneuropathy.[34] In POEMS, there is an imbalance of proinflammatory cytokines with increased IL-1β, IL-6, and tumor necrosis factor-α (TNF-α). Vascular endothelial growth factor (VEGF) may play a major role because it induces a rapid increase in vascular permeability and is a growth factor important in angiogenesis and endothelial cells.[34]

In some patients, the neuropathy responds to steroids, tamoxifen, or alkylating agents. In others, it may respond to the removal or irradiation of the solitary sclerotic lesion, suggesting that the tumor may secrete neurotoxic factors. IVIG and plasmapheresis are ineffective. The median survival is 165 months.[35]

Recently, autologous peripheral blood stem cell transplantation has been shown to result in significant improvement with reduction of VEGF, improved nerve conduction velocity, and increased survival.[35]

Cryoglobulinemic Neuropathy

Cryoglobulins are proteins that precipitate in the cold and redissolve when heated (Chapter 58). There are three types of cryoglobulin: type I, which is monoclonal, often of the IgM and IgG class; type II, which is mixed polyclonal, with one monoclonal (often monoclonal IgM with polyclonal IgG); and type III, which is polyclonal (often IgM and IgG). Polyneuropathy occurs most often with mixed cryoglobulinemias and presents as distal, sensory, symmetrical polyneuropathy or as mononeuropathy multiplex. These patients also have purpura, polyarthralgias, cutaneous vasculitis, Raynaud phenomenon, renal involvement with proteinuria, and polyneuropathy. Type II cryoglobulinemia may be associated with an underlying lymphoproliferative process. There is an increased incidence (up to 90%) of hepatitis C virus infection in patients with mixed cryoglobulinemia. The nerve biopsy shows perivascular inflammatory cuffing with axonal degeneration.

PARANEOPLASTIC PERIPHERAL NEUROPATHIES WITH ANTI-HU ANTIBODIES

Peripheral neuropathy is not an uncommon complication of cancer, related either to the systemic effects of the tumor or, more often, to various neurotoxic chemotherapeutic agents. It usually affects the small nerve fibers causing numbness or painful dysesthesias. The most distinct immune-related neuropathy in patients with cancer is paraneoplastic sensory neuronopathy (PSN), often associated with small cell lung cancer, and to a lesser degree with breast cancer or other neoplasms, such as lymphoma or thymoma.[36] It might be the presenting symptom preceding the discovery of the tumor by months. PSN has a unique clinical picture, characterized by burning or aching paresthesias; sensory loss of the large fibers, causing profound sensory gait ataxia and choreoathetotic movements related to loss of proprioception in the feet and hands; normal strength; and areflexia. Some patients may have autonomic dysfunction, encephalopathic symptoms, or cerebellar disturbances. CSF protein is increased, electrophysiological testing shows an axonal sensory neuropathy, and nerve biopsy demonstrates axonal degeneration with rare mononuclear cell infiltrates. PSN is a ganglionopathy (sensory neuronopathy) caused by a variable degree of inflammation in the dorsal root ganglionic neurons. These patients have specific IgG anti-Hu autoantibodies directed against a closely spaced group of proteins with a molecular weight of 35–40 kDa.[36] The antibodies are found in higher titers in CSF, suggesting intrathecal synthesis. The Hu protein is also present in the tumors of patients with PSN. Further, low titers of anti-Hu antibodies can be seen in up to 20% of patients with small cell lung cancer, even without neurological symptoms, suggesting that PSN may be the result of an autoimmune reaction against antigens shared by both the tumor cells and the dorsal root ganglionic neurons. Although the role of anti-Hu antibodies in the causation of PSN is unclear, these antibodies are specific markers to detect an occult small cell lung cancer in patients who present with sensory ataxic neuropathy. Some patients may have other paraneoplastic antibodies, such as collapsing response mediator protein (CRMP-5) often referred to as anti-CV2.[36]

AUTOIMMUNE AUTONOMIC NEUROPATHIES

Autoimmune autonomic neuropathy (AAN) is highlighted by circulating antibodies against the ganglionic nicotinic acetylcholine receptors (AChRs).[37] These patients present with a subacute (within 4 weeks) or chronic (within months) onset of neurogenic orthostatic hypotension, defined as a systolic blood pressure reduction of at least 30 mm Hg or mean blood pressure reduction of at least 20 mm Hg that occurs within 3 minutes of head tilting. The subacute onset is often preceded by a viral infection. In addition, patients demonstrate three or four parasympathetic/enteric symptoms: sicca (dry eyes and dry mouth); abnormal pupillary response to light; upper gastrointestinal symptoms (early satiety, postprandial nausea, and vomiting that lead to severe weight loss); and neurogenic bladder.

Patients with more severe cholinergic impairment have higher-titer antibodies against ganglionic AChRs. Some of these symptoms can be passively transferred to mice injected with the patient's IgG, suggesting that these antibodies may be pathogenic. Further, rabbits immunized with a fragment of ganglionic AChR protein exhibit autonomic failure, similar to the human disease.[37] Because ganglionic AChRs have also been found in small cell lung carcinoma cell lines, cancer may be a potential initiator of ganglionic AChR autoimmunity.

MONONEUROPATHY MULTIPLEX AND LOCALIZED, ISOLATED VASCULITIS OF THE PERIPHERAL NERVES

Polyneuropathy is a common manifestation of systemic vasculitis. It occurs in patients with polyarteritis nodosa; connective tissue diseases, such as rheumatoid arthritis or Sjögren syndrome; hypersensitivity vasculitis; Churg-Strauss syndrome; temporal arteritis; and viral infections, such as those with HIV, human T-lymphocyte virus (HTLV)-1, and hepatitis B and C viruses. It classically presents as mononeuritis multiplex affecting several individual nerves with painful weakness and paresthesias caused by ischemia and infarcts caused by inflammation of endoneurial blood vessels. There is, however, a distinct vasculitic entity localized only to the peripheral nerve, known as *isolated peripheral nerve vasculitis* (PNV). PNV involves the small and medium-sized arteries of the epineurium and perineurium and causes ischemic changes within the peripheral nerve. The presentation is similar to the vasculitic neuropathy seen in systemic vasculitis—the only difference is the lack of systemic organ involvement, slower onset and progression, and negative serology. The diagnosis is confirmed with nerve biopsy of the sural, superficial peroneal, or superficial radial nerve. When nerve biopsy is combined with muscle biopsy, the diagnostic yield is higher. PNV has a better prognosis compared with systemic vasculitides and is a treatable form of neuropathy. An evaluation for PNV should include all the tests needed to exclude systemic vasculitis and cryoglobulinemia, as well as hepatitis B and C infections, which can be associated with PNV.

NEUROPATHY WITH VIRUSES AND HUMAN IMMUNODEFICIENCY VIRUS

Neuropathy can be seen in a setting of infectious, viral, or bacterial processes. In patients with Lyme disease, various neuropathies, including GBS and mononeuritis (Bell palsy), have been noted. Other infections, such as CMV, hepatitis, herpes, leprosy, Chagas disease, and diphtheria, can affect the peripheral nerves, triggering autoimmune peripheral neuropathy.

Common neuropathies seen today in a setting of a viral infection are those associated with HIV and include GBS, CIDP, acute ganglioneuritis, or mononeuritis multiplex; they occur early in the infection, or they are the presenting manifestation of unsuspected HIV infection.[38] HIV has been cultured from the peripheral nerves, and HIV viral RNA has been amplified from sural nerve biopsies of some patients in the author's laboratory. However, there is no convincing evidence that the neuropathy results from direct infection of the peripheral nerves by the virus. Immunocytochemical studies have shown that HIV is present only in rare endoneurial macrophages, but not within Schwann cells or axons. A strong expression of HLA class I and class II molecules on Schwann cells, endothelial cells, and/or macrophages, but sparse presence of CD8 and CD4 T cells, is also noted (Fig. 67.5). It is possible that systemic viral infection or rare HIV-infected endoneurial lymphoid cells may release cytokines that expose new nerve antigens against which there is no self-tolerance, generating a tissue-specific autoimmune attack.

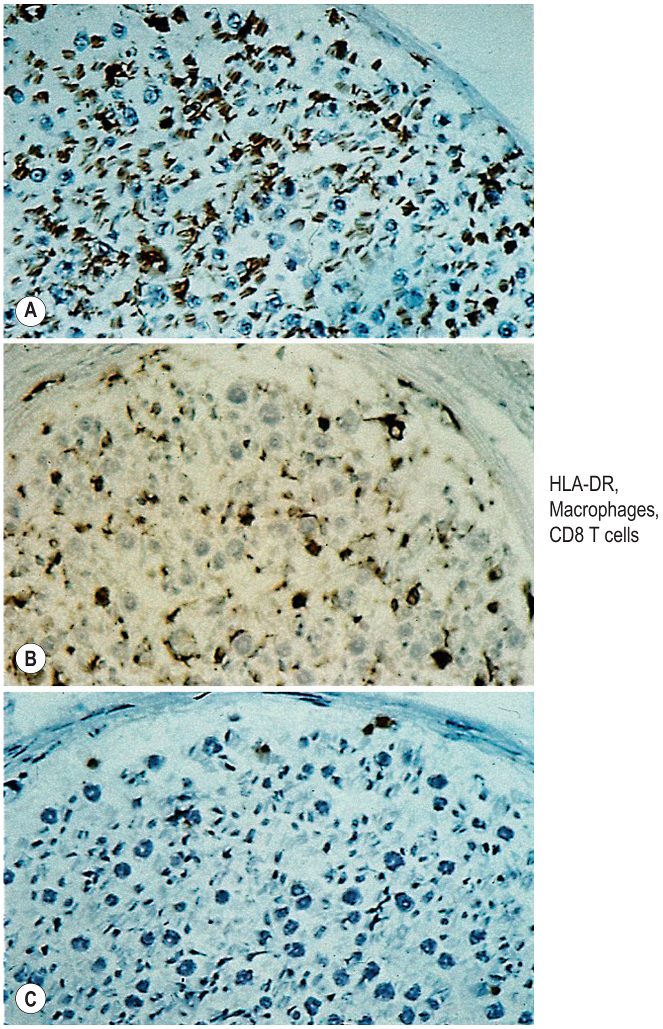

FIG 67.5 Serial sections of a nerve biopsy from a patient with human immunodeficiency virus (HIV)–chronic inflammatory demyelinating polyneuropathy stained for (A) human leukocyte antigen (HLA)-DR, (B) macrophages, and (C) CD8 T shows that the majority of the endoneurial cells are macrophages. Only rare CD8 cells are noted.

A rare neuropathy seen in later-stage HIV infection is a lumbosacral polyradiculoneuropathy related to CMV infection that affects roots and sensory ganglia. It presents with lower-extremity muscle weakness, sacral and distal paresthesias, areflexia, and atrophy, mostly of the legs, associated with sphincteric dysfunction resembling cauda equina syndrome. CMV inclusions can be found within Schwann cells or endothelial cells (Fig. 67.6). Early recognition is important because anti-CMV therapy with ganciclovir or foscarnet can be helpful.

At present, the most common neuropathy in patients with acquired immunodeficiency syndrome (AIDS) is a painful sensory axonal neuropathy that affects up to 70% of adults with AIDS and

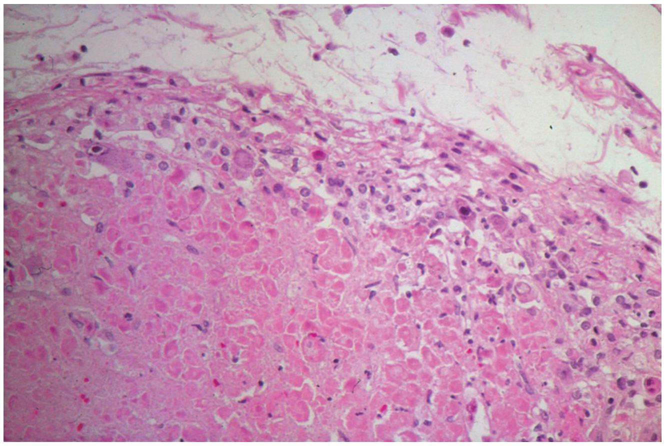

FIG 67.6 Cross-section of a root from a patient with human immunodeficiency virus (HIV)–associated Guillain-Barré syndrome (GBS) shows cytomegalovirus inclusions within the Schwann cell.

occurs later in the disease.[38] It is caused by a cumulative effect, on the peripheral nerves, of various endogenous or exogenous neurotoxins related to a multisystem disease and dysfunction of many organs along with toxicity from various antiretroviral drugs. Clinical findings include distal painful dysesthesias, sensory loss or hypesthesia, areflexia, and, in advanced cases, distal weakness. Despite the relative lack of motor involvement, the severity of neuropathic pain can be disabling.

TREATMENT

APNs are clinically important because they are potentially treatable with various immunosuppressive, immunomodulating, or chemotherapeutic agents. The selection of an effective protocol is based on the results of experimental therapeutic trials, clinical experience, and the risk–benefit ratio of available therapies. The author's approach to the treatment of these disorders is described below.

Guillain-Barré Syndrome

Supportive Care

The dramatic reduction in the mortality of GBS is mainly attributed to the availability of ICUs, improvement of respiratory support, antibiotic therapy, and control of autonomic cardiac dysregulation. A patient with GBS is best monitored in an ICU, even if respiratory compromise is not evident at the time of admission. When forced vital capacity (FVC) drops or bulbar weakness is severe, intubation is necessary.

Plasmapheresis

In several double-blind controlled studies, plasmapheresis has been shown to be effective if performed within the first week from onset of the illness. A series of five or six exchanges, with one exchange every other day, is sufficient. Early relapses can occur in up to 20% of patients, who may require a second series of plasma exchanges.[1-5] Plasmapheresis has been shown to be effective even in mild cases of GBS; two exchanges are sufficient for mild GBS, and four are optimal for moderate cases, but there is no difference between those who receive four plasma exchanges and those who receive six.

High-Dose Intravenous Immunoglobulin

On the basis of the results from two controlled studies,[1,4] IVIG (Chapter 84), given at 2 g/kg over 2–5 days, has been shown to be equally effective as plasmapheresis, with no added benefit when the two procedures were combined. The decision as to which treatment to choose is governed by circumstances, availability of the treatment modality, experience, age of the patient, and other associated conditions. Early relapses can also occur with IVIG, as often as with plasmapheresis. IVIG has become the therapeutic choice worldwide because it is easy to administer and more readily available and because time to initiate treatment is of the essence.

Steroids are ineffective in GBS and may even increase the incidence of future relapses. Combining IVIG with IV methylprednisolone has shown no significant added benefit.

Chronic Inflammatory Demyelinating Polyneuropathy

Prednisone

CIDP has been originally described as a classic steroid-responsive polyneuropathy. The efficacy of steroids was proven in a controlled study, albeit with inadequate blinding, but reconfirmed in another.[2,3,11,12,39] A high-dose regimen of 80–100 mg prednisone daily is preferred, followed by tapering to every-other-day dosing. Azathioprine, cyclosporine, or mycophenolate can be used as steroid-sparing agents, but their efficacy, although not tested in controlled studies, has been disappointing overall. Methotrexate in a controlled study was ineffective.[2,3,11,12,39]

Intravenous Immunoglobulin

In several controlled studies,[2,3,11,12,39] IVIG has been effective in the majority of patients with CIDP. The more chronic the disease and more severe the axonal degeneration that has taken place, the lower are the chances that the recovery will be complete or significant. IVIG, in the largest-ever controlled study, has been proven an effective first-line therapy, and maintenance therapy has prevented relapses.

Plasmapheresis

Plasmapheresis has been also effective in controlled studies.[2,3,11,12] After a series of six plasma exchanges, maintenance therapy, with one exchange at least every 8 weeks, may be required if this therapy is beneficial. IVIG has now replaced plasmapheresis, although in the author's experience, some patients may benefit more from steroids, others more from IVIG, and still others more after plasmapheresis.

Polyneuropathy With Paraproteinemias

Patients with benign IgG or IgA demyelinating polyneuropathies respond in a manner similar to CIDP patients. Patients with malignant paraproteinemias should be treated with chemotherapy, as needed for the underlying disease. When the neuropathy is axonal, treatments are generally disappointing.

For IgM anti-MAG demyelinating polyneuropathies, treatments with prednisone plus chlorambucil, plasmapheresis, and IVIG[2,3,40] has shown a variably marginal benefit. Rituximab, an mAb against CD20, is the most promising therapy,[41] providing efficacy in almost 40% of the patients in a small double-blind study, as confirmed later with a larger study,[33] even though both did not reach significance. Additional, uncontrolled series with many patients, have confirmed that rituximab is effective in 30–40% of these patients.

MULTIFOCAL MOTOR NEUROPATHY

MMN responds very well only to IVIG, which is the treatment of choice based on controlled trials. In difficult cases, cyclophosphamide or rituximab may be promising, but no controlled studies have been carried out.[2,3,21]

Paraneoplastic Anti-Hu Neuropathy

Anecdotally, some of these patients have responded to plasma exchange or IVIG, but overall this neuropathy has not been consistently responsive to available therapies.

Vasculitic Neuropathies

For isolated peripheral nerve vasculitis, a combination of prednisone 1.5 mg/kg/day with cyclophosphamide 2 mg/kg/day orally, or 1 g/m^2 intravenously monthly for 6 months, are the treatments of choice; specific treatment protocol may vary from patient to patient. The administration of cyclophosphamide may not be necessary for >6 months, as in systemic vasculitis. Plasmapheresis has been tried in cryoglobulinemic neuropathies, with variable results.

Human Immunodeficiency Virus Neuropathies

The two demyelinating neuropathies, GBS and CIDP, are treated with the same immunomodulatory therapies as used in HIV-negative patients with IVIG being the preferable choice. Ganciclovir may be helpful in CMV-related polyradiculoneuropathy. Painful sensory neuropathy can be quite disabling because of intractable pain. Tricyclic antidepressants (TCAs), nonsteroidal antiinflammatory drugs (NSAIDs), anticonvulsants (carbamazepine, gabapentin, topiramate), and topical capsaicin in various combinations provide some relief from neuropathic pain.

ON THE HORIZON

- Identification of common causes that break tolerance, either in connection with the gut microbiome or exogenous agents, and expansion of the current limited data on molecular mimicry between nerve glycoproteins and viral or bacterial antigens
- Development of neuroimaging capabilities to image peripheral nerves and dorsal roots *in vivo* and quantify inflammation, demyelination and axonal degeneration, providing an accessible and reliable tool for diagnosis and monitoring response to therapies, in a model similar to magnetic resonance imaging (MRI) in multiple sclerosis
- Performance of proteome studies aimed to identify biomarkers of nerve autoimmunity that may lead to specific therapies
- Trials with target-specific therapies for acute and chronic demyelinating neuropathies, *applied in combination with the existing therapies,* targeting early in the disease process complement activation, regulatory T cell (Treg) functions, key proinflammatory cytokines, and B cells
- Identification of agents and trophic factors that could prevent axonal degeneration from the outset, promote remyelination, prevent axonal loss, or trigger axonal regeneration and reverse, early in the disease process, a seemingly "permanent" clinical deficit

ACKNOWLEDGMENTS

The author thanks the various Neurology Fellows who provided excellent care to his patients; and Drs. Amjad Ilyas and Richard Quarles for help with immunochemistry of MAG and SGPG and gangliosides.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following findings predicts an incomplete recovery in patients with Guillain-Barré syndrome (GBS)?
   A. Slow initial progression
   B. Absence of bulbar findings
   C. Presentation in the third decade
   D. Requirement of mechanical ventilation

2. Which is the most common form of GBS?
   A. Acute inflammatory demyelinating polyneuropathy
   B. Acute motor axonal neuropathy
   C. Acute motor–sensory neuropathy
   D. Miller Fisher syndrome

3. Which of the following tests is the most useful in establishing the diagnosis of GBS?
   A. Sural nerve biopsy
   B. Cerebrospinal fluid (CSF) protein levels
   C. Nerve conduction study
   D. Brain magnetic resonance imaging (MRI)

4. Which of the following finding is characteristic of chronic inflammatory demyelinating polyneuropathy (CIDP)?
   A. Asymmetrical weakness
   B. Sensory dysfunction
   C. Normal peripheral reflexes
   D. Cranial nerve involvement

Immunological Renal Diseases

Meryl Waldman, Howard A. Austin III, James E. Balow

Compelling clinical, pathological, and experimental data indicate that most forms of glomerular diseases manifest some element of immune-mediated injury.[1] Major advances in our understanding of the etiology and pathogenesis of the various glomerular diseases have occurred in the past decade. However, the primary events or inciting factors that trigger the host immune responses and secondary pathways that are directly or indirectly pathogenic to the kidney are still not fully elucidated. In some conditions, normal or allergic immune responses to exogenous infectious agents or drugs can lead to incidental nephropathic injury (*e.g.,* postinfectious glomerulonephritis, serum sickness). In the case of autoimmune diseases, nephropathic processes range from loss of self-tolerance to specific constitutive renal tissues (*e.g.,* antiglomerular basement membrane [GBM] disease) or to extrarenal tissues and cells (*e.g.*, antineutrophil cytoplasmic autoantibodies [ANCAs]). Other mechanisms include excessive and unregulated polyclonal immune responses that produce nephritogenic immune complexes (*e.g.,* lupus nephritis).[1,2] Recent advances have begun to uncover candidate antigens involved in the pathogenesis of immune-mediated renal diseases (*e.g.,* some subsets of membranous nephropathy [MN]). But it has become increasingly apparent that the immune system does not operate in isolation and that there are extraordinarily complex interactions among vast networks involving components of native and adaptive immune systems, humoral and cell-mediated immune systems, small-molecular-weight mediators derived from lymphoid and other cell types, complement factors and their regulatory proteins, other inflammatory and coagulation system pathways, microvascular biology, and tissue repair, as well as sclerosis and fibrosis reactions. Underlying this constellation are associated genetic risk factors that modulate these responses and predispose to a nephritogenic response. Rapidly evolving molecular and genetic technologies with the tools of modern systems biology and bioinformatics will continue to unravel these complex interactions.[3]

Appropriate evaluation of patients with immune-mediated kidney diseases requires particular attention to the findings of urinalysis, assessment of the type and amount of proteinuria, tests of renal functions, and renal biopsy. Urine microscopy also plays a pivotal role in the assessment of urinary disorders.

HEMATURIA

Red blood cells (RBCs) that emanate from lesions of the calices, ureters, bladder, or urethra tend to maintain their normal morphology; when nondysmorphic RBCs are present, it is usually appropriate to refer the patient to urology for further evaluation. Urinary RBCs that result from glomerular or tubulointerstitial pathology are more likely to appear dysmorphic (abnormal shapes and sizes, fragmented); when these dysmorphic RBCs, called *acanthocytes,* are present, it is usually appropriate to refer the patient to nephrology for further evaluation. Erythrocyte and/or leukocyte casts are indicative of glomerulonephritis (or interstitial nephritis). Cellular casts can be formed from erythrocytes and/or leukocytes that enter the tubular lumen because of glomerular or tubular inflammation (Fig. 68.1).

PROTEINURIA

Glomerular proteinuria results from a loss of the size-selective and/or charge-selective properties of the glomerular capillary wall and disruptions of the glomerular epithelial cells (podocytes), allowing plasma proteins (especially albumin) to leak into the filtrate. Tubulointerstitial nephropathy often leads to impaired tubular absorption of other normally filtered low-molecular-weight proteins; this so-called tubular proteinuria exhibits a characteristic pattern on urine protein electrophoresis (low fraction of albumin), rarely exceeds 2 g/day, and is often associated with other manifestations of tubular dysfunction.

Estimates of proteinuria are based on 24-hour urine collections or on the protein/creatinine or albumin/creatinine concentration ratios in random urine samples. Normally, these ratios should be <0.1. Filtration of abnormal plasma proteins can be responsible for proteinuria (*e.g.,* multiple myeloma or monoclonal immunoglobulin [Ig] light-chain disease). This type of proteinuria (paraproteinuria) may be undetected by albumin-sensitive dipstick screening. Paraproteinemia may also be undetected or underestimated by standard plasma electrophoresis; however, an assay for serum free light chains is more sensitive for detection of low levels of circulating light chain paraproteins. Identification of specific Ig-derived paraproteinuria usually requires urine immunofixation electrophoresis (Fig. 68.2)

NEPHROTIC SYNDROME

Nephrotic syndrome is characterized by substantial degrees of proteinuria (>3.5 g/day or protein to creatinine ratio >2.5) resulting in hypoalbuminemia, edema, hyperlipidemia, and lipiduria. The degree of proteinuria can offer a helpful diagnostic clue because some immune-mediated conditions with typically diffuse glomerular disease (*e.g.,* MN, systemic lupus erythematosus [SLE]) are more likely than others with typically focal disease (*e.g.*, IgA nephropathy, ANCA-associated glomerulonephritis) to be associated with nephrotic syndrome.

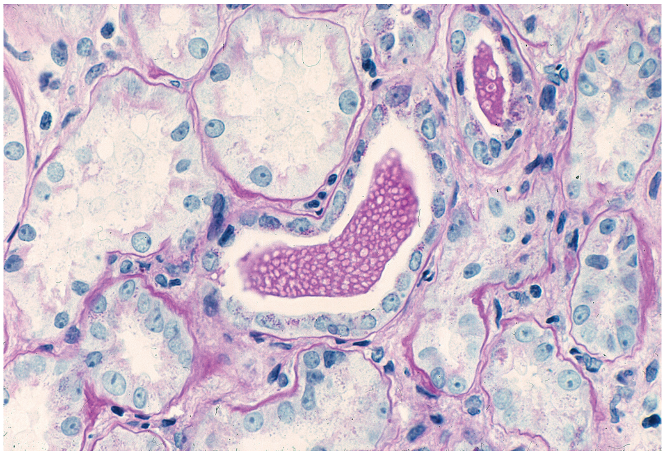

FIG 68.1 **Red Blood Cell Cast.** Cast present *in situ* within the lumen of a distal renal tubule. (Periodic acid–Schiff [PAS] stain.)

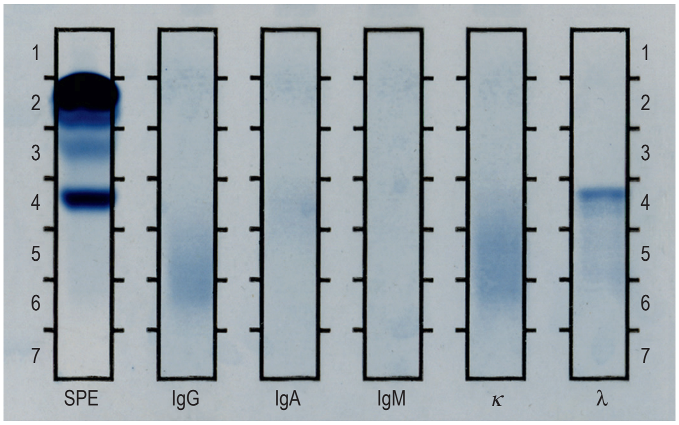

FIG 68.2 **Immunofixation Electrophoresis of Urinary Protein.** Proteins in a concentrated urine protein are separated in six replicate lanes by standard protein electrophoresis. Separated proteins are identified by overlaying specific antisera to immunoglobulin G (IgG), IgA, IgM, κ and λ. In this example, a monoclonal paraprotein composed of λlight chain is identified as an intense narrow band in the far right hand lane.

ACUTE NEPHRITIC SYNDROME

Acute nephritic syndrome is characterized by hematuria (dysmorphic cells), erythrocyte casts, abnormal proteinuria, fluid retention, azotemia, and hypertension. Histologically, this constellation of clinical findings is due to proliferative glomerulonephritis. A variant of this syndrome, called *rapidly progressive glomerulonephritis* (RPGN), is defined by ≥50% loss of glomerular filtration rate over 3 months, along with characteristically >50% of glomeruli showing cellular crescents on renal biopsy..

CHRONIC GLOMERULONEPHRITIS

Broad and waxy casts are features of chronic renal disease that are not likely to be seen in acute or subacute glomerulonephritis.

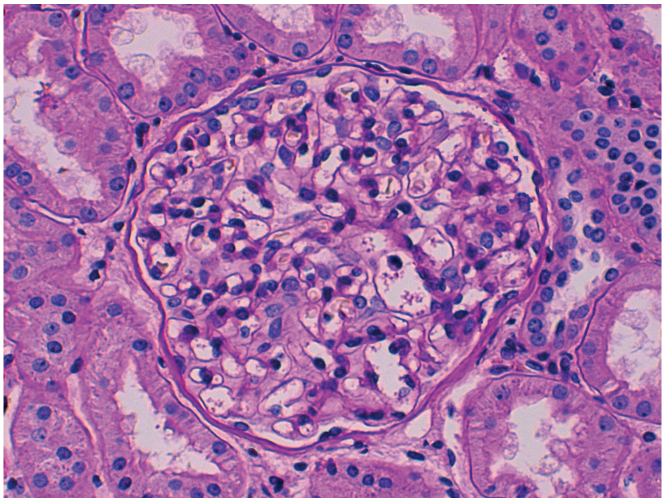

FIG 68.3 **Normal Glomerular Architecture.** The glomerular capillary loops are patent and have normal thickness. Neither increased endocapillary cells nor expanded mesangial matrix encroach upon the patency of the capillary lumina. (Periodic acid–Schiff [PAS] stain).

TABLE 68.1 Indications for Renal Biopsy

1. Active "nephritic" urine sediment
    - Dysmorphic erythrocytes: >10 per high-power field
    - Cellular casts: erythrocyte or leukocyte
2. Proteinuria >2 g/day
3. Abnormal renal function
    - Associated with the above features of active nephritis
    - Particularly important if the duration of renal disease and/or rate of change are unknown
4. Document indications for use of high-risk therapeutic interventions

RENAL BIOPSY

After extensive clinical and laboratory evaluations, renal biopsy may be indicated to establish or confirm a tissue diagnosis, to clarify the precise type of renal involvement, to formulate a prognosis, and to direct therapy. Some of the more important indications for renal biopsy are listed in Table 68.1. Light microscopy appearance of a normal glomerulus is illustrated in Fig. 68.3.

MINIMAL CHANGE DISEASE

KEY CONCEPTS

Minimal Change Nephropathy

- Most common cause of nephrotic syndrome in children
- High rate of response to glucocorticoids
- Cyclophosphamide is useful for frequent relapsers
- Renal prognosis is characteristically excellent
- Subset may evolve to focal segmental glomerulosclerosis

Nephrotic syndrome of childhood is mainly caused by minimal change disease (MCD). The frequency of MCD in adults with nephrotic syndrome is low compared with those of other entities discussed below.[4]

Clinical Features

Minimal change nephropathy characteristically presents with a rather precipitous onset of severe nephrotic syndrome in the absence of signs of a systemic disease. There are no specific tests other than kidney biopsy to establish a diagnosis of minimal change nephropathy, although proteinuria exclusively comprising albumin is characteristic; standard immunological screening tests are usually normal.

Etiology and Pathogenesis

The cause of MCD is largely unknown. There is evidence of immune dysregulation, mainly involving cell-mediated immunity, which is supported by the tendency of the disease to manifest and relapse after viral infections or an allergic reaction, the association of some cases with Hodgkin lymphoma, and its characteristically favorable response to immunosuppressive drugs. Another hypothesis is that a systemic circulating factor of immune origin results in increased glomerular permeability[5] (discussed in the section on "Focal Segmental Glomerulosclerosis")

The basic lesion of MCD is loss or neutralization of the normal high density of anionic proteoglycans in the glomerular capillary loops. Dissipation of the negative-charge barrier allows anion-charged albumin to pass freely. Interdigitating foot processes normally joined by intercellular bridges, called *slit diaphragms,* form a second barrier to the passage of protein into the urinary space. Characteristically, the podocyte foot processes and slit diaphragms are also disrupted in minimal change nephropathy.

Pathology

With the use of light microscopy, renal biopsy results are found to be essentially normal. Electron microscopy shows the characteristic pathological lesion, where there is fusion of the foot processes of the epithelial cells (podocytes) diffusely around glomerular capillaries.

Treatment

MCD is characteristically exquisitely sensitive to glucocorticoids (remitting within the first few weeks of therapy in >90% of children). The response rate to glucocorticoids in adults is somewhat lower and more delayed. A substantial portion of patients with minimal change nephropathy face long-term difficulties because of the disease and the therapy: Some are steroid-resistant from the start; others are steroid-dependent for control of nephrotic syndrome; still others become frequent relapsers and suffer substantial steroid toxicity with repeated treatments. Controlled trials have shown that alkylating agents (*i.e.,* cyclophosphamide) increase response rates and reduce rates of relapse. Cyclosporine (CSA) and tacrolimus are alternatives to prolonged and repeated courses of steroid therapy, but relapses frequently occur with drug withdrawal. Rituximab (a monoclonal antibody [mAb] to CD20 on B cells) has been used with variable success, particularly in those who are steroid-dependent or frequent relapsers. Also, rituximab may have "off target" effects on the podocyte cytoskeletal structure.[6]

The risk of progression to end-stage renal failure is extremely low in true MCD. Renal biopsy sampling errors account for a mistaken diagnosis of MCD in a proportion of cases that are, in fact, focal segmental glomerulosclerosis (FSGS). It is debated whether MCD and FSGS represent different manifestations of one disease (with MCD potentially progressing to FSGS), or if they represent two different diseases.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

Patients with FSGS have a higher frequency of microscopic hematuria, higher frequency of persistent nephrotic syndrome, a poorer response to immunosuppressive drug therapies, and a higher risk of progression to end-stage renal failure. The incidence of FSGS is clearly increasing as a cause of nephrotic syndrome, particularly among black patients.

KEY CONCEPTS

Focal Segmental Glomerulosclerosis

- Nephrotic syndrome with progressive renal insufficiency
- Glomerular permeability factor in plasma of some cases
- Unpredictable responses to glucocorticoids or cyclophosphamide
- Cyclosporine effective, but relapses common upon withdrawal
- Moderately high relapse rate in renal allografts

Etiology and Pathogenesis

Diverse etiologies may disrupt the podocyte structure and function leading to the histological expression of FSGS. Genetic mutations of key podocyte proteins, such as podocin and nephrin play a role in a subset of FSGS that occurs in children or young adults. Circulating permeability factors have been proposed as mediators of podocyte injury in FSGS (*i.e.,* soluble urokinase-type plasminogen activator receptor). In certain situations, it appears that podocytes have increased surface expression of the transmembrane protein B7-1 (CD80) that stimulates interactions with T cells and leads to foot process effacement.[7] "Secondary" forms of FSGS may result from toxic effects of drugs (*i.e.,* pamidronate), viral infections (*e.g.,* human immunodeficiency virus [HIV]) or maladaptive hemodynamic stress (*i.e.,* resulting from obesity or reduced nephron mass).

Pathology

The characteristic renal pathology includes segmental areas of podocyte damage and detachment, irregular foot process fusion, and collapse of glomerular capillaries associated with marked local increase in matrix and collagen accumulation. Segmental sclerotic areas typically stain nonspecifically with antisera to IgM and C3 (but not to IgG or IgA), particularly in areas of glomerular tuft hyalinosis (representing trapped plasma constituents), but none of these collections should be considered to represent classic immune complexes. Various histological subtypes of FSGS have been described on the basis of the type and location of lesions. One classification scheme divides FSGS into five variants: tip, perihilar, cellular, collapsing, and not otherwise specified (NOS)[8] (Fig. 68.4). The collapsing variant of FSGS, which has been associated with viral infections, notably HIV, tends to follow a particularly aggressive course.

Treatment

Patients with primary FSGS generally have hypoalbuminemia and nephrotic range proteinuria, whereas those with secondary FSGS typically have subnephrotic proteinuria, a normal or near normal serum albumin concentration, no peripheral edema, and focal rather than diffuse foot process effacement on kidney biopsy. The possibility of genetic forms of FSGS should be considered before beginning immunosuppressive therapy, but steroid resistance may also serve as a clue to genetic forms of FSGS.

Treatment of genetic and hyperfiltration-induced forms of FSGS is focused mostly on renoprotection with angiotensin antagonists and lipid-lowering agents (statins). The treatment of other forms of primary FSGS is basically similar to that of MCD and includes immunosuppression with prednisone,

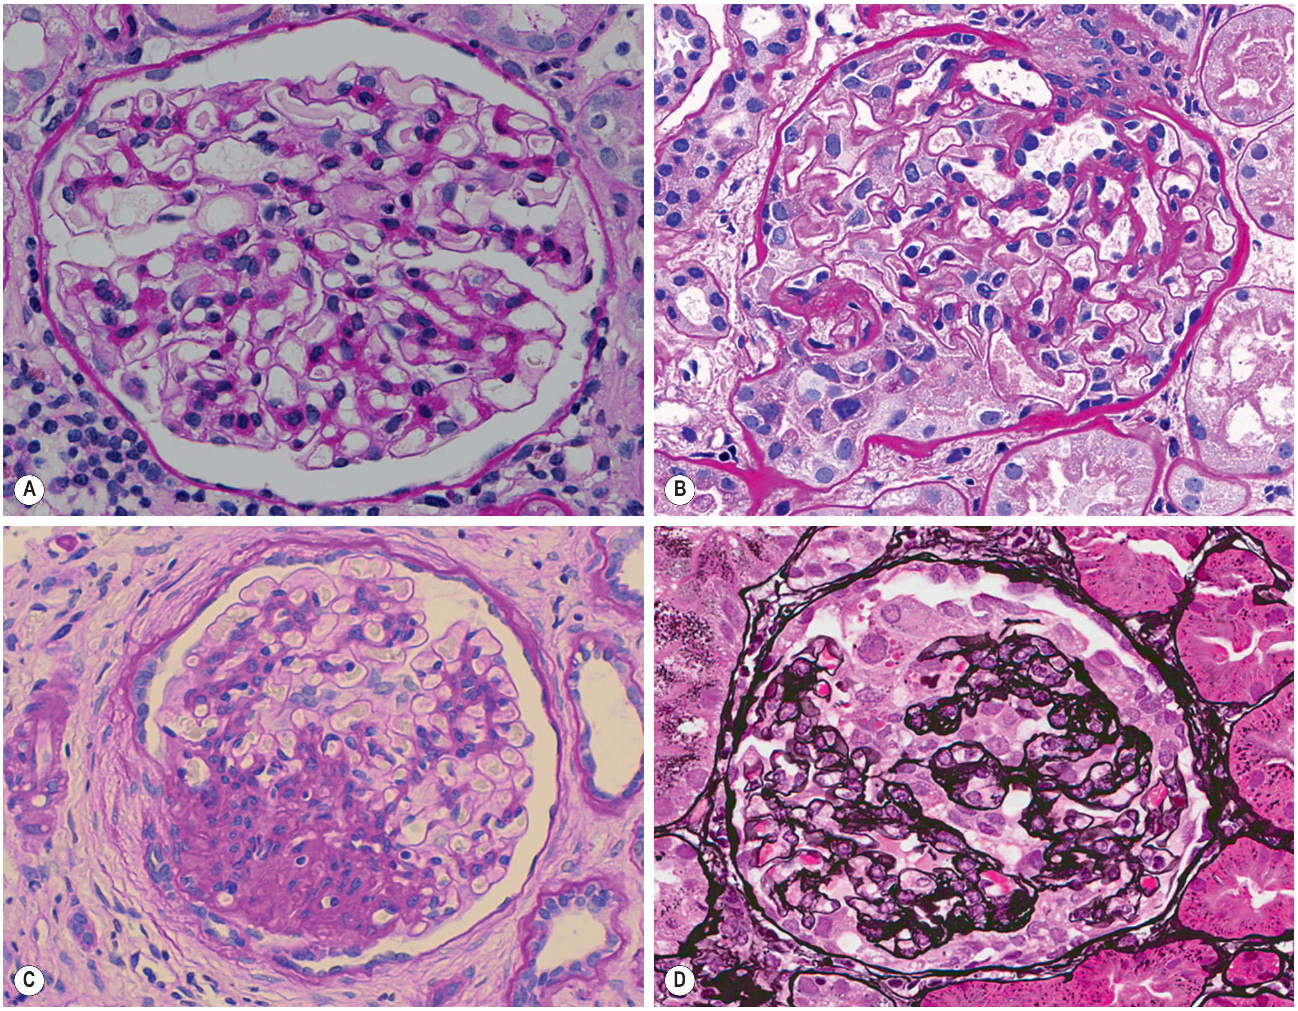

FIG 68.4 **Focal Segmental Glomerulosclerosis (FSGS).** Several forms of glomerular lesions are seen in FSGS, often within the same biopsy: A, minimal abnormality (periodic acid–Schiff [PAS] stain); B, tip lesion manifested by segmental glomerular tuft lesion near the origin of the proximal tubule (PAS stain); C, classical perihilar lesion (PAS stain); and D, collapsing glomerulopathy; the glomerulus is globally contracted with wrinkling of the basement membranes; this is associated with hyperplasia of podocytes surrounding the glomerular capillaries (methenamine silver stain).

cyclophosphamide, calcineurin inhibitors, or mycophenolate. There are mixed outcomes with use of rituximab for FSGS, but it appears less effective for steroid resistant cases.[9,10] Complete remission of proteinuria is less commonly achieved in FSGS than in MCD. Relapses of the disease and progression to end-stage kidney disease (ESKD) remains a major concern despite immunosuppression, particularly in steroid-resistant and frequently relapsing patients. Several novel therapies that target various immunological, inflammatory, and costimulatory pathways (*i.e.*, blockade of CD 80 with cytotoxic T lymphocyte antigen 4-Ig (CTLA-4-Ig) are currently under investigation for FSGS.[11,12]

MEMBRANOUS NEPHROPATHY

MN is identified in approximately 20% of adults who undergo renal biopsy for nephrotic syndrome. It is a less frequent cause of nephrotic syndrome in children. Primary MN is usually a diagnosis of exclusion after considering secondary causes, such as medication reactions, infections, neoplasms, and systemic illnesses (*i.e.*, SLE)

KEY CONCEPTS

Membranous Nephropathy (MN)

- Common cause of idiopathic nephrotic syndrome in adults
- Autoantibodies to phospholipase A_2 receptor (PLA_2R) detected in large percentage of patients with primary MN
- Several secondary causes: systemic lupus erythematosus (SLE), drugs, chronic hepatitis, certain malignancies
- One-quarter of patients have spontaneous remission
- One-quarter of patients develop end-stage renal disease within a decade
- Protracted nephrotic syndrome confers risks of cardiovascular and thromboembolic events
- Therapies: steroids, alkylating agents, calcineurin inhibitors, rituximab, lipid-lowering drugs, angiotensin antagonists

Etiology and Pathogenesis

MN is characterized by subepithelial (epimembranous) immune deposits containing IgG and complement components. The leading hypothesis based on experimental models is that immune

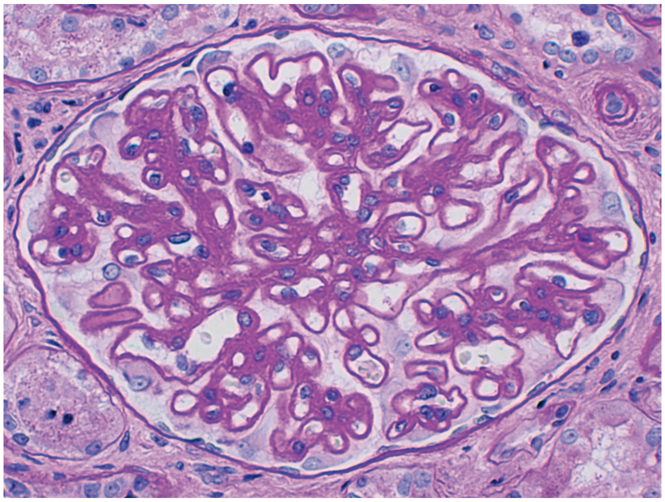

FIG 68.5 **Membranous Nephropathy.** Capillary walls are nearly uniformly thickened but remain widely patent. Cellularity of the glomerulus is normal (Periodic acid–Schiff [PAS] stain).

complexes are formed *in situ* by the interaction of a pathogenic antibody with a constitutive glomerular antigen or with an antigen that had been ectopically planted in the glomerulus. Major advances have been made with the identification of several constitutive podocyte surface antigens, which are the target of autoantibodies in some subsets of patients with primary MN.[13,14] The majority (70-80%) of patients with primary MN have circulating autoantibodies to M-type phospholipase A2 receptor (PLA_2R), a transmembrane receptor that is expressed in glomerular podocytes.[13] Antibodies to thrombospondin type-1 domain containing 7A protein (THSDA7A) and neutral endopeptidase have been identified in smaller subsets of patients.[14]

Clinicopathological Features

Patients with MN characteristically present with nephrotic syndrome. Renal biopsy is usually required to establish the diagnosis, although serological testing for relevant autoantibodies (*i.e.,* anti–PLA_2R) may be informative if renal biopsy is contraindicated.

In most cases, light microscopy shows uniform thickening of the glomerular capillary walls without endocapillary cell proliferation (Fig. 68.5). Characteristic subepithelial (epimembranous) and/or intramembranous deposits are seen on electron microscopy (Fig. 68.6). Identification of PLA_2R in glomerular immune deposits (by immunofluorescence or immunohistochemistry) favors the diagnosis of primary MN; mesangial deposits are often present in secondary MN. But a diagnosis of secondary MN depends on concurrent abnormalities in clinical and laboratory data.

Natural History

The clinical course of primary MN is highly variable. On average, about one-quarter of adult patients progress to ESKD within 10 years. Another quarter experiences a spontaneous remission of proteinuria. The majority is likely to have persistent proteinuria and moderately impaired renal function over an extended period of observation.

Baseline characteristics, such as severe nephrotic syndrome, hypertension, and azotemia, have been associated with poor outcomes. Protracted high-grade nephrotic-range proteinuria is a relatively strong predictor of an adverse renal outcome. Some studies suggest that the titer of autoantibody to PLA_2R at baseline correlates with disease activity such that higher titers may be associated with greater risk of renal function decline, whereas low titers may be associated with greater probability of spontaneous remission.[15]

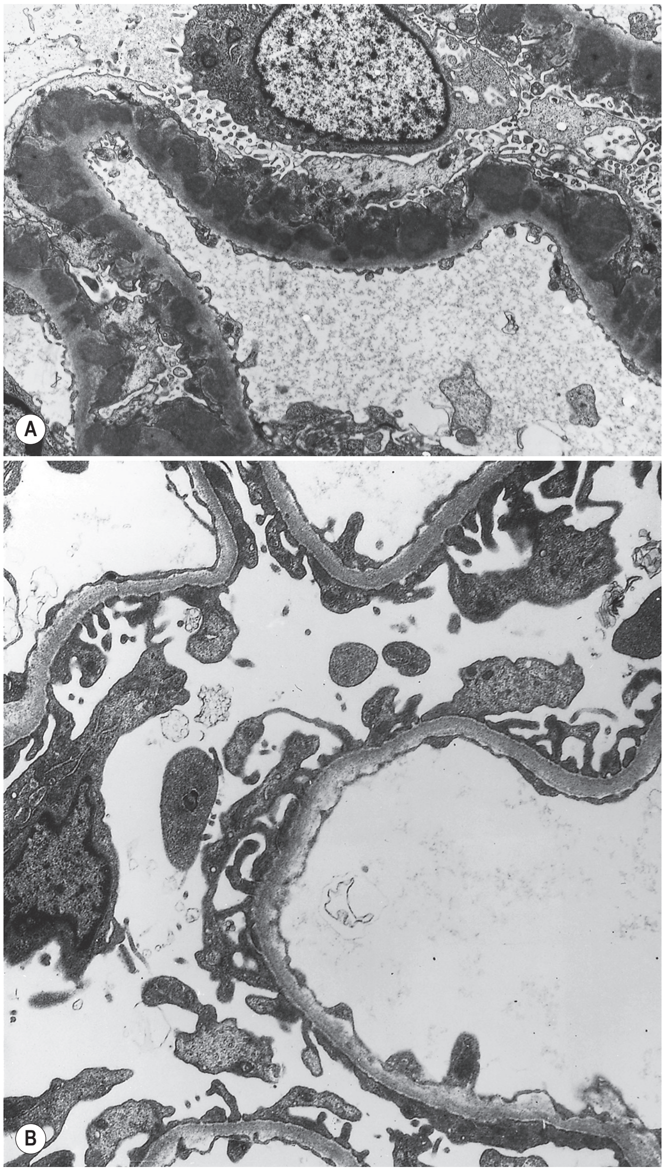

FIG 68.6 **Membranous Nephropathy (Ultrastructure).** A, Electron micrograph demonstrates heavy, dark-staining immune complex deposits along the outer surface of the glomerular basement membrane and beneath the epithelial foot processes (hence the terms *subepithelial* or *epimembranous deposits*). Note the thickening and projections of the gray-staining basement membrane between the electron-dense deposits. B, Ultrastructure of a normal glomerular capillary wall for comparison.

Treatment

Management of patients with MN usually includes diuretics to reduce edema, lipid-lowering drugs (for severe hyperlipidemia), anticoagulant therapy for thromboembolic complications, and

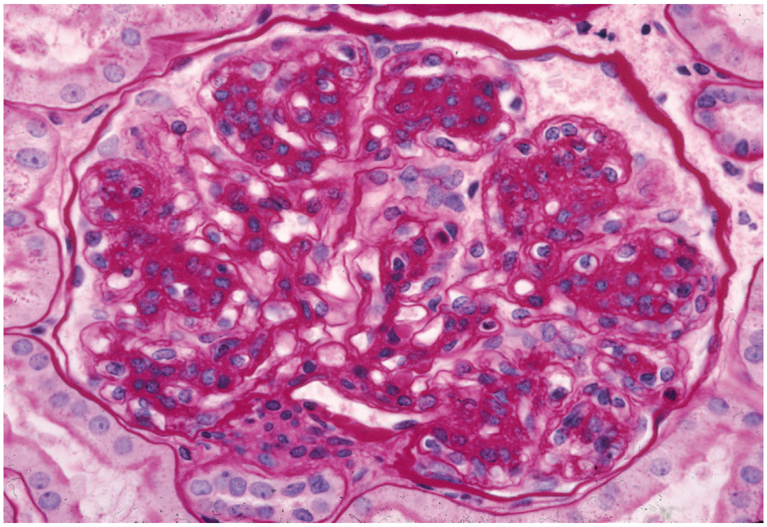

FIG 68.7 **Membranoproliferative Glomerulonephritis (MPGN).** Glomerulus exhibits the typical lobulated appearance of this disease. Markedly increased mesangial cells and matrix in all of the lobules. Mesangium extends outward into the capillary loops and forms double contours with the glomerular basement membrane. (Periodic acid–Schiff [PAS] stain).

antihypertensive agents. Angiotensin antagonists have been shown to have a substantial antiproteinuric effect. Immunosuppressive treatment is generally reserved for patients with persistent high-grade proteinuria (>4 g/day. First-line immunosuppressive therapy consists of cytotoxic drugs (usually cyclophosphamide) in combination with glucocorticoids or a calcineurin inhibitor (CSA or tacrolimus) with or without low-dose glucocorticoids.[16] The most compelling results from controlled trials have shown that patients with MN treated with alternating monthly courses of pulse methylprednisolone and chlorambucil or cyclophosphamide were more likely to experience a remission of the nephrotic syndrome and achieve stable renal function compared with controls. Rituximab may be a useful alternative for treatment of MN based on encouraging results from pilot studies and a good safety profile compared with other immunosuppressive regimens.[16–19]

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

KEY CONCEPTS

Membranoproliferative Glomerulonephritis (MPGN)

- Histologically classified into immune complex–mediated glomerulonephritis or complement-mediated glomerulonephritis based on immunofluorescence staining pattern
- C3 glomerulopathy characterized by C3 accumulation in the glomeruli in the form of electron-dense deposits.
- Genetic or acquired abnormalities in the activation of the alternate alternative complement pathway complement pathway associated with C3 glomerulopathy
- Response to immunosuppressive drug treatment generally poor
- Tends to recur in renal allografts

Membranoproliferative glomerulonephritis (MPGN) is a morphological entity that encompasses a heterogeneous group of diseases with a similar appearance at the light microscopic level. The pattern of injury is characterized by mesangial matrix expansion and increased cellularity and thickening of the glomerular capillary walls with a double contour appearance. These changes give a lobulated appearance to the glomerulus (Fig. 68.7).

Etiology and Pathogenesis

Until recently MPGN was classified into three types based on the location and type of electron dense deposits: type 1 characterized by subendothelial deposits; type II by intramembranous electron dense deposits in a ribbon-like pattern (also referred to as *dense deposit disease* [DDD]); and type III by subendothelial and subepithelial deposits (Fig. 68.8). This older classification scheme also made a distinction between secondary causes when it was possible to identify an etiology

New insight into the pathogenesis of MPGN has recently led to a major paradigm shift in the classification of this disease. Of great importance is the recognition that some cases of MPGN result from the deposition of Igs with secondary complement activation, whereas others arise from primary abnormalities in the control of complement activation.[20] The new classification system now broadly categorizes MPGN into Ig-mediated or complement-mediated disease based on the pattern and composition of the deposits, as assessed by immunofluorescence staining. The presence of both Ig and complement (C3) indicates an Ig-mediated process in which immune complexes are deposited and then secondarily activate the classical complement pathway. In contrast, the presence of complement staining (C3) without significant Ig deposition implies that an antibody-*in*dependent means of complement activation has been triggered and suggests a primary problem with regulation of the alternative complement pathway (Fig. 68.9). Such diseases are now grouped under the umbrella term, "C3 glomerulopathy" (C3G), which encompasses both C3 glomerulonephritis (C3GN) and DDD.[21] A diagnosis of C3G should prompt an evaluation for inherited mutations of complement regulatory proteins (*i.e.,* factor H or factor I) or acquired autoantibodies to regulatory proteins (*i.e.,* C3 nephritic factor or anti-factor H), which lead to dysregulation of the alternative pathway. C3 nephritic factor, an autoantibody to C3

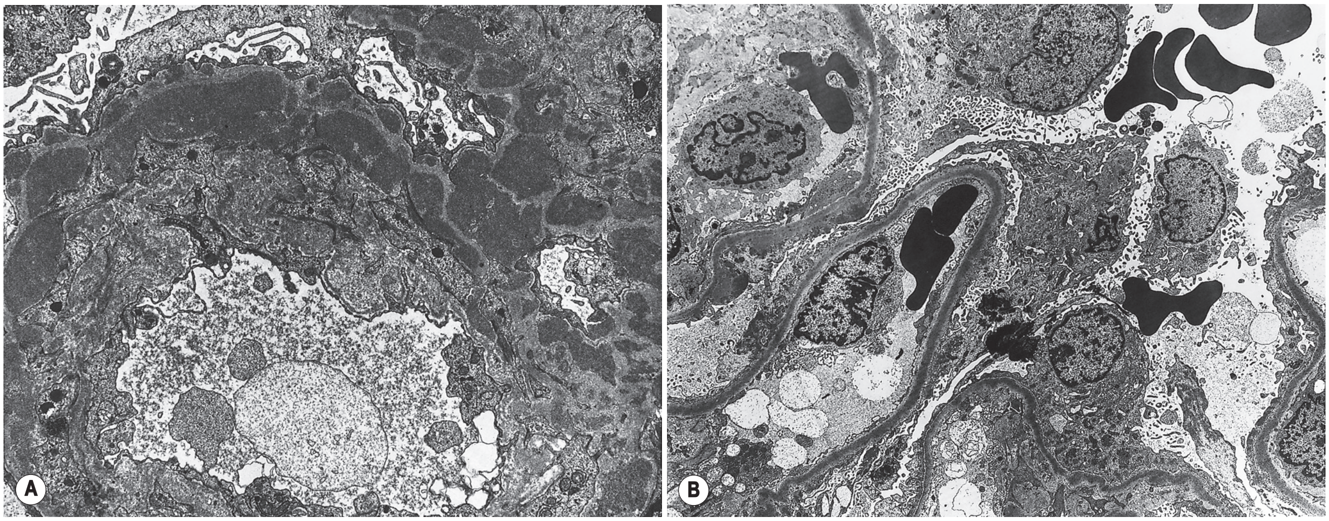

FIG 68.8 **Membranoproliferative Glomerulonephritis (MPGN) Ultrastructure.** A, Capillary wall is markedly thickened and contains heavy, dark-staining, electron-dense immune complexes in the subendothelial space. Mesangium (lighter material) extends into the capillary loop, where it is interposed between the basement membrane and the endothelium; the process gives the appearance of a massively thickened capillary loop on hematoxylin and eosin (H&E) staining, and the split appearance by periodic acid–Schiff (PAS) and silver stains. B, Dense deposit disease; capillary loops contain smooth, continuous, linear dense material within the basement membrane.

convertase, is frequently detected in C3G. C3 nephritic factor stabilizes the convertase, rendering it resistant to control by factor H, thus leading to persistent C3 activation and deposition of alternative pathway activation products in glomeruli.

Pathology

In addition to endocapillary proliferation and findings on immunofluorescence, a double contour appearance to the glomerular basement membrane (GBM) best seen with silver stain represents synthesis of GBM-like material from capillary wall remodeling. Irregular capillary wall subendothelial and mesangial deposits are seen by electron microscopy in Ig- mediated MPGN; often small intramembranous and subepithelial deposits are also present in C3GN. The hallmark of C3GN is dominant bright staining for C3 by immunofluorescence in the mesangium and glomerular capillary walls (see Fig. 68.9).

Double contours of the GBM are also present in conditions associated with chronic endothelial injury, including thrombotic microangiopathy, transplant glomerulopathy, and preeclampsia, and show a histological appearance of MPGN by light microscopy. However, there are no associated immune deposits and immunofluorescence is negative for Ig and C3.

Clinical Presentation

Although it is characteristically a chronic low-grade nephropathy, some patients experience nephrotic syndrome and even rapidly progressive and crescentic disease. Hypocomplementemia is common in all types of MPGN. In immune complex-mediated MPGN, serum C4 levels are characteristically low, consistent with classical pathway activation. Serum C3 concentration may be normal or mildly decreased. In complement-mediated MPGN, serum C4 levels are normal, and C3 is typically low, consistent with alternative pathway activation, but a normal serum C3 does not exclude the diagnosis. The renal outcome in C3 glomerulopathy is variable with up to 30% of patients progressing to ESKD. The prognosis of DDD is worse, with almost half the patients progressing to kidney failure. Idiopathic MPGN and MPGN resulting from complement dysregulation tend to recur in renal allografts; recurrences of both types of MPGN have a detrimental effect on graft survival.

Treatment

It is important to recognize that existing treatment trials for MPGN predate the new classification system and our appreciation of the different pathogenesis. Thus their relevance is questionable because of the heterogeneity of patient populations. It is anticipated that the new diagnostic categories will better define groups of patients with similar pathogenesis, thus enabling a more rational approach to targeted therapy in the future.

There is no consensus regarding treatment of "idiopathic" immune complex–mediated MPGN, but various immunosuppressants have been used with variable success, including prednisone alone or in combination with either mycophenolate or cyclophosphamide. There are limited data on the role of rituximab in this disease.

Optimal treatment of C3GN remains unclear but will likely need to be individualized on the basis of proper identification of the defect in the alternative complement system (*i.e.*, genetic vs acquired autoantibodies). Chronic infusions of fresh frozen plasma to replace missing complement factors may be beneficial in some cases. Immunosuppression with corticosteroids, rituximab, and mycophenolate is of theoretic benefit in cases resulting from pathogenic antibodies to complement regulatory proteins but is unproven. A more targeted approach using eculizumab, a mAb that blocks activation of C5 complement (C5b-9), has been tested in small series, but the data are inconclusive. Additional new complement blocking agents may also hold promise.[22]

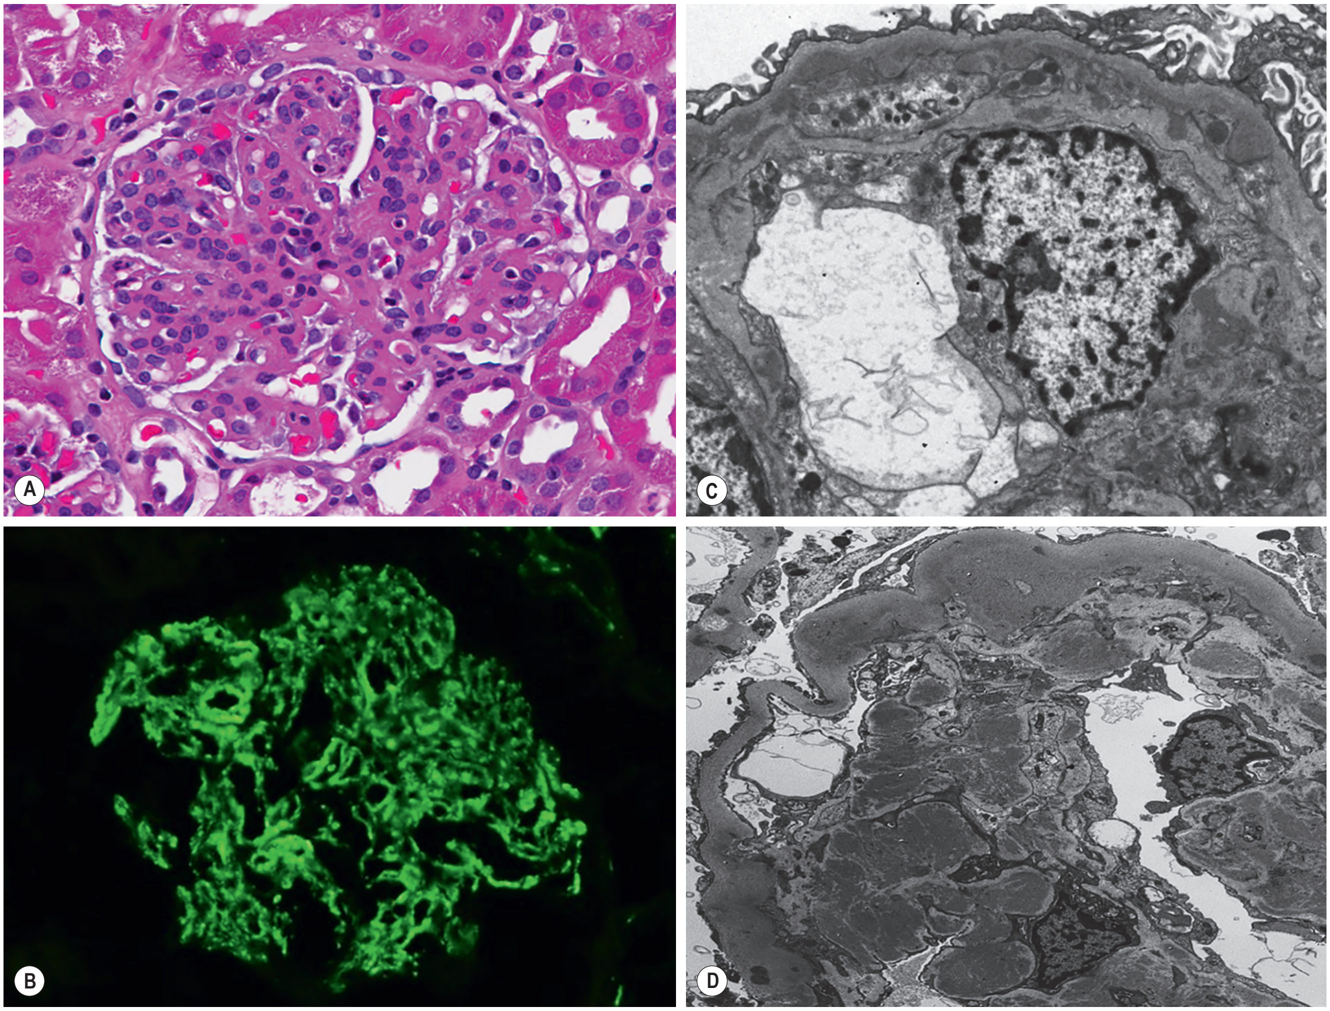

FIG 68.9 **C3 Glomerulopathy.** A, Glomerulus exhibiting the characteristic membranoproliferative pattern (hematoxylin and eosin [H&E] stain). B, Immunofluorescence showing prominent glomerular staining for C3 complement. C and D, Electron microscopy ultrastructure showing mesangial interposition giving a double contour of the glomerular capillary wall, as well as interposed electron dense deposits in the subendothelial space and the mesangium.

POSTINFECTIOUS NEPHROPATHIES

An ever-expanding list of infectious agents has been implicated in the pathogenesis of certain forms of immune-mediated nephropathies.

Viral Infections

Hepatitis B

Hepatitis B–associated nephropathy most frequently presents as nephrotic syndrome accompanied by microscopic hematuria; renal biopsy most commonly shows MN. Immunofluorescence studies usually show Ig, C3, and some IgM staining in the subepithelial region along the glomerular basement membranes and in some cases viral antigens can be detected within the glomerulus. Electron microscopy shows subepithelial and intramembranous deposits, but there may also be mesangial and even some subendothelial deposits.

Therapy for hepatitis B renal disease has focused on antiviral drugs because glucocorticoids and cytotoxic agents may promote viral replication. Treatment generally consists of interferon-α (IFN-α) or nucleoside/nucleotide analogues, such as lamividine, entacavir, adefovir, tenofovir, and telbivudine. Treatment with nucleoside/nucleotide analogues are generally used for at least 1 year and continued for at least 6 months after HBeAg seroconversion. Immunosuppression (corticosteroids with or without cyclophosphamide or rituximab) may cautiously be considered in patients with rapidly progressive glomerulonephritis, but concomitant antiviral therapy is required.

Hepatitis C

Hepatitis C virus (HCV) is a major cause of both transfusion-associated and sporadic chronic hepatitis. The most common HCV-associated renal disease is usually, but not invariably, MPGN in the context of type II mixed cryoglobulinemia. The pathogenesis of the renal disease is caused by deposition within glomeruli of immune complexes containing HCV, anti-HCV antibody and virus-related (or unrelated) cryoglobulins.

Treatment of HCV infection has greatly improved in the last few years. Historically, treatment was mainly based on IFN-α and ribavirin. These agents are now being replaced by HCV-specific antiviral drugs that are used in combination (*i.e.,* sofosbuvir plus ledipasvir), which are highly effective and often curative.[23] The evidence for antiviral treatment in HCV-related kidney disease is based mostly on IFN-based regimens, which have reported remission of proteinuria and hematuria and improvement of renal function.[24,25] There are limited data regarding use of the newer antiviral agents in HCV-associated glomerulonephritis, but these hold considerable promise.[26] For patients with progressive renal disease and/or nephrotic-range proteinuria, treatment with rituximab or pulse intravenous steroids and cyclophosphamide may be warranted in conjunction with antiviral therapy. Treatment with rituximab and plasma exchange may provide additional benefit in patients with HCV-associated severe cryoglobulinemia refractory to antiviral therapy.[27,28]

Human Immunodeficiency Virus

HIV-associated nephropathy (HIVAN), the first kidney disease to be associated with HIV infection, is a collapsing form of focal segmental glomerulosclerosis accompanied by associated tubular microcysts and interstitial inflammation. It was first described in patients with acquired immune deficiency syndrome (AIDS) but also is occasionally diagnosed in less advanced cases of HIV infection and before acute HIV seroconversion has been identified. HIVAN classically presents with significant proteinuria and rapidly progressive kidney disease. HIVAN displays a striking racial predilection for black patients, which may indicate the importance of genetic influences.[29]

A spectrum of other renal abnormalities have also been described in patients with HIV infection, including IgA nephropathy, lupus-like glomerulonephritis, postinfectious glomerulonephritis, MPGN, MN, cryoglobulinemic glomerulonephritis, fibrillary and immunotactoid glomerulopathy, and thrombotic microangiopathy.[30,31] Tubulointerstitial changes related to drug toxicity, acute interstitial nephritis, or superimposed viral, fungal, or mycobacterial infections may also be present.

The mainstay of treatment of HIVAN is combination antiretroviral therapy (cART) regardless of the CD4 lymphocyte count. Highly effective modern therapies for HIV have reduced the frequency of developing HIVAN and have greatly improved the otherwise dismal renal prognosis of HIVAN. This has greatly improved the dismal renal prognosis of HIVAN. The evidence for initiating cART in other HIV-associated immune complex glomerular diseases is inconclusive, but use of cART is a rational approach. The use of standard immunosuppressive drugs in an immunocompromised population is controversial.

Bacterial Infections

Poststreptococcal Glomerulonephritis

Poststreptococcal glomerulonephritis is the best-studied and classic immune complex–mediated glomerulonephritis. It is the result of skin or throat infection with nephritogenic strains of group A streptococci. The latent period between upper respiratory infection and nephritis is 7–10 days, and 2–4 weeks after skin infection. Antistreptococcal antibody titers are usually measured to demonstrate the existence of a preceding streptococcal infection. Antistreptolysin O titers and anti-DNase B titers are the most frequently elevated in upper respiratory and skin infections, respectively.

Poststreptococcal glomerulonephritis is characterized by a nephritic syndrome consisting of smoky or rust-colored urine, generalized edema, hypertension, and nephritic urine sediment. Proteinuria is typically mild. Patients have rising titers of antistreptolysin and depressed C3 levels early in nephritis but normal or minimally depressed C4 levels, indicating activation of the alternative complement pathway.

KEY CONCEPTS

Infection-Related Nephropathies

- *Viral:* Hepatitis B—membranous nephropathy; hepatitis C—cryoglobulinemic membranoproliferative glomerulonephritis; human immunodeficiency virus (HIV)—focal segmental glomerulosclerosis (HIV nephropathy)
- *Bacterial (mainly gram-positive):* Nephritogenic streptococcal infections, prosthetic device (shunt) infections, subacute bacterial endocarditis, chronic deep tissue abscesses—mainly diffuse or focal proliferative glomerulonephritis

Proliferative glomerulonephritis with polymorphonuclear leukocyte and monocyte infiltration, granular immune deposits of IgG and C3, and dome-shaped electron-dense subepithelial deposits (humps) are characteristic. The prognosis is excellent in children; with supportive care, almost all will recover. Progressive renal failure accompanied by severe hypertension appears to be more common in adults. Kidney biopsy is rarely needed in the child but may be warranted if there is an atypical presentation or evolution. .

The classic childhood form is still seen in developing countries but is now rare in developed countries. However, there has been an increase in the incidence of nonstreptococcal postinfectious glomerulonephritis or "infection-related" glomerulonephritis, which tends to be seen in older patients with multiple comorbidities, especially diabetes, HIV infection, and malignancy. These clinical variants are usually related to other infective agents, such as *Staphylococcus aureus,* both methicillin-resistant (MRSA) and methicillin-sensitive *S. aureus,* and may be characterized by an IgA-dominant glomerular immune complex deposition.

Etiology and pathogenesis. Glomerular injury results from passive glomerular trapping of circulating immune complexes composed of nephritogenic bacterial antigens and IgG antibody or by the *in situ* formation of immune complexes. This is followed by immune cell recruitment, production of chemical mediators and cytokines, and local activation of the complement and coagulation cascades that drive an inflammatory response.[1]

Current therapeutic strategies rely on culture-guided systemic antibiotics, especially in older patients, in whom MRSA may be the causative agent. Steroids may be used in selected cases in which crescents and severe interstitial inflammation are present.

IgA Nephropathy

KEY CONCEPTS

Immunoglobulin A Nephritis (IgAN)

- Common cause of asymptomatic microscopic hematuria, recurrent macroscopic hematuria, and/or low-grade proteinuria
- Spectrum of disease, including idiopathic IgA nephritis and Henoch-Schönlein purpura nephritis; IgA in skin and renal biopsy samples
- Mostly benign prognosis, especially in children
- Patients with progressive renal insufficiency and/or crescentic glomerulonephritis warrant trial of glucocorticoids and/or cytotoxic drug therapy

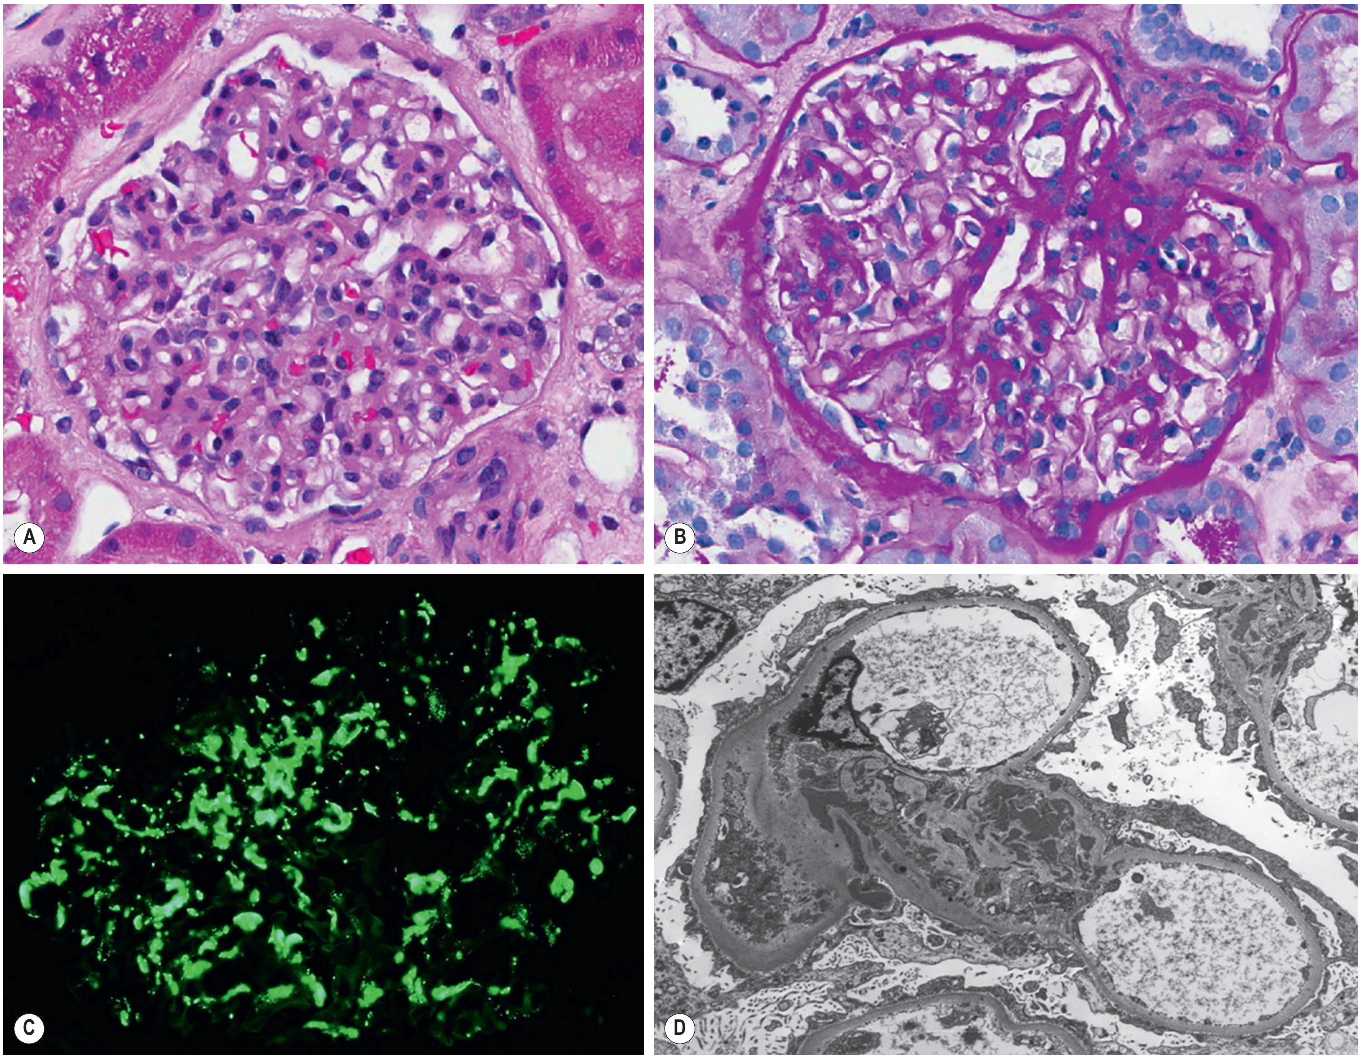

FIG 68.10 **Immunoglobulin A Nephropathy (IgAN).** (A) hematoxylin and eosin (H&E) stain and (B) periodic acid–Schiff (PAS) stain: Glomeruli manifest modestly increase mesangial hypercellularity and expanded mesangial matrix. C, Immunofluorescence showing predominantly IgA deposition within the mesangium. D, Electron microscopy showing deposits mainly within the mesangium but not along peripheral capillary loops.

IgA nephropathy (IgAN) is the most common primary glomerulonephritis worldwide.[32] IgAN can affect patients of all ages, especially children and young adults, with a male preponderance.[34] There are geographical and ethnic differences in the prevalence of IgAN. The highest frequency is found among East Asians; IgAN is very uncommon in individuals of African ancestry. This observation and examples of familial clustering of IgA nephropathy favor an important element of genetic susceptibility.

IgAN may be discovered during evaluation of asymptomatic microscopic hematuria.[34] Alternatively, patients (especially children) can present with recurrent episodes of macroscopic hematuria that occur within 24–48 hours after an intercurrent infection, usually an upper respiratory or gastrointestinal (GI) tract infection. A transient elevation in serum creatinine has been associated with macroscopic hematuria in about one-third of cases. This has been attributed to tubular injury and obstruction caused by intraluminal RBC casts. A small percentage of patients present with either nephrotic syndrome or an acute RPGN picture characterized by edema, hypertension, renal insufficiency, and hematuria.

Pathology

The characteristic findings on light microscopy are mesangial cell proliferation and mesangial matrix expansion.[32] Electron microscopy typically reveals electron-dense deposits that are primarily limited to the mesangium, but a few deposits may also be present in subendothelial and subepithelial locations. The pathognomonic finding on immunofluorescence microscopy is globular deposits of IgA (often accompanied by C3 and IgG) in the mesangium and, to a lesser degree, along the glomerular capillary wall (Fig. 68.10).

Etiology and Pathogenesis

Aberrant glycosylation of *O*-linked glycans in the hinge region of IgA1 resulting in increased serum levels of galactose-deficient IgA1 (Gd-IgA1) plays a pivotal role in pathogenesis of IgAN.[34] The aberrantly glycosylated IgA1 is recognized by antiglycan antibodies and leads to circulating IgA immune complexes that preferentially deposit in the mesangium, provoking local injury.

A genetic predisposition to IgAN has been linked with polymorphisms involving innate and adaptive immunities and the alternative complement pathway. A "second hit" may be needed in predisposed individuals. Infections may play a role because episodes of macroscopic bleeding often coincide with mucosal infections, including upper respiratory tract (synpharyngitic) or GI infections.

Natural History

Patients with IgAN who have low-grade proteinuria (<1 g/day) have a good renal prognosis and usually have a low risk of progression. However, it is recognized that at least one-third of patients with IgAN eventually progress to ESKD.[34] Twenty years after apparent disease onset, the probability of renal failure is 25%, and the probability of some renal dysfunction is 50%. Hypertension occurs frequently as the disease progresses and forebodes a poor prognosis. Other clinical features that have been associated with a poor prognosis include older age at disease onset, persistent proteinuria (>1 g/day), and persistent azotemia.

Treatment

The most effective treatment of progressive IgAN remains undefined and controversial.[34] Angiotensin antagonists are recommended to achieve blood pressure control, to reduce proteinuria, and to slow the rate of deterioration of renal function. There are conflicting data about the value of fish oil dietary supplements (eicosanoids) in preventing renal progression in patients with IgAN. The practice of tonsillectomy in IgAN has not been confirmed. A large trial (STOP-IgA nephropathy) showed that immunosuppression (glucocorticoid monotherapy or a regimen that included prednisolone, cyclophosphamide, and azathioprine) did not have a significant beneficial effect on preservation of kidney function.[33] However, a course of oral steroids may be considered in patients with high-grade proteinuria, and cytotoxic drugs are indicated in a small subset of patients with crescentic rapidly progressive IgAN. The lack of effective therapy have provided the impetus for several new phase II/III clinical trials testing novel therapies, such as B-cell activating factor (BAFF) inhibition, proteasome inhibition, and B-cell inhibition.[34,35]

Renal Vasculitis Associated With Antineutrophil Cytoplasmic Antibodies

KEY CONCEPTS

Antineutrophil Cytoplasmic Antibodies (ANCAs)–Associated Renal Vasculitis

- Renal vasculitis with glomerular involvement includes microscopic polyangiitis (MPA), granulomatosis with polyangiitis (GPA), and necrotizing crescentic glomerulonephritis (renal-limited vasculitis)
- Associated with ANCAs
- Rapidly progressive glomerulonephritis is common; early treatment includes pulse methylprednisolone, cyclophosphamide, rituximab, or possibly plasma exchange
- Maintenance therapy: azathioprine, rituximab

ANCAs are associated with a distinct form of vasculitis that can affect many different types of vessels and any organ in the body. ANCA-associated vasculitis (AAV; Chapter 58) is categorized into four main types: microscopic polyangiitis (MPA), granulomatosis with polyangiitis (GPA, formerly called *Wegener granulomatosis*), eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg-Strauss syndrome), and renal limited vasculitis. As shown in Table 68.2, the patterns of ANCAs differ, depending on the type of vasculitis.

TABLE 68.2 Prevalence of Antineutrophil Cytoplasmic Antibodies (ANCAs) in Renal Vasculitis

	ANCAS TEST POSITIVITY (%)	
Type of Renal Vasculitis	P-ANCAs or Anti-Mpo	C-ANCAs or Anti-Pr3
Polyarteritis nodosa	10–20	10–20
Microscopic polyangiitis	50–80	10–20
Granulomatosis with polyangiitis (Wegener granulomatosis)	10–20	80–90
Necrotizing and crescentic GN	50–80	10–20

MPO, myeloperoxidase; PR3, proteinase 3.

Renal involvement is common in AAV but varies in type and severity. It occurs more frequently in MPA (90%) and in GPA (80%) and less frequently in EGPA (45%). Clinically RPGN is a common manifestation of these renal vasculitides characterized by the presence of hematuria, proteinuria, active urinary sediments, and renal failure.

Pathology

The glomerular abnormalities are similar among the subtypes of ANCA-associated glomerulonephritides (Fig. 68.11). The glomerular lesions are characteristically focal and segmental in distribution, with fibrinoid necrosis and crescent formation. Breaks in the GBM may be seen. There may be accompanying necrotizing arteritis. In contrast to immune complex–mediated vasculitis, ANCA-associated vasculitis has little or no Ig deposition in injured glomerular vessels, with minimal or negative staining by immunofluorescence, a so-called pauci-immune pattern. Patients with large percentage of cellular crescents (>50%) typically present with severely reduced renal function but have a good chance for recovery of renal function with treatment, whereas those with a greater percentage of globally sclerotic glomeruli are less likely to recover renal function.[36]

Treatment and Prognosis

ANCA-associated renal vasculitis tends to be severe and fulminant, making early detection critically important in management. Even with early diagnosis, approximately one-third of patients will progress to renal failure within 5 years. Relapsing courses are common in patients with microscopic polyangiitis, particularly GPA. This underscores the importance of prompt induction treatment followed by maintenance therapy. Glucocorticoids are important in the early treatment of renal vasculitis. Cyclophosphamide-based regimens are very effective in inducing remission in patients with AAVs. Most advocate daily oral cyclophosphamide regimens, but intermittent pulse cyclophosphamide may be substituted to reduce the toxicity of extended therapy. In patients with severe pulmonary hemorrhage or rapidly progressive glomerulonephritis caused by renal vasculitis, pulse methylprednisolone, followed by prednisone and daily cyclophosphamide, is clearly indicated. Adjunctive plasma exchange is commonly used in cases of aggressive pulmonary–renal syndrome. Rituximab has become a valuable alternative to

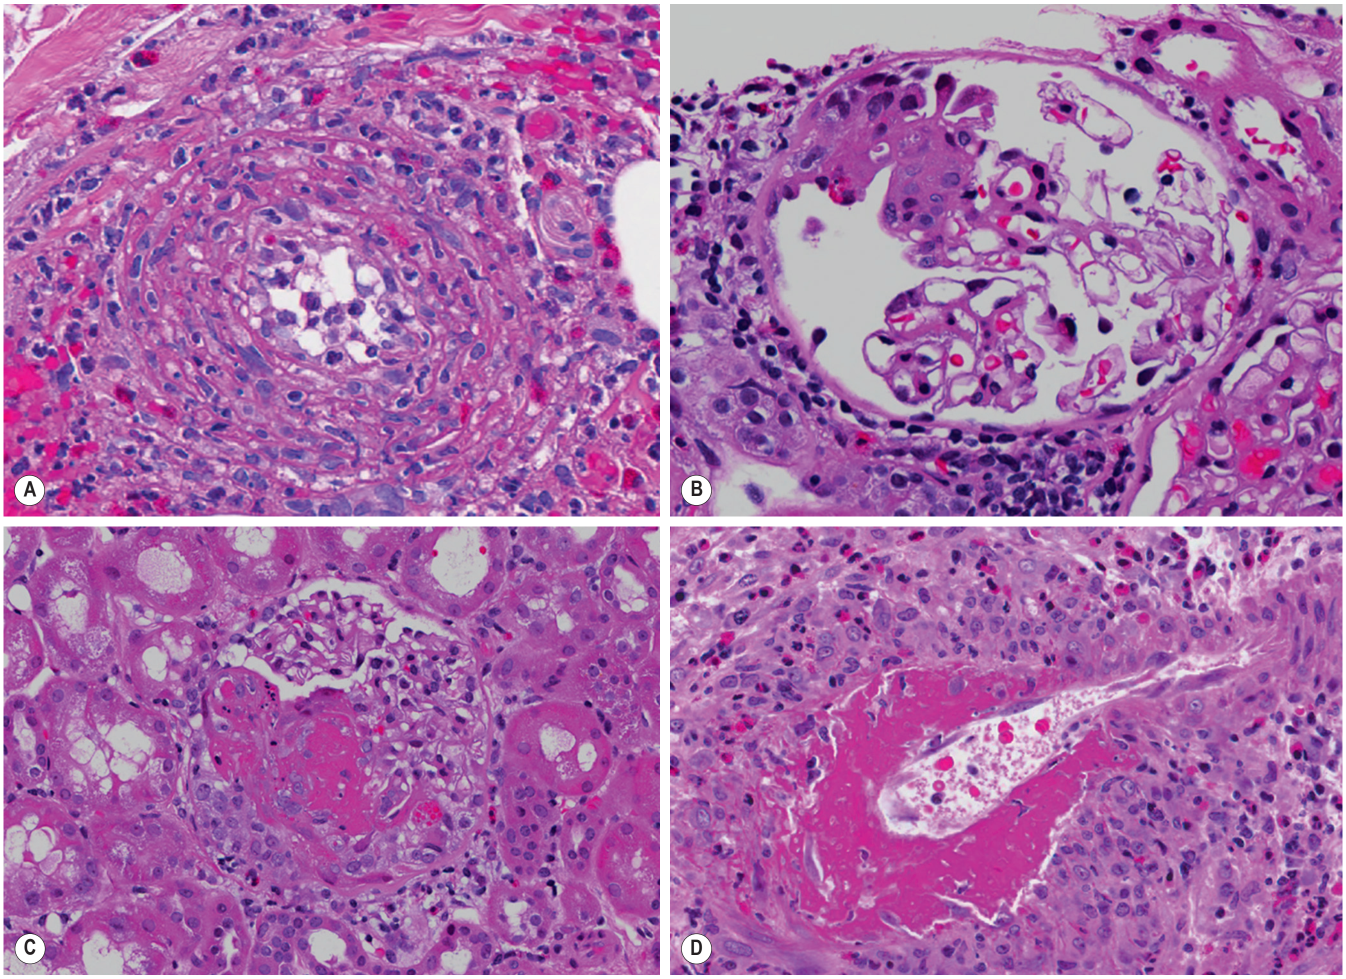

FIG 68.11 Antineutrophil Cytoplasmic Antibody (ANCA)–Associated Systemic Vasculitis. A, Skin biopsy showing leukocytoclastic vasculitis of a small dermal artery (hematoxylin and eosin [H&E] stain). B, Glomerulus illustrating a characteristic segmental proliferative lesion forming an adhesion to the Bowman capsule in an early and mild case (H&E stain). C, Glomerulus with classical fibrinoid necrosis and an associated cellular crescent of a more severe and rapidly progressive case (H&E stain). D, Necrotizing vasculitis in a small renal artery in an extreme case of ANCA-associated renal vasculitis; large numbers of eosinophils are present in the perivascular inflammatory infiltrate (H&E stain).

cyclophosphamide for induction treatment based on the results of two pivotal prospective randomized controlled trials.[37,38] Maintenance therapy is usually given for 12–18 months after achieving remission. Azathioprine has been the mainstay of maintenance therapy in AAVs after remission induction, but rituximab is also likely to have a prominent role in maintenance therapy, as indicated by favorable results from preliminary trials.[39]

Anti-GBM Antibody-Mediated Nephritis: Goodpasture Disease

KEY CONCEPTS

Goodpasture Disease

- Circulating anti–glomerular basement membrane (GBM) antibody
- Associated with pulmonary hemorrhage
- Rapidly progressive glomerulonephritis with cellular crescents and linear deposits of immunoglobulin G (IgG)
- Treated with high-dose steroids, cyclophosphamide, plasma exchange

Goodpasture disease is a rare but classic immune-mediated cause of severe pulmonary–renal syndrome. The cardinal pathogenic factor is an autoantibody to a component of type IV collagen (noncollagenous domain 1 of the α_3 chain subunit) within the GBM or the alveolar basal membrane.[40,41] These autoantibodies lead to GBM rupture with development of crescentic glomerulonephritis (Fig. 68.12) and account for the pathognomonic finding of linear deposition of IgG along the glomerular capillaries as assessed by immunofluorescence microscopy.

The genesis of anti-GBM antibodies in sporadic cases is unknown. It is postulated that an inciting event(s) *(i.e.*, viral infection or exposure to environmental factor, such as hydrocarbons, tobacco) perturbs the normal conformation of collagen in the basement membrane, exposing previously cryptic epitopes on the α_3 subunit, eliciting the pathogenic autoantibody response. Iatrogenic cases have occurred when normal kidneys have been transplanted into patients with hereditary Alport nephropathy (which is caused by mutations in the α_5 chain of type IV collagen). The absence of expression of α_5 (and associated lack of α_3 and

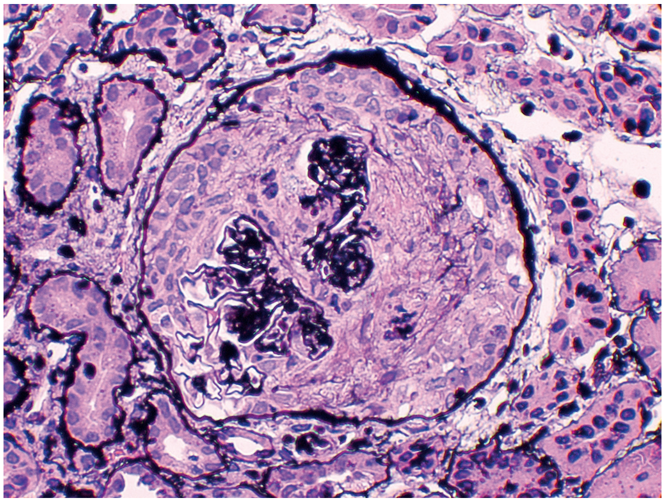

FIG 68.12 Goodpasture Disease. Circumferential cellular crescent fills the Bowman capsule and compresses the glomerular tuft (Silver stain).

α_4) means that these molecules within the renal allograft are regarded as foreign antigens. Thus recipients mount an anti-GBM antibody response to the new donor antigens.

Clinically malaise, weight loss, fever, or arthralgia may be the initial features of anti-GBM disease. Some patients present with isolated renal involvement, but more typically, pulmonary hemorrhage with hemoptysis accompanies acute renal failure. The devastating nature of the disease warrants aggressive treatment. Pulse methylprednisolone, cyclophosphamide, and plasma exchange are indicated early in the course of Goodpasture disease.[42] The role of rituximab in this disease requires further study. Reversibility of renal disease is unlikely if renal function is substantially impaired or oliguria ensues before treatment is started. Immunosuppressive treatment is normally continued until the patient has been in sustained clinical remission and anti-GBM titers are minimal or absent for at least 3 months.

Lupus Nephritis

KEY CONCEPTS

Lupus Nephritis

- *Class I:* normal glomeruli by light microscopy in patients with SLE.
- *Class II, mesangial:* Immunosuppressive treatment is usually not indicated unless patient has proteinuria >1 g/day despite renin–angiotensin–aldosterone (RAA) system blockade, especially if urine sediment is nephritic
- *Class III, focal nephritis and class IV, diffuse nephritis:* Mycophenolate mofetil (MMF) or intravenous cyclophosphamide (IVCY) plus glucocorticoids for induction followed by MMF or azathioprine plus low-dose corticosteroids as maintenance therapy
- *Class V, Membranous nephropathy:* Alternate-day prednisone with MMF, or alternatively bimonthly pulse cyclophosphamide or low-dose daily cyclosporine

Glomerular disease affects the majority of patients with SLE (Chapter 51), but lupus nephritis has a wide spectrum of disease expression and outcomes among different patient populations. Lupus nephritis occurs more often and is associated with less favorable outcomes among Hispanic, Asian, Native American, and especially African American populations compared with Caucasians. Nephritis is a major cause of morbidity and mortality and accounts for a large portion of all hospital admissions in patients with SLE.

Pathogenesis

Several different mechanisms appear to be involved in the pathogenesis of lupus nephritis, resulting in a wide spectrum of renal lesions. Deposition of immune complexes from the circulation into the kidney appears to be the initiating event in proliferative lupus nephritis; however, only a subset of immune complexes appears to be nephritogenic. DNA and anti-DNA antibodies are known to be concentrated in glomerular deposits in the subendothelial location and are likely to play a central role in the pathogenesis of proliferative lupus nephritis. Unfortunately, there are fewer insights into the pathogenesis of lupus MN with its characteristic epimembranous immune deposits. Although T cells are almost certainly involved in autoantibody production, it is unknown whether they have a direct role in the pathogenesis of lupus nephritis.

Clinical Features

Asymptomatic hematuria or proteinuria may be the presenting features, but they often progress to nephritic and/or nephrotic syndrome. Hypertension, azotemia, nephritic urine sediment (with hematuria and cellular casts), hypocomplementemia and high anti–double-stranded DNA (dsDNA) titers are more commonly found in patients with proliferative lupus nephritis. RPGN is usually associated with the appearance of cellular crescents and may be superimposed on severe proliferative or membranous forms of lupus nephritis.

Pathology

The former classification of renal biopsy in lupus nephritis by the World Health Organization (WHO) was revised by an international committee in 2004 (Figs. 68.13 to 68.15). A summary of the histological features in each class of lupus nephritis can be found in Table 68.3.

Treatment

In 2012, the American College of Rheumatology (ACR), the European League Against Rheumatism (EULAR), and the European Renal Association–European Dialysis and Transplantation Association (ERA-EDTA) published their recommendations for the management and treatment of patients with lupus nephritis.[43,44] Immunosuppressive treatment of mesangial classes of lupus nephritis (classes I and II) is usually not indicated (ACR). However, the distinction between early mesangial lesions that are in transition to more ominous classes from those that reflect mild and stable nephropathy is difficult. Consequently, treatment with prednisone alone or in combination with azathioprine has been recommended for patients with proteinuria that exceeds 1 g/day despite blockade of the renin–angiotensin–aldosterone (RAA) system, especially if the patient also has a nephritic urinary sediment (EULAR/ERA-EDTA). For patients with focal or diffuse proliferative glomerulonephritis (classes III and IV), ACR and EULAR/ERA-EDTA recommended mycophenolate mofetil (MMF) or intravenous cyclophosphamide (IVCY) plus glucocorticoids. Low-dose IVCY (500 mg IV every 2 weeks in six doses) offers a favorable balance of efficacy and relatively low toxicity for Caucasian patients with Western or Southern European ancestry. Higher dose, monthly IVCY for 6 months, plus 3 daily IV infusions of methylprednisolone initially, followed by

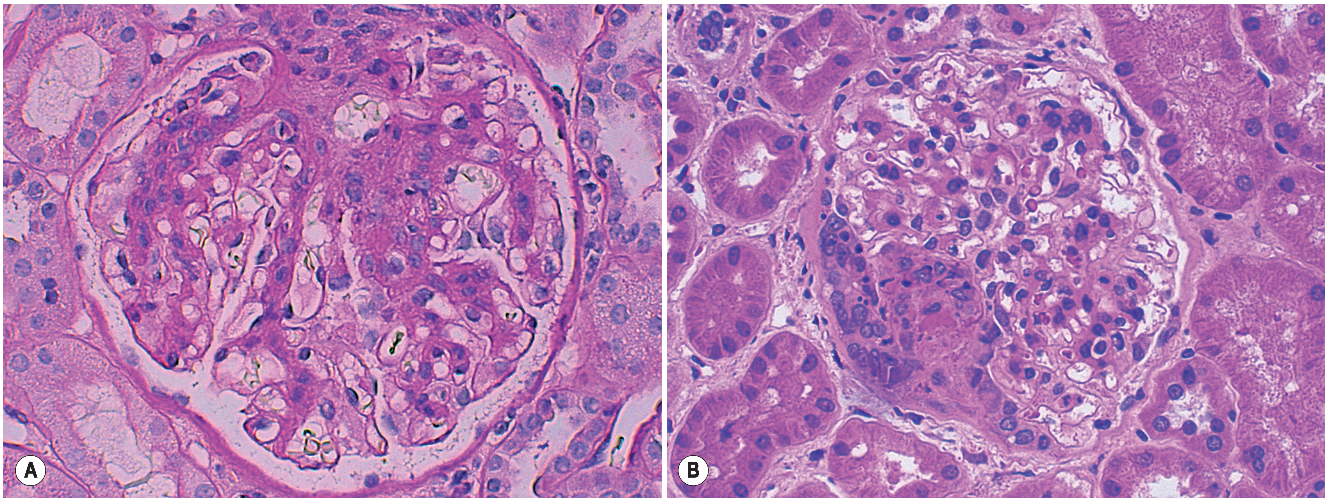

FIG 68.13 **Classes of the Pathology of Lupus Nephritis (1).** A, Class II, mesangial proliferative lupus nephritis; mesangial areas are expanded by cells and matrix but the peripheral capillary loops remain widely patent (periodic acid–Schiff [PAS] stain). B, Class III, focal lupus nephritis; solid lesion at the lower right portion of this glomerulus demonstrates segmental fibrinoid necrosis. Note the nuclear fragments (karyorrhexis) in the fibrinous exudate (hematoxylin and eosin [H&E] stain.)

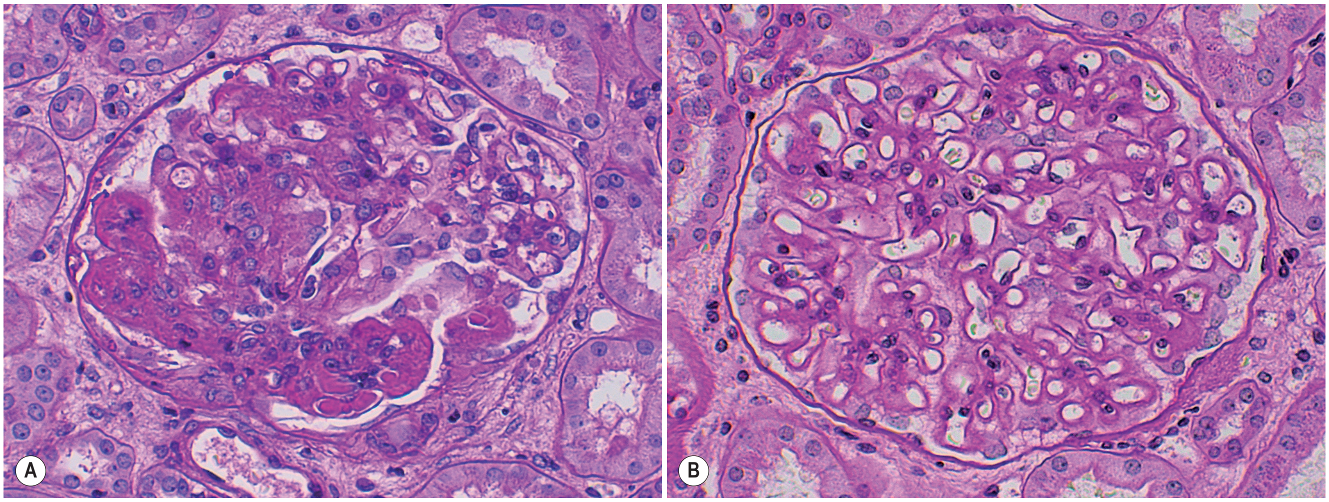

FIG 68.14 **Classes of the Pathology of Lupus Nephritis (2).** A, Class IV, diffuse lupus nephritis; glomerulus with irregular but nearly global changes, including obliteration of many capillary loops resulting from endocapillary hypercellularity, "wire loop" thickening and hyaline thrombi (periodic acid–Schiff [PAS] stain). B, Class V, membranous lupus nephritis; glomerulus shows minimally increased mesangial cellularity with thickened but widely patent capillary loops (PAS stain).

prednisone has also been recommended for patients with ominous clinical and histological prognostic indicators, including cellular crescents and fibrinoid necrosis. ACR and EULAR/ERA-EDTA recommended either azathioprine (AZA) or MMF as maintenance therapy for patients showing a favorable response after initial immunosuppressive therapy. Although AZA and MMF appeared to be equally effective maintenance therapies in a European study, patients randomized to maintenance therapy with MMF had more favorable outcomes than those randomized to AZA in a larger study conducted worldwide. The duration of maintenance immunosuppressive therapy involves careful consideration of the risks of another renal flare-up versus the risks of drug toxicity. EULAR/ERA-EDTA recommended at least 3 years of therapy in patients showing improvement after initial therapy. In general, we have offered a comparable recommendation that treatment should continue for at least 1 year after remission of renal disease to prevent exacerbations.

Neither IVCY nor MMF is universally effective in the management of lupus nephritis, hence the search for more efficacious treatment regimens, including rituximab, belimumab (binds to BAFF), immunomodulators (*e.g.*, laquinimod), cytokine inhibitors, immunoablation without or with stem-cell reconstitution, and immunological costimulation inhibitors (*e.g.*, CTLA-4-Ig), continues.[35,45] The importance of these ongoing efforts to

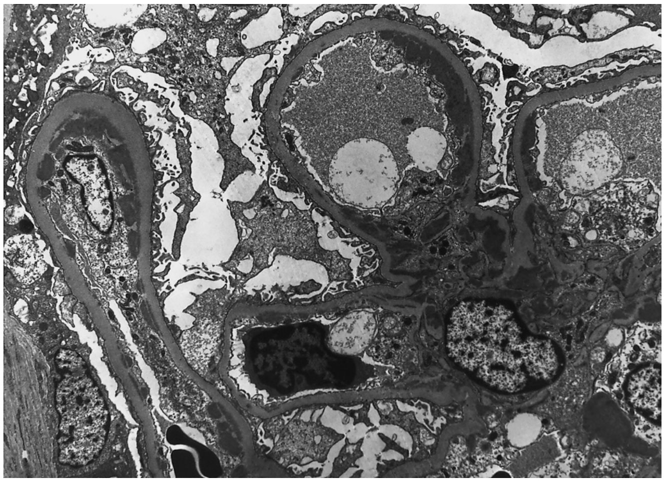

FIG 68.15 Ultrastructure of Proliferative Lupus Nephritis. Electron micrography demonstrates the characteristic mesangial deposits (dark materials interspersed within the centrally located amorphous, gray mesangial matrix) and subendothelial deposits (dark materials extending along the peripheral capillary loops).

TABLE 68.3 International Society of Nephrology/Renal Pathology Society 2004 Classification of Lupus Nephritis

Class	Histologic Features/Comments
I. Minimal mesangial	Normal light microscopy (LM); mesangial deposits by immunofluorescence (IF) and electron microscopy (EM)
II. Mesangial proliferative	Pure mesangial hypercellularity and matrix expansion *IF* and *EM:* mesangial immune deposits
III. Focal	Glomerular capillary obliteration in <50% of nephrons as a result of proliferation or sclerosis *LM:* Increased numbers of mesangial, endothelial, and/or hematogenous cells. Active inflammatory lesions (karyorrhexis, fibrinoid necrosis, adhesion to the Bowman capsule, cellular crescents, interstitial inflammatory infiltrates). Wire loop lesions. Hyaline thrombi *IF* and *EM:* Mesangial and peripheral capillary loop (subendothelial) immune complex deposits
IV. Diffuse	Qualitatively similar histologic lesions as in class III. Glomerular capillary obliteration involving >50% of nephrons. Subsets defined as primarily global (class IV-G) or primarily segmental (class IV-S) involvement
V. Membranous	*LM:* Regular thickening of the peripheral capillary loops of the glomerulus. Mesangial expansion *EM:* Subepithelial, intramembranous, mesangial (but no or very rare subendothelial) immune complex deposits
VI. Advanced	>90% global sclerosis without residual active lesions

investigate novel approaches to treatment is underscored by observations that although the risk of renal failure caused by lupus nephritis decreased from the 1970s to the mid-1990s (coincident with the increased use of cyclophosphamide), that risk has shown a reverse trend and increased slightly in the last two decades.[46]

For patients with "pure" class V lupus MN and nephrotic-range proteinuria, both the ACR and the EULAR/ERA-EDTA have recommended oral prednisone and MMF. A prospective controlled trial showed that both IVCY and CSA were more effective than steroids alone in inducing remission of proteinuria in lupus MN but that relapse of nephrotic syndrome occurred significantly more often in the CSA group than in the IVCY treatment group.

Scleroderma (Systemic Sclerosis) Renal Disease

KEY CONCEPTS

Nephropathies of Selected Connective Tissue Diseases

- *Scleroderma renal crisis:* Predominantly renal vasculopathy; moderate to severe (high renin) hypertension with progressive renal failure—treated with angiotensin-converting enzyme inhibitors (ACEIs); additional antihypertensive agents may be needed
- *Sjögren syndrome:* Distal renal tubular acidosis, nephrogenic diabetes insipidus, interstitial nephritis, hypokalemia, and/or renal calculi; glomerulonephritis rare

The most common and potentially devastating renal manifestation of systemic sclerosis (Chapter 55) is scleroderma renal crisis (SRC).[47] Most cases of SRC occur within 4 years of the onset of systemic sclerosis in patients with diffuse cutaneous scleroderma affecting the proximal extremities and the trunk. Several features, including rapid progression of skin thickening, palpable tendon friction rubs, anti-RNA polymerase III antibody, recent-onset cardiac events (*e.g.,* pericardial effusion or heart failure), new-onset anemia (especially if associated with microangiopathic hemolysis and thrombocytopenia), and recent treatment with high-dose corticosteroids, help identify patients at increased risk for developing SRC. A classic clinical presentation may obviate the need for renal biopsy. However, renal biopsy may be necessary in atypical cases. For example, about 20% of SRC cases occur before the diagnosis of scleroderma has been established. Furthermore, patients with scleroderma have rarely developed other renal diseases, such as ANCA-associated vasculitis, which are important to recognize because they require treatments different from those usually recommended for SRC.

Scleroderma renal crisis is characterized by abrupt onset of renin-mediated moderate to severe hypertension, rapid deterioration of renal function, and proteinuria (usually nonnephrotic). Associated findings may include microangiopathic hemolysis, hypertensive encephalopathy (including seizures), and hypertensive retinopathy, acute left ventricular failure, and pulmonary edema. Normotensive renal crisis occurs infrequently and may be recognized by the presence of microangiopathic hemolysis and/or unexplained azotemia. The primary pathogenic process appears to be a renal vasculopathy involving predominantly the interlobular arteries and arterioles. Marked intimal thickening with an attendant "mucoid" appearance, and fibrinoid necrosis in the absence of vasculitis, are common and characteristic of the disease (Fig. 68.16). Immune deposits are rarely observed by fluorescence or electron microscopy studies.

Although a variety of treatments have been proposed for patients with scleroderma, none has been proven to be consistently efficacious. The most significant therapeutic advance in the treatment of SRC is the use of angiotensin-converting enzyme (ACE) inhibitors (ACEIs), which have dramatically

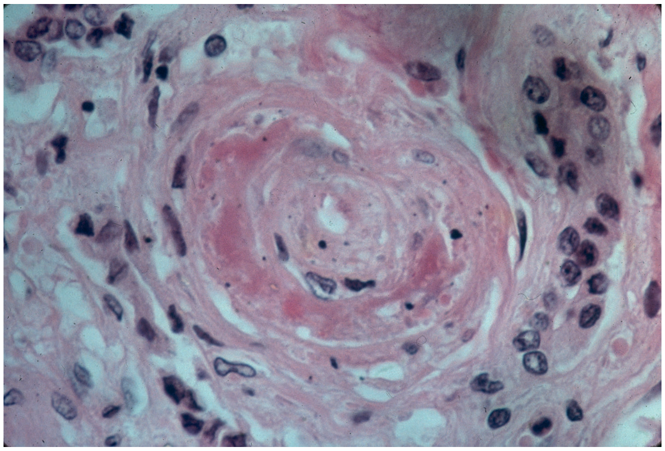

FIG 68.16 **Scleroderma Renal Crisis.** Renal arteriole demonstrates extensive fibrin deposition (dark material) within multiple layers of its wall. The lumen is further compromised by severe swelling and intimal hyperplasia (Masson trichrome stain).

increased the 1-year survival of patients with SCR. Prompt treatment with ACEIs is recommended for hypertensive and normotensive SRC because these agents may reverse the process by interfering with angiotensin II–mediated vasoconstriction and by inhibiting the degradation of the potent vasodilator bradykinin by ACE. Despite this impressive impact of ACEIs on clinical outcomes, approximately one-third to one-half of patients still progress to early death or renal failure. This has prompted continued investigation of additional treatment strategies, including blockade of the RAA system at multiple sites (using, for example, a direct renin inhibitor) as well as addition of potent vasodilators (*e.g.*, prostacyclin or an endothelin receptor antagonist).

Renal Disease of Sjögren Syndrome

A variety of renal manifestations occur in approximately one-third of patients with primary Sjögren syndrome (Chapter 54), including tubular dysfunction (proximal or, more often, distal tubular acidosis, Fanconi syndrome, hypokalemia that may be profound and associated with paralysis, Bartter syndrome, Gitelman syndrome, nephrogenic diabetes insipidus), as well as renal calculi, nephrocalcinosis, interstitial nephritis, pseudolymphoma, necrotizing vasculitis, and glomerulopathy.[48] Studies of renal pathology among patients with primary Sjögren syndrome have shown that acute and/or chronic tubulointerstitial nephritis is the predominant lesion. A diverse range of glomerular diseases, including MN and proliferative glomerulonephritis (focal or diffuse, and membranoproliferative), have been reported in primary Sjögren syndrome. In such cases, the possibility of overlap with SLE should be considered. Immunosuppressive therapy for renal manifestations of primary Sjögren syndrome should be individualized on the basis of activity and severity of the glomerular and/or tubulointerstitial nephritis. Patients with serious complications of tubular dysfunction may warrant immunosuppressive therapies based on preliminary evidence that autoantibodies (against, for example, carbonic-anhydrase-II) as well as cell-mediated injury likely contribute to at least some of those disorders.

ON THE HORIZON

- The advent of new genetic and molecular techniques and new disease models has led to exciting progress in our understanding of the biology of the glomerulus, the pathogenesis of many glomerular diseases, and the influence of genetic variants on disease predisposition and progression.
- It is anticipated that these insights should lead to better noninvasive diagnostic techniques, biomarkers, and predictors of prognosis and relapse and facilitate a more personalized approach to therapy rather than a one-size-fits-all approach.
- Novel targeted therapies are on the horizon that will interrupt or modulate the underlying pathophysiology of the individual diseases and also halt the downstream pathways of injury and fibrosis common to all of the glomerular diseases.

MULTIPLE-CHOICE QUESTIONS

1. A 45-year-old woman presented to the emergency department (ED) with swelling in both ankles, 15-lb weight gain over the past 3 months and shortness of breath. During a physical examination 1 year prior, 1+ protein was noted on dipstick urinalysis, but no further workup was done. There was no family history of renal disease. The patient has blood pressure of 120/80 mm Hg, elevated respiratory rate of 25, and oxygen saturation of 90%. Physical examination was notable for pitting edema in her legs up to the mid-thighs. Lungs were clear. Laboratory testing revealed a hemoglobin level of 14 g/dL, hematocrit of 42%, serum creatinine level of 1.0 mg/dL, blood urea nitrogen (BUN) of 28 mg/dL, albumin level of 1.6 g/dL, serum total cholesterol level of 350 mg/dL (normal, <200 mg/dL), and serum triglyceride level of 800 mg/dL (normal, <150 mg/dL). Serum complement levels were within normal limits. Urinalysis demonstrated 4+ protein on dipstick. Urine microscopy revealed 0–2 nondysmorphic red blood cells per high-power field, oval fat bodies, and fatty casts. A spot protein/creatinine ratio was 8 g/g. The chest radiography result was negative. Computed tomography (CT) angiography revealed multiple pulmonary emboli, and therapeutic anticoagulation was immediately initiated. Renal biopsy was deferred because of the need for urgent anticoagulation. What would have been the most likely biopsy finding if biopsy had been done?
   A. Acute post infectious glomerulonephritis
   B. Alport syndrome
   C. Antineutrophil cytoplasmic antibodies (ANCAs)–associated crescentic glomerulonephritis
   D. Membranous nephropathy (MN)

2. A 20-year-old male with history of short bowel syndrome was admitted to the hospital with elevated creatinine, macroscopic hematuria and proteinuria, and renal insufficiency. He had been on long-term peripheral nutrition via a central venous catheter for 4 years. He was admitted 6 months ago with a line infection and was given antibiotics for 7 days, but the line was not removed. He was noted to have trace proteinuria and hematuria 6 months ago. Upon admission, he was afebrile, and his blood pressure was 140/80 mm Hg. The catheter site was clean, and the remainder of the examination was unremarkable. There was trace edema. Laboratory findings were notable for mild hypoalbuminemia (serum albumin of 3.1 g/dL), serum creatinine of 2.1 mg/dL, hypocomplementemia (C3, 4 mg/dL, C4, 5 mg/dL, and CH50, 10 U/mL). Urinalysis was notable for proteinuria 2+, and urine microscopy revealed 15 acanthocytes per high-power field. The spot urine protein/creatinine ratio was 1.8 g/g. Human immunodeficiency virus (HIV), antinuclear antibody (ANA), and hepatitis B and C screen results were negative. Renal biopsy was performed after admission. Light microscopy (LM) revealed diffuse mesangial and endocapillary hypercellularity, lobulation in the glomeruli, and double contours in the glomerular capillary. Two of 18 glomeruli had segmental crescents. Immunofluorescence microscopy revealed staining for IgG (3+) and C3 (3+) along the capillary and mesangial regions in a granular pattern. Electron microscopy (EM) revealed subendothelial and mesangial electron-dense deposits. What further workup is indicated?
   A. ANCAs testing
   B. Anti–glomerular basement membrane (GBM) antibody
   C. Blood culture
   D. Evaluation for genetic mutations of complement regulatory proteins, including complement factor H (CFH), CFI, and Membrane cofactor protein (MCP).

3. A 60-year-old male with new diagnosis of Hodgkin lymphoma was noted to have 3+ edema on examination by his oncologist. Serum creatinine was 1.1 mg/dL. Serum albumin was 2.5 g/dL. Urinary protein excretion revealed 6 g/24 hr. Urine microscopy showed fatty casts but no cellular elements. Kidney biopsy result was consistent with minimal change disease (MCD). What is the appropriate treatment?
   A. High-dose prednisone
   B. Cyclosporine with prednisone
   C. Mycophenolate mofetil
   D. Chemotherapy

Inflammation and Atherothrombosis

Giovanna Liuzzo, Daniela Pedicino, Davide Flego, Filippo Crea

The spectrum of the clinical syndromes caused by coronary atherosclerosis ranges from asymptomatic disease and stable angina (SA) to acute coronary syndromes (ACSs). The latter include unstable angina (UA) and acute myocardial infarction (MI), which is further classified according to electrocardiographic changes as non-ST elevation myocardial infarction (NSTEMI) and ST elevation myocardial infarction (STEMI), and sudden cardiac death.

Although the early outcome of ACS has considerably improved in the past decade, cardiovascular diseases still represent the main cause of morbidity and mortality worldwide, mainly because chronic-smoldering ACS eventually leads to heart failure and sudden cardiac death. The gravity of the syndrome calls for a reappraisal of the mechanisms responsible for coronary instability and for innovative preventive and therapeutic strategies.

The life-threatening complications of coronary artery disease arise as nonlinear events in an otherwise slowly progressive process. This nonlinearity has been attributed to a combination of factors, of which plaque rupture or erosion and superimposed thrombosis are considered to be the most important. Although the pathways leading to plaque rupture or erosion are incompletely understood, our understanding of the importance of inflammation in the process has considerably increased. Atherosclerosis is a chronic inflammatory disease by itself, but an outburst of the inflammatory process within the atherosclerotic plaque of coronary arteries can lead to plaque rupture with thrombosis, resulting in myocardial ischemia and necrosis. The latter is an additional source for local and systemic inflammation. Furthermore, patients with ACS frequently undergo percutaneous coronary intervention (PCI), which may cause iatrogenic myocardial injury, a further source of inflammation. Moreover, plaque instability promotes hyperreactivity to the inflammatory stimulus of myocardial necrosis, which in turn accelerates plaque instability: Inflammation begets inflammation (Fig. 69.1). Thus it is not surprising that a plethora of previous studies have consistently shown a marked elevation of circulating levels of high-sensitivity C-reactive protein (hs-CRP) or of other soluble markers of inflammation at the time of hospital admission. Interestingly, the intensity of this inflammatory surge predicts short- and long-term outcome. Overall, these observations suggest that specific antiinflammatory treatment might improve the outcome of ACS.[1]

ATHEROSCLEROSIS: A CHRONIC INFLAMMATORY DISEASE

Atherosclerosis is a chronic nonresolving inflammatory process that typically occurs at sites of blood flow disturbance (Table 69.1).[2] The atherogenic process develops over the course of decades, beginning in the early teenage years. It is the same worldwide, regardless of gender and race, and proceeds at a faster speed in patients with risk factors such as hypertension, tobacco smoking, diabetes mellitus, obesity, and genetic predisposition. In the early phase, this process is triggered by subendothelial retention of cholesterol-containing plasma lipoproteins and by flow-mediated inflammatory changes in endothelial cells (Table 69.2). At this stage of the disease, endothelial cells show an altered response to vasodilator and vasoconstrictor stimuli, due in part to nitric oxide reduction as well as to increased expression of endothelin. Moreover, the cells express increased levels of adhesion molecules such as intercellular adhesion molecule (ICAM) and vascular cell adhesion molecule (VCAM) and produce higher levels of chemotactic molecules such as interleukin (IL)-8 and monocyte chemotactic protein (MCP), with the consequent increase in leukocytes' recruitment. These mechanisms act together to induce endothelial dysfunction and a chronic self-maintaining inflammatory state. Plaque formation is preceded by a fatty streak, an accumulation of lipid, macrophages/foam cells, and T cells beneath the endothelium. Fatty streaks may disappear or progress to atherosclerotic plaques, asymmetrical focal thickenings of the intima with a core region of foam cells and extracellular lipids surrounded by a cap of smooth-muscle cells and collagen. Atherosclerotic lesions contain monocyte-derived macrophages and T cells interspersed with lipids and debris from dead cells; the lesions are embedded in an extracellular matrix composed of collagen fibers and other constituents produced primarily by vascular smooth muscle cells. T cells, macrophages, and mast cells infiltrate the lesion; they are particularly abundant in the shoulder region of the atheroma, producing proinflammatory cytokines, costimulatory factors for immune activation, eicosanoids, and reactive oxygen and nitrogen species. On the other hand, many immune cells beneath the plaque show antiinflammatory features: Macrophages internalize cholesterol through their scavenger receptors and produce antiinflammatory cytokines, and T cells of the regulatory phenotype produce antiinflammatory and immunosuppressive cytokines. The perturbation of this delicate balance between pro- and antiinflammatory signals is involved both in the nonresolving, chronic inflammation linked to disease progression and in the eventual breakdown of endothelial continuity, with thrombus formation and plaque instability (Fig. 69.1). Fibrous plaques appear in a later stage of the disease, with the chronic accumulation of collagen and calcification. Erosion of the surfaces of some plaques and rupture of a plaque's calcific nodule into the artery lumen may trigger thrombosis.[3] Overall, mechanisms

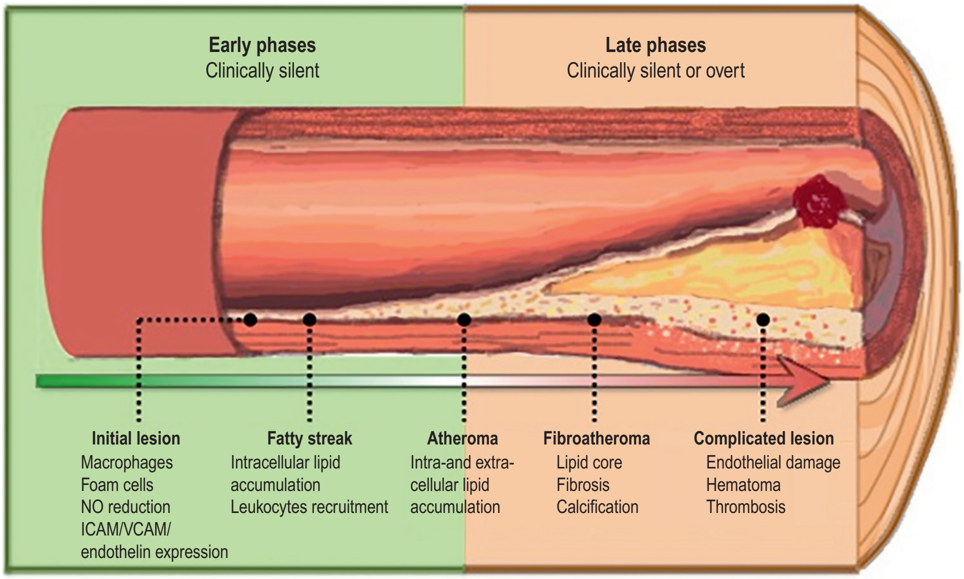

FIG 69.1 **Schematic Representation of the Natural History of Atherosclerotic Disease.** This figure shows the development of the atherogenic process. In the early phase, this process is triggered by subendothelial retention of cholesterol-containing plasma lipoproteins and by flow-mediated inflammatory changes in endothelial cells. Endothelial cells show an altered response to vasodilator and vasoconstrictor stimuli, with nitric oxide (NO) reduction and increased expression of endothelin. Moreover, they express increased levels of adhesion molecules such as intercellular adhesion molecule (ICAM) and vascular cell adhesion molecule (VCAM) and produce higher levels of chemotactic molecules such as interleukin (IL)-8 and monocyte chemotactic protein (MCP), with a consequent increase in leukocyte recruitment. The fatty streak is an accumulation of lipid, macrophages/foam cells, and T cells beneath the endothelium. Fatty streaks may disappear or progress to atherosclerotic plaques, asymmetrical focal thickenings of the intima with a core region of foam cells and extracellular lipids surrounded by a cap of smooth-muscle cells and collagen. Fibrous plaques appear at a later stage of the disease and are characterized by the deposition of collagen and calcification.

TABLE 69.1 Key Steps in Atherogenesis

1. Endothelial activation with increased infiltration of atherogenic lipoproteins at sites of low or oscillating shear stress (branch points and flow dividers).
2. Subendothelial retention and modification of atherogenic lipoproteins (low-density lipoprotein/very-low-density lipoprotein).
3. Endothelial activation with increased mononuclear leukocyte (inflammatory cell) adhesion, chemotaxis, and subendothelial recruitment.
4. Subendothelial inflammatory cell activation with lipid ingestion through monocyte scavenger receptor expression resulting in foam cell formation.
5. Intimal migration and proliferation of medial/adventitial smooth-muscle cells/myofibroblasts in response to growth factors released by activated monocytes with matrix production and formation of the fibrous cap and fibrous plaque.
6. Abluminal plaque growth with positive (outward) arterial adventitial remodeling preserving lumen size in early stages; later, plaque growth or negative remodeling results in luminal narrowing.
7. Neoangiogenesis due to angiogenic stimuli produced by inflammatory cells (macrophages) and other arterial wall cells (vascular endothelial growth factor, interleukin-8).
8. Death of foam cells by necrosis/apoptosis leading to necrotic lipid core formation.
9. Plaque disruption (rupture of fibrous cap or endothelial erosion) due to inflammatory cell–mediated matrix degradation and death of matrix-synthesizing smooth-muscle cells.
10. Exposure of thrombogenic substrate (lipid core–containing tissue factor derived from inflammatory cells) following plaque disruption with arterial thrombosis.

TABLE 69.2 Factors Promoting Endothelial Activation/Dysfunction in Atherosclerosis

- Reduced vasodilator and increased vasoconstrictor responsiveness
- Enhanced oxidant stress with inactivation of nitric oxide
  - Increased expression of endothelin
- Enhanced leukocyte (inflammatory cell) adhesion and recruitment
- Increased adhesion molecule expression (ICAM, VCAM)
  - Increased chemotactic molecule expression (MCP-1, IL-8)
- Increased prothrombotic and reduced fibrinolytic activity
- Increased growth-promoting phenotype
- Dyslipidemia and atherogenic lipoprotein modification
  - Elevated LDL, VLDL, LP(a)
  - LDL modification (oxidation, glycation)
  - Reduced HDL
- Increased angiotensin II and hypertension
- Estrogen deficiency
- Smoking
- Hyperhomocysteinemia
- Advancing age
- Infection?

HDL, high-density lipoprotein; ICAM, intercellular adhesion molecules; IL-8, interleukin-8; LDL, low-density lipoprotein; LP, lipoprotein; MCP-1, monocyte chemotactic protein-1; VCAM, vascular cell adhesion molecules; VLDL, very-low-density lipoprotein.

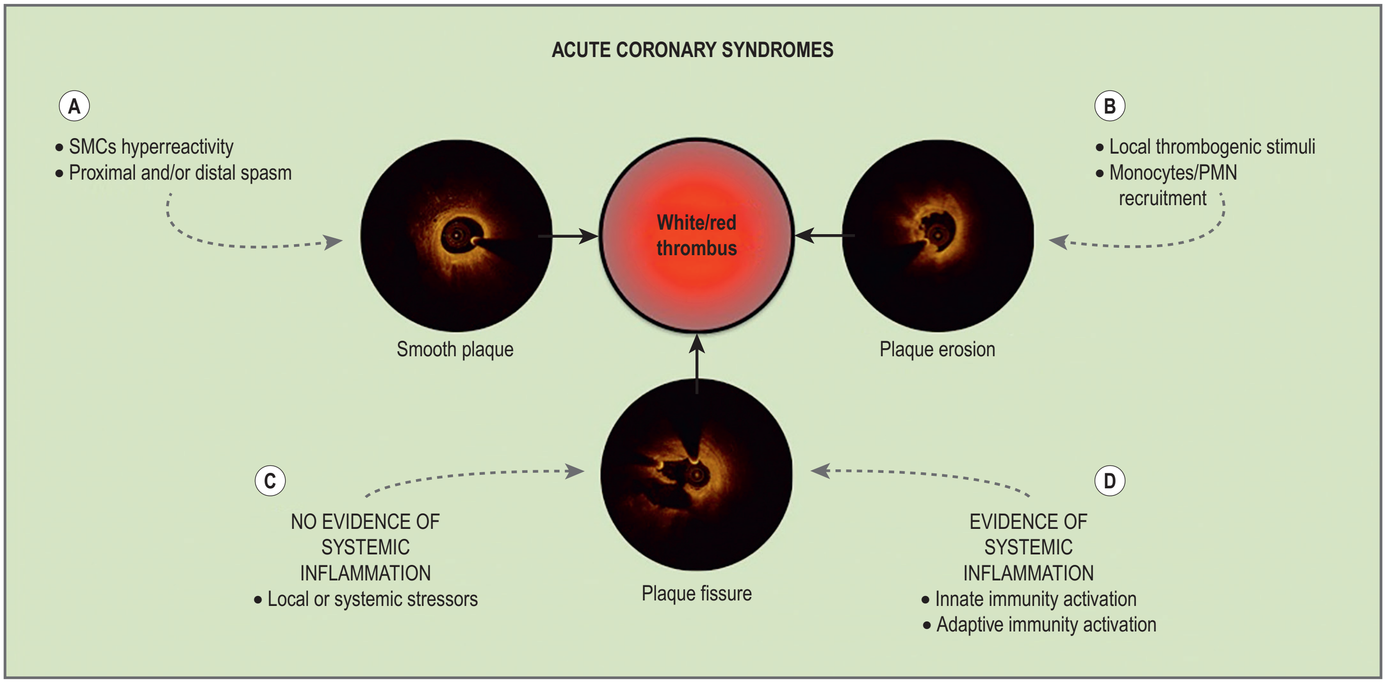
responsible for coronary instability are multiple and insufficiently understood.

ROLE OF INFLAMMATION IN THE PATHOGENESIS OF ACUTE CORONARY SYNDROMES

Experimental models of atherogenesis have provided a growing body of information about molecular mechanisms of plaque growth; however, transition from coronary stability to instability is less well understood due to lack of animal models reflective of human disease.[1] The abrupt clinical presentation of ACS gives a strong signal of discontinuity in the natural history of atherothrombosis. When primary prevention of atherosclerosis fails, the progression of coronary atherosclerosis can remain clinically silent for years, decades, or even for life, as indicated by the high prevalence of coronary atherosclerosis in subjects dying of noncardiac causes. In contrast, some patients at a certain point in their lives exhibit acute coronary instability, followed by a period of stability that can be short or last for years or decades. These simple clinical observations suggest that the mechanisms responsible for plaque growth and for plaque instability are different and that the causes and mechanisms of plaque instability are multiple. Accordingly, the paradigm that implies a single type of culprit coronary plaque as a cause for instability does not adequately fit the findings of postmortem studies.[1] The concept that inflammatory cell activation plays a key role in the pathogenesis of ACS is now commonly accepted, and it is believed that activation of inflammatory cells in the culprit stenosis is the cause of coronary instability in all patients. However, about 40% of ACS patients have low or very low levels of high-sensitivity C-reactive protein (hs-CRP), a very sensitive marker of inflammation.[4] Coronary angiography fails to demonstrate obstructive atherosclerosis in up to one-third of patients with symptoms suggestive of an ACS along with raised troponin levels and/or ischemic-like ST segment changes, suggesting that functional alterations of epicardial arteries and/or of coronary microcirculation may also play an important pathogenetic role.[5]

We have recently proposed a pathogenetic classification of ACS: (i) patients with plaque fissure and systemic inflammation; (ii) patients with plaque fissure without systemic inflammation; (iii) patients with plaque erosion; and (iv) patients with smooth plaques and functional alterations in the coronary circulation (Fig. 69.2). For the first group, multiple studies have highlighted the prominent role of inflammation in generating plaque instability, with three main features characterizing these ACS patients: (i) the widespread involvement of epicardial arteries, coronary microcirculation, and myocardium; (ii) the activation of innate immunity; and (iii) the activation of adaptive immunity, with a consequent dysbalance between antiinflammatory and proinflammatory immune responses.

In patients in whom plaque rupture and coronary instability occur in the absence of systemic evidence of inflammation, the precise causes of instability are still poorly understood. However, mechanisms such as extreme emotional disturbance, intense physical exertion, and local mechanical stress at the level of the artery wall are likely to play a key pathogenetic role.



ACUTE CORONARY SYNDROMES

D
EVIDENCE OF SYSTEMIC INFLAMMATION
• Innate immunity activation
• Adaptive immunity activation

FIG 69.2 Pathogenetic Classification of Acute Coronary Syndromes. In patients with a similar clinical presentation, mechanisms responsible for coronary instability can be significantly different. The figure shows optical coherence tomography (OCT) images of different plaques and the proposed pathogenetic classification of acute coronary syndromes (ACS). This classification is based on the mechanisms responsible for coronary instability in homogeneous groups of patients: (D) patients with plaque fissure and systemic inflammation; (C) patients with plaque fissure without systemic inflammation; (B) patients with plaque erosion; (A) patients with functional defects in coronary circulation. PMN, Ppolymorphonuclear neutrophil; SMCs, smooth muscle cells (SMCs).

The mechanisms of plaque erosion are still largely unknown, although increasing evidence suggests that local neutrophil activation possibly plays a role.

Among the majority of patients who present with ACS in the absence of obstructive atherosclerosis, functional alterations of epicardial coronary arteries or of coronary microcirculation are the likely cause of instability.

PLAQUE FISSURE WITH SYSTEMIC INFLAMMATION

Plaque fissure is caused by the combined action of metalloproteinases, which digest the intercellular matrix and reduce collagen synthesis. This results in the exposure of the highly thrombogenic content of the underlying lipid plaque that triggers occlusive or subocclusive thrombus formation.

Plaque Fissure: Pathological and Clinical Findings

The role played by plaque fissure was initially established in postmortem studies and then confirmed *in vivo* by using angioscopy, intravascular ultrasound, and, more recently, optical coherence tomography (OCT), a light-based imaging technique with high spatial resolution. OCT allows the detection of intracoronary thrombi and the precise measurement of fibrous cap thickness and plaque components such as lipid core, calcium nodules, and microvessels.[6] OCT has been used in clinical studies to obtain more detailed information about the vulnerable plaque and to find specific features to differentiate between erosion-prone and rupture-prone plaques. In particular, the high resolution of OCT has recently clarified that *in vivo* plaque rupture is associated with ACS in about half of patients. It is worth noting that fissures do not necessarily lead to ACS, as asymptomatic plaque fissure is a frequent event leading to plaque progression. Yonetsu et al. using OCT found that about 15% of patients with SA presented with plaque fissure.[7] A larger plaque burden, a thinner fibrous cap, and a smaller lumen size appear to predispose to thrombus formation and ACS.[8]

Among the several inflammatory biomarkers tested in ACS, levels of hs-CRP are typically elevated, in line with CRP's high sensitivity and wide dynamic range.[9] However, it is difficult to establish a cutoff at the present time. Whereas in primary prevention hs-CRP levels ≥2 mg/L (and even ≥1 mg/L) might be recommended, in ACS patients two different cutoffs have been suggested as clinically useful: an admission value ≥10 mg/L and a discharge value ≥3 mg/L. These cutoffs, although confirmed in larger studies, have not yet led to a general consensus.[4,10]

Experimental studies have clarified the molecular mechanisms through which activation of inflammatory cells in the plaque can trigger thrombus formation. Inflammatory responses increase the fragility of the fibrous cap as well as the thrombogenic potential of the plaque. The main mediators of inflammation-induced activation of coagulation are proinflammatory cytokines. Several studies have shown the importance of IL-6 in the initiation of coagulation activation and the role of tumor necrosis factor-α (TNF-α) and IL-1 in the modulation of anticoagulant pathways.

Widespread Coronary Inflammation

In patients with ACS and systemic evidence of inflammation, widespread coronary inflammation is suggested by transcardiac neutrophil activation in the effluent of myocardial regions not perfused by the culprit artery. This event appears unrelated to coronary atherosclerosis or recurrent ischemia, as it is not observed in patients with chronic SA and multivessel coronary disease or in patients with vasospastic angina.[11] Widespread acute coronary inflammation is, therefore, the likely cause of multiple complex stenoses, multiple thrombi, and multiple fissured plaques involving different coronary artery branches observed in clinical studies in ACS, based on angiography and intravascular imaging.[6] The number of disrupted coronary plaques correlates with systemic hs-CRP levels. The notion of widespread coronary inflammation is confirmed by postmortem studies.[1]

Activation of Innate Immunity

The notion that innate immunity plays an important role in ACS is supported by the demonstration of activated monocytes, polymorphonuclear neutrophils (PMNs), eosinophils, and mast cells not only at the site of plaque rupture but also in the whole coronary circulation of patients with ACS (Fig. 69.3).[1] High telomerase activity in PMNs has been reported coming from the culprit coronary plaque of patients with ACS, but not from plaque of patients with SA or in PMNs from the peripheral blood. Telomerase activity is normally absent in differentiated cells such as PMNs. The only predictor of telomerase reactivation in coronary plaques of ACS patients was a short time interval from symptom onset to PMN sampling. Neutrophil apoptosis has been identified as one of the key mechanisms to switch off inflammation. Accordingly, delayed apoptosis of peripheral PMNs in ACS patients has been demonstrated.[12]

Macrophages account for the majority of leukocytes in plaques. Plaque-resident macrophages differentiate from monocytes recruited from circulating blood. However, monocytes represent a heterogeneous cell population, exemplified by the differential expression of CD14 and CD16.[13] Human coronary artery lesions contain macrophage subpopulations with different gene-expression patterns. Patients with coronary atherosclerosis have higher numbers of circulating $CD14^+CD16^+$ monocytes than healthy subjects. Finally, peak levels of $CD14^{hi}CD16^{lo}$ monocytes after acute MI correlate negatively with the recovery of left ventricular ejection fraction 6 months after MI. Noninvasive imaging technologies have now been developed to follow and quantify subpopulations of monocytes and macrophages *in vivo.*

Monocytes accumulated within thrombi, obtained during primary PCIs, specifically overexpress Toll-like receptor 4 (TLR4), together with specific patterns of locally expressed chemokines and cytokines compared with circulating monocytes.[14] TLR are key pattern-recognition receptors expressed by innate immunity cells that recognize a large number of pathogen-associated molecular patterns (PAMPs). Interestingly, Niessner et al. demonstrated that interferon (IFN)-α produced by plasmacytoid dendritic cells in atherosclerotic plaques could enhance TLR4 signaling by sensitizing these cells to lipopolysaccharide and other microbial molecules as well as to (modified) endogenous molecules, all abundantly present in the atherosclerotic lesion microenvironment. These sensitized antigen-presenting cells (APCs) strongly upregulate the production of cytokines such as TNF-α, IL-12, IL-23, and matrix metalloproteinase-9 (MMP-9), thus enhancing plaque instability.[15]

It has been demonstrated that human platelets express functional TLRs capable of recognizing bacterial components. TLR activation directly induces platelet aggregation and increased platelet adhesion to collagen under flow conditions. Moreover, stimulation of TLR, in particular TLR2, induces a significant

FIG 69.3 **Histological Features of Fissure-Prone Plaques.** Both innate immunity and adaptive immunity play a key role in the pathogenesis of coronary plaque instability. Multiple types of inflammatory cells are present in atherosclerotic plaques. Macrophages (MØ) and mast cells infiltrate the lesion and are particularly abundant in the shoulder region where the atheroma grows and where the risk of plaque rupture is highest. T-cell infiltrates are always present in atherosclerotic lesions. Such infiltrates are predominantly CD4 T cells, which recognize protein antigens processed and presented by activated antigen-presenting cells (APCs). Regulatory T cells (Tregs) maintain the homeostasis of cell subsets involved in adaptive immunity. In human atherosclerotic lesions, Treg colocalize with interleukin-10 (IL-10) and transforming growth factor (TGF)-β expression. increase in the interactions of platelets and leukocytes and in the amplification of platelet-derived inflammatory signals. These findings highlight the role of platelets as immunological cells, critically participating in both inflammatory and thrombotic processes. Indeed, platelet TLR2 and related innate immune transcripts have been associated with cardiovascular disease and its risk factors. Expression of TLR2 in megakaryocytes suggests that inflammatory processes, through TLR2 stimulation, can increase megakaryocyte maturation and can modulate megakaryocyte phenotypes, potentially influencing platelet function and thrombosis.

Activation of Adaptive Immunity

In patients with ACS and systemic evidence of inflammation, the higher frequency of activated T cells in comparison to patients with SA suggests that the sudden changes leading to coronary instability might be related to mechanisms involving T-cell immunity. In particular, in ACS patients CD4 T-cell subpopulations are dysregulated, and their abnormalities are associated with worse outcomes, especially in patients with diabetes mellitus.[16-18]

ACS patients have a skewed T-cell differentiation oriented toward aggressive effector phenotypes and defective regulatory T cells, suggesting that the lymphocyte compartment fails to suppress excessive immune responses. Overall, such T-cell abnormalities characterize about half of ACS patients.[16] In this subset of ACS patients, helper T-cell dysregulation might affect the biological outcome of the immune response and contribute to plaque destabilization through multiple damaging pathways (Fig. 69.3).

T cells physiologically drive B-cell hypersomatic mutation, isotype switch, and affinity maturation in the germinal centers of lymphoid organs and also in extranodal sites in autoimmune diseases[19]. Indeed, coronary atherosclerotic plaques obtained by endoluminal directional atherectomy are sites of B lymphocyte proliferation in patients with ACS, strongly suggesting the local presence of an activating or recruiting antigen in these lesions (Table 69.3).

T-helper 1 (Th1) Cells

The importance of Th1 and IFN-γ in atherosclerosis progression and in plaque destabilization is confirmed by numerous studies showing a marked increase in Th1 frequency and increased expression of Th1-related effector molecules such as IFN-γ, signal transducer and activator of transcription 4 (STAT4), and T-bet[20]. Th1 cells are suspected of regulating the fragility of the fibrous cap as well as the thrombogenic potential of the plaque. IFN-γ can contribute to plaque destabilization in several ways: by the recruitment and activation of macrophages in the atherosclerotic lesions; by reducing collagen synthesis; by increasing the production of extracellular matrix–degrading proteins; and by activating APC. Furthermore, increased IFN-γ expression induces a positive feed-forward loop of Th1 induction sustaining a proinflammatory state. When activated in the intima, Th1 cells produce proinflammatory cytokines and enhance the expression of CD40 ligand. Ligation of CD40 on APC by CD40 ligand induces release of extracellular matrix–degrading metalloproteinases and the expression of tissue factor, a key initiator of the coagulation cascade.

TABLE 69.3 **Potential Role of Infection in Atherosclerosis and Thrombosis**

Infectious Organisms Implicated

Viruses
  Herpes viruses (*e.g.*, cytomegalovirus)
Bacteria
  Chlamydia pneumonia
  Helicobacter pylori
  Porphyromonas gingivalis?

Mechanism(s) by Which Infections May Contribute to Atherothrombosis

Direct infection of the vascular wall with endothelial injury, inflammatory cell recruitment, and activation (*Chlamydia pneumoniae, herpes virus, cytomegalovirus*)
Immune-mediated vascular injury through molecular mimicry (*Chlamydia pneumoniae*)
Remote infections with systemic activation of the inflammatory response (*Helicobacter pylori, Porphyromonas gingivalis*)

$CD4^+CD28^{null}$ T Cells

$CD4^+CD28^{null}$ T cells are distinct from classic helper T cells in several aspects. This terminally differentiated subpopulation shows an increased resistance to apoptosis and a wide range of proinflammatory properties.

$CD4^+CD28^{null}$ T cells are present preferentially in unstable ruptured atherosclerotic plaques, and their frequency significantly increases the risk of ACS, particularly in patients with diabetes.[16-18] $CD4^+CD28^{null}$ T cells from ACS patients show several abnormalities such as the ability to mediate endothelial cytotoxicity by triggering the NK stimulatory receptor KIR2DS2, killer Ig-like receptor 2DS2 (KIR2DS2) in the absence of T-cell receptor (TCR) activation and higher levels of costimulatory receptors, *e.g.*, OX40 and 4–1BB.

Th17 Cells

Th17 cells are characterized by the expression of retinoid orphan receptor (ROR)-γt, the master regulator transcription factor responsible for the production of IL-17.

Although the precise role of IL-17 in atherosclerosis and ACS remains controversial,[21] experimental studies in mice have provided direct evidence that IL-17 is predominantly proatherogenic. Indeed, in combination with IFN-γ, IL-17 induces a proinflammatory response in vascular smooth muscle cells. On the other hand, Th17 cells are involved in wound healing and exert powerful fibrogenic activity. These cells activated in the context of the atherosclerotic plaque promote the formation of thick collagen fibers that can resist the mechanical assault exerted by hemodynamic forces. This is due to the capacity of the IL-17 to promote procollagen expression.

Regulatory T Cells

In atherosclerosis, the role of regulatory T cells (Treg) is well appreciated. Indeed, this T-cell subpopulation inhibits atherosclerosis development and progression by suppressing effector T-cell responses. A defective Treg compartment has been demonstrated in the peripheral blood of ACS; these patients show low levels of circulating Treg, a reduced suppressive efficiency of Treg, and an increased Treg susceptibility to apoptosis.[16] In a small study, Treg have been identified as the major T-cell subset in aspirated coronary thrombus adjacent to the culprit lesion in patients with ACS, associated with a restricted TCR diversity in thrombus-resident T cells; this suggests an increased antigen-specific Treg redistribution between the peripheral blood and local sites of inflammation.[22] Nevertheless, ACS patients have a lower induction of Treg after TCR stimulation with anti-CD3 and anti-CD28 antibodies.[23] Notably, the defective TCR-induced Treg generation is partially recovered 1 year after the index event, suggesting a transient phenomenon present during the acute phase of the disease. Thus defects in the Treg compartment might affect the plaque stability by impairing a balanced immune response in atherosclerosis. Indeed, Treg have been implicated in the inhibition of effector T cells, in the suppression of endothelial and macrophage activation, and in the modulation of cholesterol metabolism.

B Cells

The contribution of B cells in autoimmunity is well recognized. The function of B cells has been evaluated in various animal models of atherosclerosis; B1a cells and their secretion of IgM seem to mediate the protective effects of B cells, whereas B2 cells are proatherogenic through modulation of T cell–dependent mechanisms.

Moreover, antibodies against several oxidation-specific epitopes of low-density lipoprotein and other atherosclerosis-related antigens are found in animals and humans, both in the circulation and in atherosclerotic plaques.[24] The mechanisms by which these antibodies act remain unclear, and it is unresolved whether they represent an epiphenomenon of chronic immune stimulation or a disease-specific phenomenon.

TCR Signaling Alteration in ACS

The first step in lymphocyte activation is TCR binding of specific peptides presented by APC. TCR triggering initiates a cascade of phosphorylation events that culminate in the activation and nuclear translocation of transcription factors (Chapter 12). A complex molecular coordination is required, including positive and negative feedback loops necessary to avoid lymphocyte hyperreactivity and the breaking of immune tolerance. The proper tuning of TCR signaling is critical also for T-cell differentiation. Indeed, in addition to the cytokine environment, the induction of different T-helper cell lineages is driven by TCR-mediated signal strength.

CD4 T cells from ACS patients show enhanced response to TCR stimulation and have a lower setting of the T-cell activation threshold, attributable to enhanced amplification of proximal TCR-mediated signals.[23,25] Intriguingly, some of these abnormalities are confined to the acute phase of ACS, whereas others persist also during the stable phase of the disease, suggesting the existence of chronic lymphocyte hyperreactivity.

The molecular TCR signaling alterations observed in ACS include an increase in the positive activation signals, including higher accumulation of CD3 complexes and zeta-chain associated protein kinase of 70 kD (Zap70) in the immunological synapse during antigen presentation; higher early tyrosine phosphorylation after TCR stimulation; and a defective deactivation of the lymphocyte-specific protein tyrosine kinase (LCK). On the other hand, ACS patients exhibit reduced activity of the inhibitory molecular patterns such as reduced phosphorylation of Zap70 at its inhibitory residue Tyr-292, a residue implicated in TCR deactivation; lower expression of PECAM-1, a molecule implicated in downmodulation of T cell activity; and reduced activation of CREB, a transcription factor believed to be particularly important for the generation and maintenance of Treg and for IL-2 and IL-10 production.[25] Finally, ACS patients show enhanced expression of the protein tyrosine phosphatase non–receptor type 22 (PTPN22). This enzyme plays a key role in controlling the intensity of the early TCR signal transduction acting on LCK and on Zap70.[23]

PLAQUE FISSURE WITHOUT SYSTEMIC INFLAMMATION

When plaque fissure occurs without systemic inflammatory activation, other mechanisms, including emotional and physical stress or changes in plaque composition, may play a pathogenic role.[1] The ability of systemic stress to induce plaque fissure might be related to sympathetic nervous system activation and catecholamine release associated with increased heart rate, increased blood pressure, and coronary vasoconstriction. Besides the fissuring of vulnerable plaque, these conditions favor platelet activation, hypercoagulability, and intense coronary microvascular constriction. It has been demonstrated that the highest shear stress is present at the level of the shoulder region of the fibrous cap. Changes in plaque composition may be another possible cause of plaque fissure. Indeed local changes in pH, temperature, cholesterol saturation, and hydration promote cholesterol crystallization in the lipid core associated with quick volume expansion, potentially causing plaque fissure and thrombosis. These mechanisms may be amplified by crystallization of free cholesterol from erythrocyte membranes when intraplaque hemorrhage occurs.

PLAQUE EROSION

Plaque Erosion: Pathological Findings

Plaque erosion is associated with coronary instability in about one-third of patients. Eroded plaques are characterized by thrombus formation at the site of a denuded fibrous atherosclerotic plaque. Endothelial denudation leads to the exposure of the intima that often shows a pathological thickening and consists predominantly of vascular smooth muscle cells and proteoglycans, heavily glycosylated proteins able to form large complexes by binding other proteoglycans, hyaluronan, and collagen. There are no pathognomonic features to identify plaque erosion. An eroded plaque in a histological specimen is recognized when serial sectioning of thrombosed arterial segments fails to reveal plaque rupture. Compared with plaque fissure, which typically has a large lipid pool, plaque erosion shows intact internal and external elastic laminas and a well-developed media (unlike plaque rupture, where the internal lamina is often disrupted and the underlying media is thin and disorganized), rare calcifications, and a lower grade of inflammation.[26] There is still no agreement on the grade of luminal obstruction related to plaque erosion because some groups have demonstrated that eroded plaques are less obstructive than ruptured plaques with thrombosis, and others report the opposite[26] (Fig. 69.4).

The detection of eroded plaques by OCT is based upon exclusion criteria.[6] Similar to histological detection, OCT confirmation of plaque erosion derives from the absence of fibrous cap discontinuation after intraluminal thrombi aspiration. It is not always possible to obtain a proper distinction between fissured and eroded plaque by imaging, and it is even more challenging to distinguish erosion-prone plaques from stable plaques.

Mechanisms of Plaque Erosion

Several studies have highlighted the high frequency of ACS associated with plaque erosion in women and in young persons, mostly after stressful events[1] and possibly reflecting acute changes

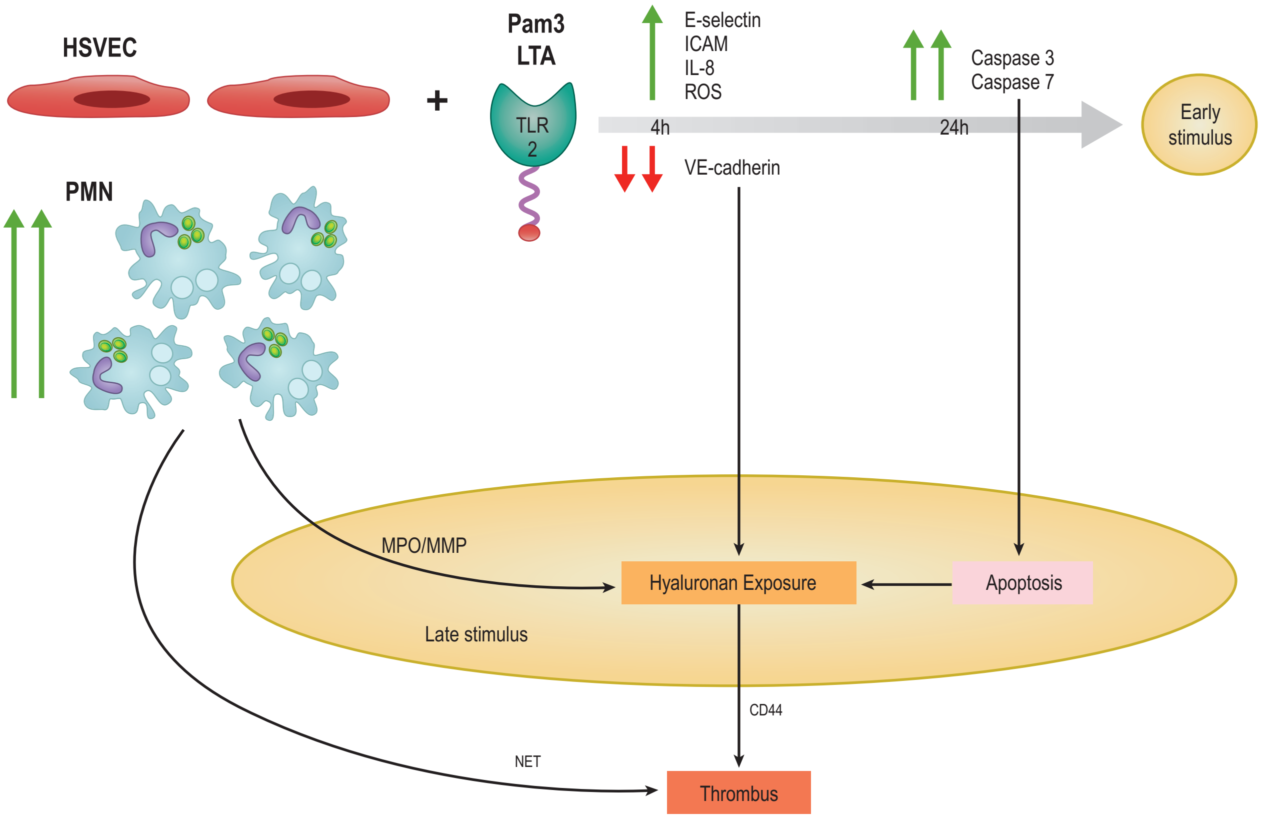

FIG 69.4 **A Hypothetical Model of Plaque Erosion.** Toll-like receptor (TLR) 2 stimulation on endothelial cells (HSVEC [human saphenous vein endothelial cells]) with Pam3 or lipoteichoic acid (LTA) has been reported to induce endothelial activation and apoptosis, as suggested by increased levels of adhesion molecules (E-selectin, ICAM), interleukin-8, and caspases -3 and -7. This process is markedly potentiated but not necessarily initiated by polymorphonuclear neutrophil (PMN) and leads to endothelial damage and extracellular matrix (ECM) exposure. Hyaluronic acid, a component of ECM, is a ligand for TLR2 and for the receptor CD44 and might be involved in the propagation of the inflammatory process. In humans, eroded plaques typically harbor abundant hyaluronan and proteoglycans. Thus hyaluronic acid could be considered a relevant TLR2 agonist. Also, products from infectious microorganisms may operate to promote atherothrombosis through this mechanism. MPO, myeloperoxidase; MMP, metalloproteinase; NET, neutrophil extracellular trap; ICAM, intercellular adhesion molecule; ROS, reactive oxygen species.

in local hemodynamics and atherosclerotic artery. Animal models have demonstrated that local vasoconstriction that precedes myocardial ischemia is occasionally accompanied by intracoronary thrombosis with endothelial lesions resembling human plaque erosion. A role of the innate immune system in this process has also been proposed, specifically a possible involvement of neutrophils. Coculture of neutrophils with endothelial cells induced endothelial injury and triggered endothelial cell apoptosis. Plasma from patients with eroded culprit plaques exhibited elevated systemic myeloperoxidase (MPO) levels, produced primarily by PMNs, compared with levels in patients showing plaque fissure. Moreover, in postmortem coronary specimens, eroded plaque showed a much higher density of MPO-positive cells in luminal thrombi compared with fissured plaque.[6] Endothelial cells overlying atherosclerotic lesions abundantly express the pattern-recognition receptor TLR2.[27] TLR2 has been localized mostly in areas of disturbed blood flow, and animal models have shown that the inhibition of this receptor reduces endothelial dysfunction by low shear stress. In lesions prone to erosion, lipoproteins and proteoglycans could serve as endogenous activators for TLR2.[28] Intense immunostaining for hyaluronan and its receptor, CD44, has been detected along the interface between luminal thrombus and eroded plaque compared with fissured or stable plaque.[28] These data led to the intriguing hypothesis that the accumulation of hyaluronan along the plaque may be involved, through CD44 activation, in the promotion of endothelial discontinuity, thrombus formation, and leukocyte accumulation. The ligation of TLR2 has been shown to result in inflammation and endothelial apoptosis in a process that could be markedly potentiated but not necessarily initiated by polymorphonuclear leukocytes. A “two-step model” has been proposed in which the first hit derives from TLR2 activation and leads to an initial endothelial injury, with subsequent apoptosis and desquamation; the second hit is mediated by neutrophil recruitment, with propagation of the local process and amplification of endothelial damage.[29] In humans, eroded plaques typically harbor abundant hyaluronan and proteoglycans, and TLR2 ligands typically include both endogenous and exogenous gram-positive derived hyaluronan. Thus it has been proposed that hyaluronic acid could be considered a disease-relevant TLR2 agonist, and that endogenous as well as infectious factors may operate to promote atherothrombosis through this mechanism.

Endothelial erosion occurs on plaques scarcely calcified, less prone to expansive remodeling, and only sparsely inflamed. However, neutrophil infiltration that typically follows plaque erosion is considered a hallmark of this distinct morphology of vulnerable plaques. No specific morphological features have been identified to distinguish eroded plaques from stable plaques and rupture-prone plaques, and both the limitation of imaging techniques and the relative lack of animal models have hampered progress in this field.

KEY CONCEPTS

Epidemiology of Ischemic Heart Disease

- Main cause of morbidity and mortality
- Recurrence of ACS eventually leads to the pandemics of heart failure and sudden cardiac death
- Need for a reappraisal of the mechanisms responsible for coronary instability and for innovative preventive and therapeutic strategies

Current Concepts on Atherosclerosis and Chronic Inflammation

- Atherosclerosis is a chronic non-resolving inflammatory disease
- Atherosclerotic plaques can remain stable indefinitely
- The mechanisms responsible for coronary instability are multiple

Pathogenic Classification of Acute Coronary Syndromes

- Plaque fissure with systemic inflammation
- Plaque fissure without systemic inflammation
- Plaque erosion
- Functional alterations of coronary circulation (epicardial or microvascular spasm)

Main Feature of Inflammation and Immunity Associated With Plaque Fissure

- Often associated with systemic inflammation
- Widespread coronary inflammation
- Innate immunity activation (monocytes, neutrophils, Pattern Recognition Receptors)
- Adaptive immunity alterations (unbalances between pro-inflammatory and anti-inflammatory activity)

Main Feature of Inflammation and Immunity Associated With Plaque Erosion

- Neutrophil accumulation
- Hyaluronan accumulation
- TLR2 activation

FUNCTIONAL ALTERATIONS OF CORONARY CIRCULATION

Epicardial coronary vasospasm is a possible cause of ACS when coronary angiography fails to demonstrate the presence of an obstructive atherosclerotic plaque.[1] The mechanisms underlying coronary spasm are multifold and may involve enhanced Rho kinase activity in smooth muscle cells.

Vasoconstriction causing ACS can be located also at the microvascular level. In particular, intense coronary microvascular vasoconstriction plays an important role in the pathogenesis of Takotsubo syndrome, which is diagnosed by ischemic pain at rest, ischemic ST-segment changes, and rise in cardiac enzymes. The syndrome also is characterized by a regional akinesia that more frequently affects distal myocardial regions but also is associated with hypercontractility of the remaining regions.

CLINICAL PERSPECTIVE

Precision medicine does not generally imply the creation of drugs or medical devices that are unique to a single patient. Instead, precision medicine signifies the ability to classify individuals into subpopulations that differ in their susceptibility to a particular disease, in the biology and/or prognosis of those diseases they may develop, or in their response to a specific treatment. Preventive or therapeutic interventions can then be concentrated on those who will benefit, sparing expense and side effects for those who will not. Indeed, coronary thrombosis is the final common pathway leading to ACS. More potent antithrombotic regimens have recently been found to increase the risk of major bleedings, which are associated in turn with a higher risk of mortality. Although the early outcome of ACS has considerably improved in the past decade, cardiovascular diseases still represent the main cause of morbidity and mortality overall. The rate of death, MI, and recurrent ACS at 1-year follow-up in contemporary NSTE-ACS registries is still very high, approaching about 25%.[30] Furthermore, recurrent ACS heralds a progressive impairment of myocardial function leading to chronic heart failure. Importantly, ischemic heart disease is by far the most important cause of heart failure and thus a public health problem of pandemic proportions. Thus the best prevention of heart failure is the prevention of recurrent episodes of coronary instability (Table 69.4).

CLINICAL RELEVANCE

- Different mechanisms and triggers are involved in ACS. The pathogenic classification of ACS might be a useful tool to select the best approach for different patients
- Histological studies have shown that ACS could be initiated by different types of unstable plaque
- Plaque fissure is strictly associated with systemic and coronary inflammation, with an altered cross-talk between innate and adaptive immunity leading to the unbalance between pro- and anti-inflammatory stimuli
- Plaque erosion rely on less clear mechanisms, however an inflammatory trigger might be also involved, with different triggers as compared with plaque fissure, such as hyaluronan exposure and PMN recruitment.

Plaque Fissure With Systemic Inflammation

The experience gained in the diagnosis, risk stratification, and management of chronic inflammatory diseases may provide important clues to the management of atherothrombosis. Extensive studies regarding helper T-cell subset dysregulation in ACS strongly support the notion that adaptive immunity is critically involved in the disease process. Investigating the mechanisms underlying T-cell dysregulation is pivotal to identifying new clinical biomarkers and potential therapeutic targets in the subset of ACS patients in whom a T cell–dependent inflammatory outburst is the likely cause of coronary instability. In this subset of ACS patients, raised levels of hs-CRP or of other soluble markers of inflammation are associated with a worse outcome.[4,10] A specific adaptive immune system signature proved to be more predictive than biomarkers in the identification of homogeneous subsets of patients at higher risk for acute coronary event recurrence.[16] A change of focus from soluble markers of inflammation to markers of adaptive immunity regulation, such as the molecules involved in TCR signaling, might be more rewarding.

TABLE 69.4 Pathogenical Mechanisms, Diagnosis, and Potential Tailored Therapy of Acute Coronary Syndromes

	Mechanism	Diagnosis	Potential Therapeutic Target
Plaque fissure with systemic inflammation	1. Innate immunity Early neutrophil activation Inflammatory macrophages Platelet activation (TLRs) 2. Adaptive immunity $CD4^+CD28^{null}$ T-cell expansion Treg imbalance Th17 cells B cells	Hs-CRP levels T-cell phenotyping Functional imaging	Immunosuppression (cyclosporine, tacrolimus, sirolimus, AZT, imatinib) TCR signaling regulation (synthetic CD31-derived peptide, PTPN22 inhibitor) IL-1β antagonists (anakinra, canakinumab, rilonacept) Treg expansion, anti-CD3-Ab (mice) Vaccines High-dose statins
Plaque fissure without systemic inflammation	1. Sympathetic nervous system activation 2. Changes in plaque composition	Anatomical imaging	Statins PLA_2 inhibitors Enhancement of cholesterol Efflux/impairment of foam cells formation (3-hydroxyanthranilic acid)
Plaque erosion	1. PMN producing MPO 2. Hyaluronan/CD44 interaction 3. TLR2 activation and endothelial injury 4. Acute local hemodynamic changes	MPO levels Functional imaging	Antithrombotic drugs
Functional alterations	1. Epicardial coronary spasm (enhanced Rho kinase activity) 2. Microvascular spasm	Functional tests of vasomotility Rho kinase activity	Nitrates Calcium antagonists Rho kinase inhibitors

AZT, azathioprine; Hs-CRP, high-sensitivity C-reactive protein; IL-1β, interleukin-1β; MMPs, matrix metalloproteinases; MPO, myeloperoxidase; PLA2, phospholipase A2TCR; PMN, polymorphonuclear neutrophil; PTPN22, protein tyrosine phosphatase non–receptor type 22; TCR, T-cell receptor; Th17, T-helper cell-17; TLRs, toll-like receptors.

An unmet need in this patient subset is a specific antiinflammatory treatment.[31,32] Indeed, TCR activation signaling offers several targets for immunosuppressive therapy such as cyclosporine, tacrolimus, sirolimus, azathioprine, and imatinib mesylate. These drugs prevent T-cell activation and reduce hyperreactivity of the adaptive immune system and development of autoimmunity. A synthetic CD31-derived peptide, able to engage a truncated extracellular CD31 fragment expressed by T cells that apparently lack CD31, has an immunosuppressive effect *in vivo* through restoration of the CD31 inhibitory pathway. The development of a novel series of inhibitors of PTPN22 might contribute to a better understanding of the role of this phosphatase in the immune dysregulation of ACS patients.

Another intervention target might be restoring the balance between effector T cells and Treg cells. Adoptive transfer of *ex vivo* expanded Treg might be considered. Of note, in mice anti-CD3 antibody treatment induced rapid regression of established atherosclerosis by reducing CD4 T cells and increasing the proportion of Treg.[33] Additionally, it has been shown that the tryptophan metabolite 3-hydroxyanthranilic acid has immune regulatory properties that can be used to decrease atherosclerosis in mice by regulating T cell–dependent inflammation and lowering plasma lipids. Finally, the identification of antigens that trigger adaptive immunity may open the way for specific vaccinations. Notably, strengthening antiviral immunity in at-risk patients, *e.g.*, by vaccination against influenza, has been associated with reduction in cardiovascular events, demonstrating the value of host protection through health maintenance.[34]

Plaque Fissure Without Systemic Inflammation

Clinical history of extreme emotional disturbance or intense physical exertion might help to identify this subset of patients. Anatomical (more than functional) features of the atherosclerotic plaque are important in determining coronary instability. Thus noninvasive imaging of stress-related plaque fissure might reveal a thinner cap compared with plaque fissure occurring at rest, indicating greater susceptibility to biomechanical forces. The development of micro-OCT that enables imaging of coronary artery microstructure on a scale comparable to that of histopathology might shed some new light on the role played by cholesterol crystallization. Inflammasome activation due to cholesterol crystals has been discussed as a potential mechanism.

Plaque Erosion

In plaque erosion, MPO is an important bystander and might even play a pathogenic role. Molecular imaging techniques can visualize MPO in atherosclerotic plaques in carotid arteries; these methods are more difficult, however, in coronary circulation. Elevated plasma concentration of MPO might represent an important biomarker for the identification of this subset of patients.[6] In patients with plaque erosion, the mechanism of inflammation is probably an intense local thrombogenic stimulus. Thus potent antithrombotic treatment, based perhaps on double antiaggregation and an oral anticoagulant, might be the treatment of choice, but this approach must be tested in prospective studies.

Functional Alterations of Coronary Circulation

Clinical history and 24- to 72-hr ambulatory ECG monitoring are usually sufficient to achieve the diagnosis of vasospastic angina, whereas the use of provocative tests of coronary artery spasm (*e.g.*, intravenous ergonovine, intracoronary ergonovine, or acetylcholine administration) is required in about 10% of patients. Rho kinase activity in circulating neutrophils is increased and might represent a useful biomarker for diagnosis and disease activity assessment. Although nitrates and calcium antagonists are helpful in patients with vasospastic angina, further efforts are needed to identify the molecular alterations responsible for smooth muscle cell hyperreactivity because a sizable proportion of these patients are refractory to standard doses of vasodilator.

Similarly, further efforts are warranted to identify a therapeutic target in Takotsubo syndrome.

CONCLUSION

As observed above, inflammation plays a detrimental role in the setting of ACS not only in determining plaque instability, but also in cardiac remodeling after myocardial necrosis and in PCI-related myocardial injury. The different mechanisms contributing to the inflammatory outbursts observed in ACS might need different forms of antiinflammatory treatment.

In addition to specific interventions targeting adaptive immunity in plaque fissure and systemic markers of inflammation as discussed above, IL-1 blockade might specifically address inflammation due to myocardial necrosis and prove to be useful in ventricular remodeling after myocardial necrosis, as suggested by the results of small pilot studies in STEMI patients.[31,32,34] Finally, IL-6 blockade might prevent inflammation associated with distal embolization in the setting of PCI in NSTEMI, resulting in less myocardial injury.[34]

ON THE HORIZON

Translational research is needed:

- To improve diagnostic criteria of vulnerable plaque
- To find novel predictive markers of plaque instability
- To find specific triggers linked to different types of unstable plaque
- To clarify the role of inflammation in plaque destabilization
- To evaluate alternative treatments and drug targets to prevent and treat plaque instability
    Toll-like receptor (TLR) antagonists
    Repair T-cell signaling abnormalities and CD31 signaling potentiation
    Restore Treg number and activity
    Target myeloperoxidase (MPO) in plaque erosion

MULTIPLE-CHOICE QUESTIONS

1. Indicate which of the following represents the correct timeline in the natural history of atherosclerosis:
   - **A.** Subendothelial retention of lipoproteins and flow-mediated inflammatory changes → endothelial dysfunction → self-maintaining inflammatory state → fatty streak → atheroma→ fibroatheroma
   - **B.** Fatty streak → endothelial dysfunction → self-maintaining inflammatory state → subendothelial retention of lipoproteins and flow-mediated inflammatory changes → atheroma→ fibroatheroma
   - **C.** Fibroatheroma → endothelial dysfunction → fatty streak → self-maintaining inflammatory state → subendothelial retention of lipoproteins and flow-mediated inflammatory changes → atheroma
   - **D.** Self-maintaining inflammatory state → atheroma → fibroatheroma → endothelial dysfunction → fatty streak → subendothelial retention of lipoproteins and flow-mediated inflammatory changes
2. Which of the following represents a recognized mechanism involved in plaque instability?
   - **A.** Increase in regulatory T cells (Tregs) around the plaque
   - **B.** Widespread coronary inflammation
   - **C.** Smooth muscle cells hyperreactivity
   - **D.** Metabolic disturbances
3. The mechanisms involved in plaque erosion are still poorly understood; according to recent experimental evidence, which of the following seems to be the most probable trigger involved in endothelial erosion?
   - **A.** Inflammasome activation through cholesterol crystals inside the plaque
   - **B.** Coronary artery dissection
   - **C.** Fibrous cap rupture
   - **D.** Toll-like receptor (TLR) activation, extracellular matrix and hyaluronan exposure, neutrophil recruitment

Autoimmune Thyroid Diseases

Anna L. Mitchell, Simon H.S. Pearce

Autoimmune thyroid disorders are common, and, indeed, as a group, they are the most prevalent autoimmune disorders in humans. Despite many common underlying features, such as a marked female preponderance, shared susceptibility alleles, and common autoantigens, Graves disease and autoimmune hypothyroidism have contrasting clinical characteristics. Over recent years, our knowledge about the underlying pathogenesis has increased as a result of advances in human genomics, molecular immunology, and the availability of murine models of disease. Novel therapies based on this increased understanding are now emerging.

KEY CONCEPTS

Classification of Autoimmune Thyroid Disease

Autoimmune hyperthyroidism	Graves disease
Autoimmune thyroiditis	Hashimoto thyroiditis Atrophic thyroiditis Postpartum thyroiditis

GRAVES HYPERTHYROIDISM

Graves disease (GD) is a common autoimmune condition that accounts for the majority of cases of hyperthyroidism in the developed world. Its pathogenesis is unique among the autoimmune endocrinopathies because a key feature is the presence of stimulating autoantibodies directed against the thyrotropin (thyroid-stimulating hormone [TSH]) receptor, which mimic the action of TSH, a native hormone produced in the pituitary, to drive thyroid overactivity. Interestingly, thyroid dysfunction is commonly associated with other extrathyroidal manifestations of GD, the most common being Graves ophthalmopathy (GO).

Epidemiology

GD is one of the most common autoimmune diseases, with a prevalence of approximately 1% in women in the developed world.[1] It is more common in iodine-sufficient countries, where it accounts for 60–90% of cases of hyperthyroidism.[2] GD is seven times more common in women than in men and may affect individuals at any age; however, the peak incidence occurs between the ages of 35 and 40 years.

Etiology

GD is a complex genetic condition, implying that environmental stimuli precipitate disease in genetically predisposed individuals who harbor multiple susceptibility alleles. A large Danish twin study estimated that about 80% of the propensity to develop GD is attributable to genetic factors.[3] Further evidence for the heritability of GD comes from the observation that it clusters within families. Up to one-quarter of individuals with GD have a first-degree relative with the condition or with another autoimmune thyroid disease, such as autoimmune hypothyroidism.[4] Should an individual have a sibling with GD, it is estimated that the relative risk (λ_s) of that individual developing GD is around 10, which is comparable with that of other heritable autoimmune conditions, such as type 1 diabetes, which has a λ_s of 15.

A number of genetic loci have been shown to contribute to GD susceptibility (Fig. 70.1). These genes encode proteins in biological pathways that regulate immune system activity or thyroid biology.[4,5] The major histocompatibility complex (MHC) region on chromosome 6p21 has long been associated with multiple autoimmune conditions. Human leukocyte antigen (HLA) genes found within the MHC region play a vital role in pathogen and self-peptide recognition and therefore have a clear role in immunity and in establishing and maintaining immune tolerance (Chapter 5).

In European populations, the primary association between MHC and GD is with alleles of the class II MHC genes. The HLA-DR3 allele is detected twice as frequently in subjects with GD as in healthy controls (*i.e.,* 50% of GD subjects vs 25% of controls). At the protein level, neutral amino acids alanine or glutamine are substituted for positively charged arginine at position 74 in the HLA-DR peptide-binding pocket, which is thought to alter the binding-pocket configuration, more readily allowing self-peptides to enter the antigen binding site.[5] Importantly, 50% of individuals with GD do not have the *HLA-DR3* allele, implying that there is unlikely to be a single antigenic epitope responsible for GD.

The cytotoxic T lymphocyte antigen-4 (*CTLA4)* gene (chromosome 2q33) encodes a costimulatory molecule expressed on the surface of activated T cells, which plays a pivotal role in downregulating T-cell responses and in checking T-cell activation, emphasizing the contribution of inhibitory signals in setting immune response thresholds (Chapter 18). The *CT60* single nucleotide polymorphism (SNP) downstream from the 3' untranslated region (3'UTR) was found to influence GD susceptibility (odds ratio [OR] 1.5) and has been suggested as a possible etiological variant[6]; however, the functional effects of this variant remain poorly defined and contributions from other variants, such as at codon 17 in the CTLA-4 signal peptide remain likely. About 50% of individuals from healthy European populations carry the autoimmune "susceptible" *CTLA4* haplotype; therefore other important factors are clearly at play. CTLA-4

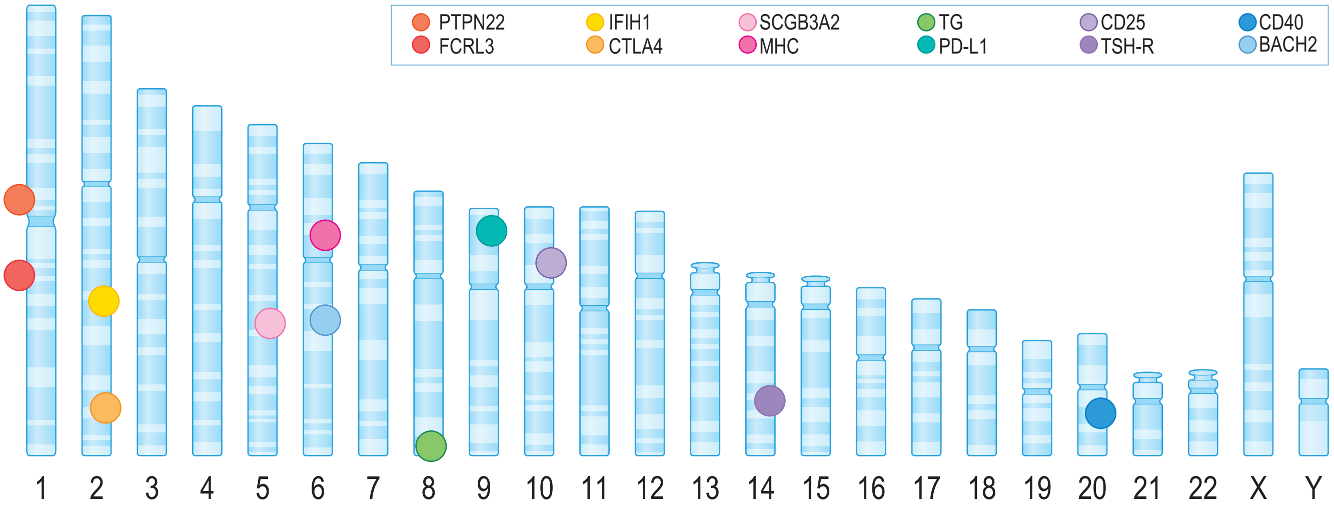

FIG 70.1 Schematic diagram to illustrate the loci that have been associated with Graves disease to date. Each locus is shown on its respective chromosome, with chromosome 1 depicted on the left and chromosome Y on the right.

polymorphisms also contribute to susceptibility to type 1 diabetes, autoimmune adrenal insufficiency, celiac disease, and several other autoimmune conditions.

The protein tyrosine phosphatase, non–receptor type 22 (*PTPN22)* gene on chromosome 1p13 encodes the lymphoid tyrosine phosphatase (LYP) molecule, which, like CTLA-4, is involved in the regulation of T-cell activation. In GD, a coding variant (R620W) was found more frequently in Caucasians with GD than in controls (13 vs 7% respectively, OR 1.8).[7] This variant results in a short-lived protein product, which is believed to alter T-cell receptor signaling compared with the wild-type protein. The PTPN22*620 W variant is very rare in non-Caucasian populations, but different *PTPN22* alleles have been associated with autoimmunity in Asian cohorts.

Products of several other genes involved in immunoregulation have been demonstrated to have allelic variants associated with GD, including CD25, CD40, PD-L1, IFIH1, BACH2, SCGB3A2, and FCRL3. In addition to these variants in immune regulatory pathways, loci specific to GD have been identified on the basis of known thyroid pathophysiology. The gene encoding the TSH receptor (TSH-R) on chromosome 14q31 is an obvious candidate for GD, as the TSH-R is directly stimulated by autoantibodies in affected individuals. Although initial studies reported conflicting results, a definite association between a number of SNPs in intron 1 of the *TSHR* gene and GD has now been confirmed in Caucasians.[5] The mechanism by which these intronic SNPs confer disease susceptibility is unknown. Another GD candidate is the *thyroglobulin* (*TG*) gene (8q24). This encodes the thyroglobulin Tg protein, the precursor for the thyroid hormones triiodothyronine (T_3) and thyroxine (T_4). SNPs in the *TG* gene have been associated with GD in some Caucasian cohorts, and an epistatic interaction between a SNP in *TG* exon 33 and HLA-DR has been suggested. This interesting interaction has raised the possibility that Tg polymorphisms predispose to GD by modulating Tg peptide presentation by antigen-presenting cells on HLA class II molecules to T cells.

Despite years of research into the genetic etiology of GD, 30–40% of the inherited susceptibility has yet to be accounted for. This "hidden" heredity is a common theme in genetically complex traits, but it is likely to be owing to rare genomic variants, polymorphisms in regulatory DNA sequences, including noncoding or microRNAs (miRNAs), and/or epigenetic factors.

GD is one of the few autoimmune conditions for which links to environmental factors have been definitively established.[8] Iodine is one of the most common precipitants of thyroid dysfunction. With regard to GD, more cases are observed in iodine-sufficient areas. A study of individuals in Iceland, where iodine intake is high, and age-matched individuals in East Jutland, Denmark, where iodine intake is low, showed that the incidence of GD was more than double in the higher iodine environment.[2]

Cigarette smoking also influences GD susceptibility and severity, in particular of GO. Meta-analysis of eight studies showed the OR for developing GD was 3.3 for current smokers compared with that for lifelong nonsmokers.[9] The same study also revealed that current smokers are more likely to develop GO compared with nonsmokers (OR 4.4). The mechanism for this interaction remains to be fully elucidated; however, cigarette smoke extract has been shown, *in vitro,* to stimulate adipogenesis and glycosaminoglycans (GAGs) production by orbital fibroblasts, which accumulate in the orbital tissues in GO.[10]

Stress appears to influence both GD disease onset and clinical course. In one study, individuals with GD retrospectively reported more negative life events in the preceding year compared with matched controls.[11] This finding is replicated even when a group of "nonautoimmune" individuals with hyperthyroidism are used as controls, suggesting that stress is truly a precipitant for autoimmune GD.[12]

Changes in immune system function appear to influence the onset of GD. During pregnancy, which is a relatively immunosuppressed state, hyperthyroid GD is often mild and can be managed with smaller doses of antithyroid drugs. In some cases, it remits entirely, allowing the individual to stop medication in the short term. However, in the postpartum period, when the immune system normalizes, there is typically worsening or relapse of GD. A similar phenomenon is seen in individuals who have been significantly immunosuppressed and then have recovered. For example, new-onset GD has been reported in people who have been successfully treated with highly active antiretroviral therapy (HAART) for human immunodeficiency virus (HIV) infection. During treatment, as the immune system recovers, immune

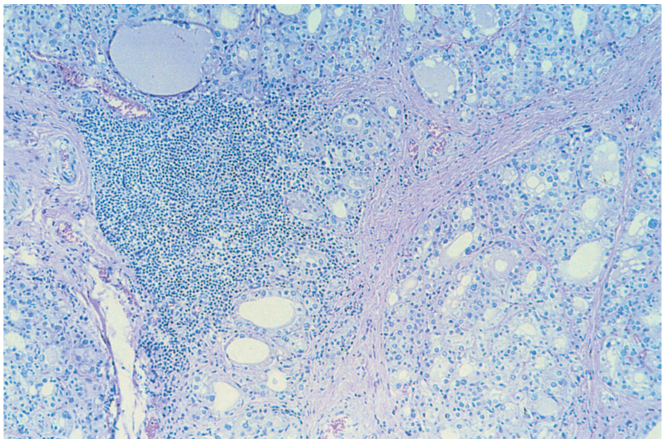

FIG 70.2 Diffuse lymphocyte infiltrate and thyrocyte hyperplasia in a patient with Graves disease.

activation increases. T cells are exposed to thyroid antigens, resulting in an autoimmune response at the time of immune reconstitution.[13] A similar phenomenon has been seen in individuals with multiple sclerosis (MS) treated with alemtuzumab, the lymphocyte-depleting anti-CD52 antibody. An alternative explanation is the weakening of physiological antiinflammatory pathways, which unleashes the immune system. As more novel biological agents become available, this phenomenon is likely to become more common.

KEY CONCEPTS

Environmental Factors Known to Influence Graves Disease Susceptibility

- Smoking
- Iodine
- Stress
- Immune system reconstitution states
    - Post-partum state
    - Successful treatment of human immunodeficiency virus (HIV) with highly active antiretroviral therapy (HAART)
    - T-cell depletion therapy (*e.g.*, alemtuzumab)
- Infections (*e.g.*, hepatitis C)

Immunopathogenesis

Histologically, the thyroid in GD is characterized by a diffuse lymphocytic infiltrate, consisting of both T and B cells, associated with thyrocyte hyperplasia (Fig. 70.2). Although T cells play a major role in inflammatory cell recruitment, cytokine secretion, antigen recognition, and thyrocyte damage, infiltrating B cells also produce antibodies, including those that drive hyperthyroidism. The major autoantigens in GD are the TSH-R, the thyroid peroxidase (TPO) enzyme, and Tg. More than 95% of patients with GD have detectable circulating TSH-R autoantibodies,[14] which are necessary for hyperthyroidism, and approximately 90% have detectable TPO autoantibodies.[15] Antibodies directed against the sodium iodide symporter and the apical iodide transporter, pendrin, have been reported in smaller numbers of patients.[15]

GD is unique among autoimmune conditions in that the TSH-R autoantibodies directly stimulate thyroid gland activity. This is exemplified by neonatal GD, where maternal TSH-R autoantibodies cross the placenta, resulting in transient hyperthyroidism in the newborn. However, although TSH-R autoantibodies are sufficient to result in transient hyperthyroidism in these infants, these autoantibodies are not sufficient, *per se*, to result in the persistent thyroid autoreactivity of true GD. TSH-R antibodies are classically immunoglobulin G1 (IgG1) subclass and target an epitope in the aminoterminal region of the leucine-rich repeat motif in the extracellular domain of the TSH-R (Fig. 70.3).[16] When the autoantibody binds to the TSH-R, this activates intracellular G proteins, which, in turn, induce transcription of genes, such as *TPO* and *TG*, via the cyclic adenosine monophosphate (c-AMP) and phospholipase-C pathways. This results in thyrocyte hyperplasia and increased thyroid hormone synthesis. The TSH-R antibody–induced expression of TPO and Tg, which are also thyroid antigens, may be a mechanism for disease perpetuation. TSH-R autoantibodies can also be “blocking” in nature and prevent receptor activation. This can result in hypothyroidism. These two types of autoantibodies can also coexist, resulting in fluctuating thyroid function. Thus although it is common to equate GD with hyperthyroidism, individuals with GD may occasionally be hypothyroid or euthyroid (presenting with GO).

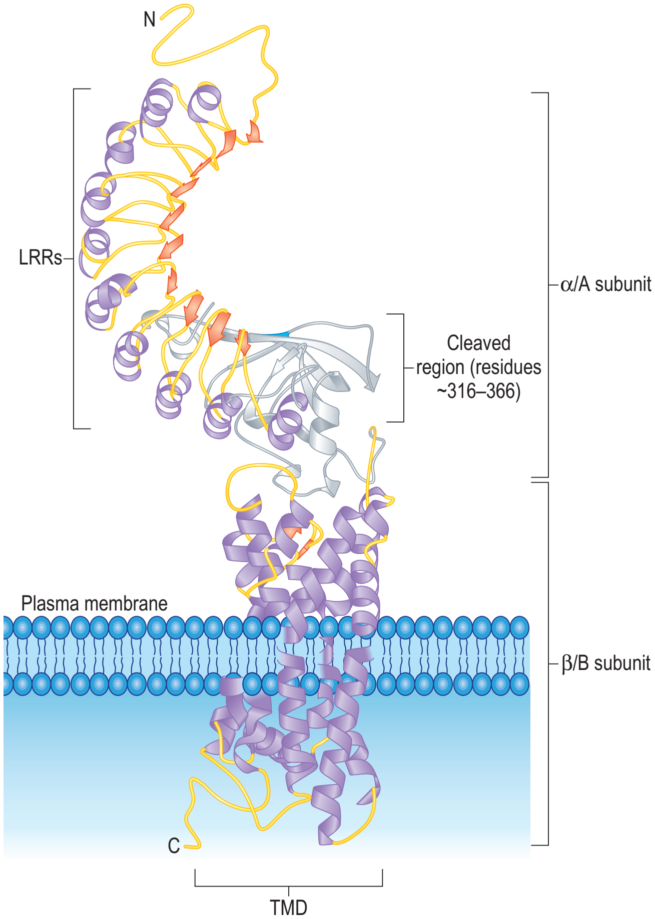

FIG 70.3 Structure of the thyroid-stimulating hormone receptor (TSH-R). (Courtesy of R. Latif; adapted from Davies TF, Ando T, Lin RY, et al. Thyrotropin receptor-associated diseases: from adenomata to Graves’ disease. J Clin Invest 2005;115: 1972–83.)

TPO antibodies can be of IgG subclass 1, 2, or 4 and typically circulate in concentrations 1000-fold higher than those of TSH-R antibodies. They are directed against two structurally complex regions of the TPO molecule, the epitopes involving residues from both the myeloperoxidase-like and the complement control protein-like domains. TPO antibodies may have pathogenic significance in that they can fix complement and target the thyrocyte for cell-mediated cytotoxicity.[17] In contrast to TSH-R antibodies, they do not appear to either stimulate or block the enzymatic activity of TPO.

Clinical Presentation

Hyperthyroid GD can present with manifestations affecting almost any organ system in the body, and as with many endocrine conditions, affected individuals may report a gradual onset of nonspecific symptoms, typically over a period of months. This often leads to a delay in seeking medical attention and in the initial diagnosis being made. The signs and symptoms of GD can be divided into those associated with hyperthyroidism in general and those specific to GD. These are summarized in Table 70.1.

TABLE 70.1 Common and Rarer Clinical Manifestations of Hyperthyroidism

Common	Rare
Neuropsychiatric	
Anxiety	Chorea
Fatigue and exhaustion	Collapse (periodic paralysis)
Fine tremor	Pseudobulbar palsy
Restlessness and fidgeting	Spasticity
Gastrointestinal	
Increased appetite	Hepatosplenomegaly
Loose stools	
Increased frequency of defecation	
Nausea	
Weight loss	
Cardiorespiratory	
Palpitations	Congestive cardiac failure
Shortness of breath on exertion	
Tachycardia (sinus, atrial fibrillation)	
Peripheral vasodilation, flushing	
Systolic hypertension	
Genitourinary	
Menstrual irregularities	
Cutaneous	
Itch	Thyroid acropachy
Heat intolerance	Pretibial myxedema
Hair loss	Onycholysis
Musculoskeletal	
Hyperreflexia	
Proximal muscle weakness	
Ophthalmic	
Lid lag	Optic neuropathy
Lid retraction	
Exophthalmos and proptosis	
Eye dryness	
Chemosis	
Ophthalmoplegia	
Miscellaneous	
Thirst	
Thyroid bruit	

CLINICAL PEARLS

Clinical Signs Specific to Graves Disease

- Graves orbitopathy
- Thyroid bruit
- Thyroid acropachy
- Pretibial myxedema

Investigation and Diagnosis of GD

The diagnosis of GD is a clinical one, supported by laboratory investigations. Imaging is occasionally required if the diagnosis is in doubt. Thyrotoxicosis is diagnosed biochemically on the basis of an elevated serum free T_3 (fT_3) or free T_4 (fT_4) in the presence of a completely suppressed TSH. If thyrotoxicosis is found in a patient with extrathyroidal signs, such as GO or pretibial myxedema, the diagnosis of hyperthyroid GD is clear and further investigations are not required. If no extrathyroidal signs are present, the presence of serum autoantibodies should be sought. TSH-R antibodies are highly sensitive for GD, and assays are now available in many laboratories. The TSH-binding inhibitory immunoglobulin (TBII) assay is also commonly used, which is an indirect means of detecting TSH-stimulating antibodies. TPO antibodies are often measured as a surrogate for thyroid autoimmunity, as the presence of either TSH-R antibodies or TPO antibodies has more than 90% sensitivity for GD.

Imaging is reserved for individuals in whom the diagnosis is not clear. Radionuclide scanning, for example, ^{99}Tc or ^{123}I, is favored over ultrasonography, as the former gives functional information on the activity of the thyroid gland, although Doppler flow studies are making ultrasound evaluation of the thyroid increasingly informative (Fig. 70.4). In GD, there is diffuse uptake in the thyroid gland on radionuclide scanning.

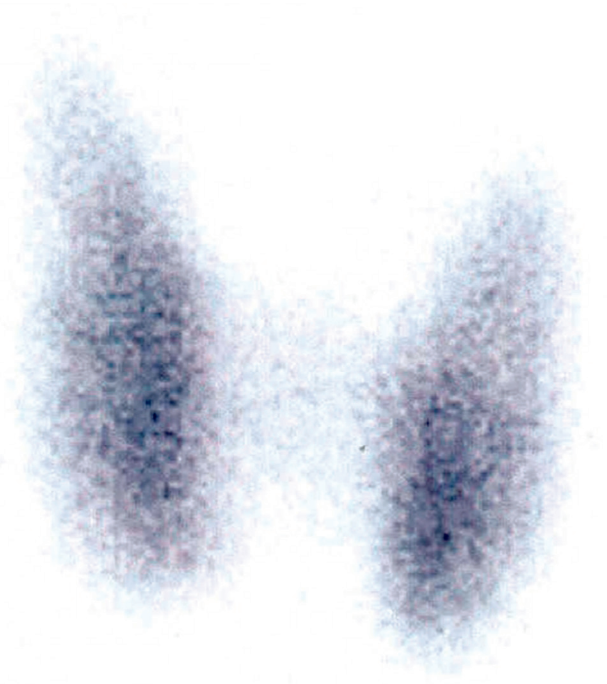

FIG 70.4 ^{99}Tc pertechnetate radionuclide scan image from an individual with Graves disease showing diffuse uptake throughout the thyroid gland.

Management of GD

The management of hyperthyroid GD can be divided into three broad categories: medical management, radioiodine (RAI) treatment, and surgery.[18]

Medical Management—Antithyroid Drugs

The thionamide drugs (carbimazole, its metabolite methimazole, and propylthiouracil) compete with Tg to act as substrates for iodination by TPO. Once iodinated, they are metabolized peripherally, depleting thyroid iodine stores. When the thyroid iodine stores are depleted and the intrathyroidal thionamide concentration is high enough, thyroid hormone synthesis is abrogated. Most individuals become euthyroid following 4–8 weeks of treatment; however, euthyroidism may take longer to achieve in those with poor medication compliance or with a history of recent iodide exposure. Following initial treatment, thionamides may either be administered as a fixed high dose, with levothyroxine supplementation to prevent hypothyroidism (known as a "block and replace" regimen), or at progressively lower doses, titrated to allow adequate thyroid hormone generation. Following 6–18 months of thionamide treatment, about 50% of patients will remain in remission following cessation of therapy. There is no improvement in remission rate in individuals with GD who are treated for longer than 18 months. The mechanism of the thionamide-induced remission in GD remains obscure; however, the lymphocytic infiltrate in the GD thyroid is rapidly abolished by thionamide treatment, and serum TSH-R and TPO autoantibodies also decrease during treatment, suggesting an immunomodulatory effect. It is telling that several induced murine models of thyroiditis can be ameliorated by thionamide treatment, suggesting an immunomodulatory role that is distinct from the antithyroid hormone synthesis action. If the patient's disease relapses following medical treatment, definitive treatment should be considered, as a second course of thionamide treatment rarely induces prolonged remission.

Definitive Treatment

Radioactive iodine (RAI) therapy (^{131}I) and surgical thyroidectomy are both efficacious treatments for GD, effectively removing functional thyroid tissue and rendering the patient hypothyroid and dependent on levothyroxine replacement over the long term. RAI therapy takes advantage of the thyroid's ability to concentrate iodine. RAI is administered orally and concentrates in the thyroid, primarily emitting beta-radiation to produce local thyrocyte DNA damage. These cells then undergo necrotic change, and the thyroid atrophies over the subsequent year. RAI renders more than 80% of those with GD hypothyroid and needing long-term thyroid hormone replacement. RAI is generally well tolerated, and long-term follow-up studies in adults have shown reassuring results with regard to carcinogenicity. RAI is absolutely contraindicated in pregnancy and is best avoided in those with active, inflammatory GO. Total or near-total thyroidectomy is also an effective treatment for GD and is particularly suitable for individuals with a large goiter, those with severe hyperthyroidism who cannot tolerate thionamides, or in those with active GO when RAI is relatively contraindicated. The complications of thyroidectomy include change in voice because of intraoperative damage to the recurrent laryngeal nerve and hypocalcemia (often transient) caused by parathyroid gland damage.

GRAVES OPHTHALMOPATHY

Epidemiology

GO is the most common extrathyroidal manifestation of GD. It is clinically apparent in 25–50% of those presenting with GD, although almost all patients have radiological changes consistent with GO to some degree. The peak age of incidence is in the fifth and seventh decades of life. GO precedes thyroid gland dysfunction in about 20% of patients, arises at the same time in 40%, and occurs after diagnosis of thyroid dysfunction in the remaining 40%. Males, older adults, and smokers are more likely to have severe disease. Ninety-three percent of cases of GO occur in those with hyperthyroid GD. However, 3% and 4% of GO occurs in hypothyroid and euthyroid patients, respectively. A proportion of these patients with "euthyroid Graves" will eventually become hyperthyroid; however, some will remain hypothyroid or euthyroid despite the presence of TSH-R antibodies.

Etiology

GO shares many etiological factors with GD. Smoking is the major environmental risk factor for GO, with smokers or ex-smokers four times more likely to develop GO compared with lifelong nonsmokers. The number of cigarettes smoked per day correlates with the risk of developing GO, suggesting a "dose-dependent" effect. RAI therapy is also known to occasionally cause flare-ups of GO. This is thought to be largely related to uncontrolled post-RAI hypothyroidism. Smokers and those with active GO seem particularly susceptible to this complication, and therefore RAI is relatively contraindicated in patients with active GO.[19]

Immunopathogenesis

The molecular mechanism that links thyroid dysfunction with GO remains incompletely understood. The TSH-R is widely believed to be the primary autoantigen linking the thyroid and the orbit. Orbital fibroblasts (OFs) have been shown to express cell-surface TSH-R, and these are thought to be functional because of the observation that TSH stimulation *in vitro* results in an increase in intracellular cAMP. Mechanistically, the orbital changes that occur in GO are better understood. TSH-R autoantibodies that bind to the TSH-R on OFs (or possibly other OF receptors, such as the insulin-like growth factor receptor; IGF-1R) are believed to activate OFs to secrete cytokines and chemokines, which attract lymphocytes and other inflammatory cells. These infiltrate the orbital tissues, augmenting further the proinflammatory cytokine environment, causing OFs to proliferate and to secrete excessive GAGs.[20] GAGs accumulate in the extraocular muscles, increasing their size. These matrix molecules are also osmotically active, resulting in edema and swelling of surrounding tissues. In addition, the adaptive arm of the immune system is thought to interact via HLA and CD40 molecules expressed by the OFs to increase the presentation of autoantigens, thus perpetuating the cycle. OFs are also thought to differentiate into adipocytes, resulting in increased retroorbital fat deposition. The resulting inflammation gives rise to redness and edema of the orbital tissues, with the cellular proliferation and GAG accumulation producing proptosis (protrusion of the eyeball from the socket), increased intraorbital pressure, and restriction of extraocular eye movements.[20]

Diagnosis and Clinical Presentation

When the clinical signs of GO are associated with thyroid dysfunction and/or circulating thyroid autoantibodies, the diagnosis is

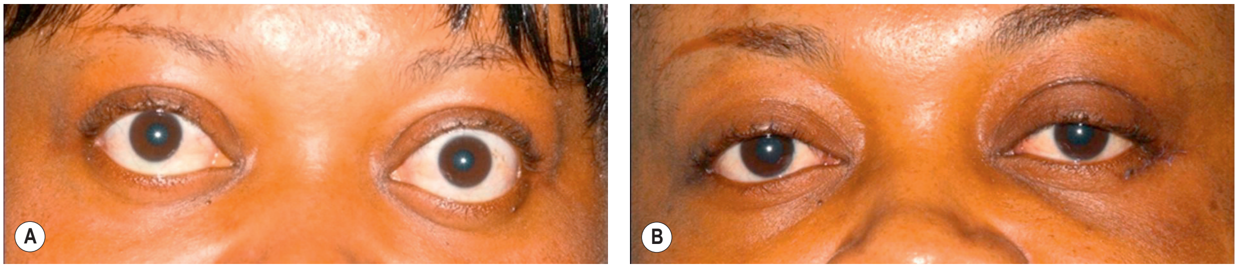

FIG 70.5 (A) Clinical photograph of the eyes of an individual with Graves ophthalmopathy prior to treatment. (B) Clinical photograph of the same patient's eyes following surgical orbital decompression and rehabilitative surgery.

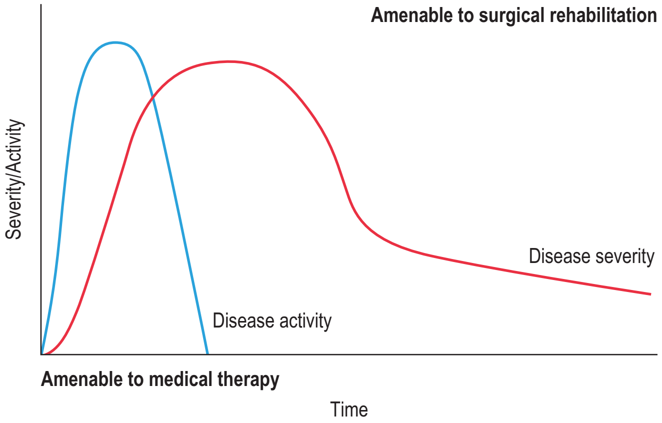

FIG 70.6 Rundle curve illustrating the natural history of Graves ophthalmopathy.

TABLE 70.2 Assessment of Graves Ophthalmopathy (GO)

A: The "NO SPECS" Classification System to Assess the Severity of GO

Class 0—No signs or symptoms
Class 1—Only signs (limited to upper lid retraction and stare, with or without lid lag)
Class 2—Soft tissue involvement (edema of conjunctivae and lids, conjunctival injection, etc.)
Class 3—Proptosis
Class 4—Extraocular muscle involvement (usually with diplopia)
Class 5—Corneal involvement (primarily due to lagophthalmos, the inability to completely close the eyelids)
Class 6—Sight loss (caused by optic nerve involvement)

B: The Clinical Activity Score (CAS) to Assess Activity of GO

A single point is scored for each of the features present. Each feature has equal weighting. A higher score indicates more active disease.

1. Spontaneous orbital pain
2. Gaze evoked orbital pain
3. Eyelid swelling that is attributed to active GO
4. Eyelid erythema
5. Conjunctival redness that is considered to be due to active GO
6. Chemosis
7. Inflammation of caruncle or plica
8. Increase of >2 mm in proptosis
9. Decrease of >8 degrees in uniocular ocular excursion in any one direction
10. Decrease of acuity equivalent to 1 Snellen line

generally straightforward. If proptosis is completely unilateral, or GO features occur without upper lid retraction, then the diagnosis needs to be confirmed by imaging, as the differential diagnosis for unilateral proptosis is a space-occupying retroorbital lesion. The patient with GO may complain of gritty, watery, or uncomfortable eyes, with or without a change in appearance (upper eyelid retraction, soft tissue swelling, redness of the eyes, and proptosis) (Fig. 70.5). Diplopia occurs if eye movements are restricted by stiffness of the extraocular muscles or high intraorbital pressure. Deteriorating visual acuity and color desaturation are sinister symptoms in GO, indicating incipient optic neuropathy.

GO has a predictable and generally monophasic natural history (Fig. 70.6). There is an early phase of increasing disease activity that can be targeted by medical therapy, and it is followed by a plateau phase and then gradual improvement until a stable, inactive phase is reached. GO manifestations can be classified in two ways: on the basis of severity, which indicates the extent of functional, anatomical, and cosmetic features; and on the basis of activity, which denotes the intensity of any acute inflammatory reaction. Severity of GO is assessed using the "NO SPECS" classification system (Table 70.2, panel A) and activity is assessed using the clinical activity score (CAS) (see Table 70.2, panel B). A CAS of 3 or more indicates active GO.[19] These classifications allow determination of which patients require treatment and which therapy is most appropriate.

Treatment

Patients with GD (with and without GO) should be strongly encouraged to stop smoking and offered smoking cessation support. The general health benefits of smoking cessation are numerous; in addition, smokers are more likely to relapse after a course of medical therapy compared with nonsmokers.

In parallel to restoring and maintaining euthyroidism, the successful treatment of GO depends on staging the activity and severity of the disease. In patients with mild, active GO, an observational policy can be employed with symptomatic measures, such as artificial tears and dark glasses. Selenium supplements, at a dose of 100 μg twice daily for 6 months, have been shown to significantly improve quality of life, slow disease progression, and reduce ocular involvement in these patients.[21] In those with moderate to severe, active, and progressive GO, a course of oral or intravenous (IV) glucocorticoids (steroids) is indicated. Orbital radiotherapy is also efficacious in people with active inflammation and diplopia, but since it has a delayed onset of action, it often needs to be used in conjunction with other therapies, such as steroids or orbital decompression surgery. In patients with sight-threatening optic neuropathy, high-dose IV steroids are used, and orbital pressure is relieved by urgent orbital decompression surgery. In patients whose eyelids do not close completely, eye ointments and protective eye pads are essential to protect the eyes against corneal damage and ulceration. Once disease activity has burned out, rehabilitative surgery can greatly improve the function and cosmetic appearance of the eyes. Orbital decompression, strabismus correction, and eyelid surgery are commonly used procedures.[22]

FUTURE DEVELOPMENTS FOR GRAVES HYPERTHYROIDISM AND OPHTHALMOPATHY

Novel approaches to modulating the immune response in GD and GO as a therapeutic strategy are under investigation. In light of the significant side effects associated with steroid therapy for GO, steroid-sparing agents, including methotrexate and mycophenolate mofetil, are of particular interest. Novel biological agents have been evaluated to a limited extent in these conditions and are subject to further ongoing studies.[23] Rituximab, a CD20 monoclonal antibody (mAb) that depletes circulating B cells, appeared to be potentially efficacious in early studies; however, in two randomized controlled trials in individuals with moderate to severe active GO, results have been conflicting, and therefore further studies are now needed. A longer-term goal is the development of an anti–TSH-R antibody or small molecule antagonist that could block binding of stimulatory TSH-R antibodies or inhibit TSH-R signaling, thus ameliorating the cause of hyperthyroidism.

AUTOIMMUNE HYPOTHYROIDISM

The most common cause of autoimmune hypothyroidism (AH) is chronic (or lymphocytic) autoimmune thyroiditis. There are two variants, atrophic and goitrous (Hashimoto thyroiditis).

Epidemiology

In populations living in iodine sufficient areas, AH is common, affecting between 1 and 10% of the population. The prevalence increases with age, with 3–20% of individuals over 75 years of age being hypothyroid. Like GD, AH is more common in women than in men. In a UK community survey, the incidence of hypothyroidism in women was 3.5/1000/year, which increased to 13.7/1000/year in women between 75 and 80 years of age. In men, the incidence was just 0.6/1000/year.[24]

Etiology

AH, like GD, is a complex genetic condition. Familial clustering provides evidence for a genetic etiology, which, in several studies, appears stronger than that for GD. The λs for AH is estimated to be between 10 and 45, suggesting that AH is more heritable compared with GD. In families with autoimmunity, frequently a mixture of individuals affected by AH and GD are seen, suggesting some shared genetic factors. The differing prevalence of AH in different ethnic groups, with AH being more common in Caucasian than in black populations, also supports a genetic background. Knowledge about the genetics of AH is limited.

The MHC class II *HLA-DR3, -DR4,* and *-DR5* alleles have been associated with AH in Caucasians only. Conflicting results have been reported for *HLA-DQ* alleles. One study reported that the *HLA-DQ* alleles *DQA1*0301* and *DQB1*0201* confer susceptibility to AH in Caucasians, with certain *HLA-DQ* alleles (*DQA1*0102* and *DQB1*0602*) reported to confer a protective effect. These data highlight the need to further investigate the MHC region to clarify its role in AH susceptibility.

In common with GD, the *CTLA-4* gene also appears to influence AH susceptibility. Three *CTLA-4* polymorphisms have been associated with AH in a number of populations. An A/G SNP located downstream of the 3’UTR (designated CT60), an A/G polymorphism at codon 17, and a 106-bp microsatellite repeat in the 3’UTR of exon 3. A locus on chromosome 8q24 containing the thyroglobulin gene was linked to AH, and a number of SNPs were subsequently studied in AH individuals with modest reported ORs for association of between 1.32 and 1.56. Other loci implicated in AH susceptibility include the tumor necrosis factor (*TNF-α*) gene, *PTPN22, CYP27B1,* T-cell receptor (TCR) genes, and several immunoglobulin genes and cytokine regulatory genes.

In contrast to GD, environmental factors in AH susceptibility have been challenging to identify. However, the role of iodine is widely accepted, since population studies have reported an increase in the prevalence of thyroid lymphocytic infiltration and autoantibodies following public health salt iodization programs. Infectious agents have also been implicated in susceptibility to AH. Several studies have identified an increased prevalence of IgG and/or IgA antibodies to virulence-associated outer membrane proteins of *Yersinia enterocolitica* in AH patients and in relatives of individuals with AH, suggesting that susceptibility genes for *Yersinia* infection may also confer risk for AH.

The effect of radiation, either “internal” (nuclear “fallout” or from RAI treatment) or “external” (radiotherapy or direct exposure during a nuclear accident), on AH susceptibility has been extensively studied. Following the nuclear reactor accident at Chernobyl, a rise in thyroid autoantibodies was noted 15 years following exposure; however, this was not accompanied by thyroid dysfunction.[25] Long-term follow-up studies of thyroid function in Japanese survivors of the atomic bombing of Nagasaki and Hiroshima have demonstrated a clear link between radiation exposure and thyroid cancer; however, the association with AH remains disputed. One study, at 40 years follow-up, demonstrated a significant relationship between dose of radiation exposure at Nagasaki and AH. However, a further study, at more than 50 years of follow-up, showed that radiation exposure did not correlate with either the occurrence of thyroid autoantibodies or AH.[26]

Immunopathogenesis

The mechanisms by which tolerance to thyroid antigens is lost in the first instance remain obscure. It appears that both a susceptible genetic background and a permissive environment are required before AH develops. Notably, AH is much more frequent in the autoimmune polyendocrinopathy type 1 (APECED) syndrome than GD, suggesting that central thymic T-cell selection, and therefore central tolerance, may be more important in AH than in GD. Histologically, lymphocytic infiltrates can be seen in the thyroid, consisting of both T and B cells (Fig. 70.7). These infiltrates can be diffuse or focal. Scarring and fibrosis may also be seen, with destruction of the normal thyroid architecture and an absence of colloid in thyroid follicles.

Both cell-mediated and humoral immune mechanisms are important in the continuing thyroid damage seen in AH. T cells are known to play a pivotal role in both the initiation and perpetuation of AH. Studies in which researchers induced hypothyroidism in Rag1-deficient transgenic mice that were unable to produce autoantibodies confirm this.[27] T cells respond to antigen-presenting

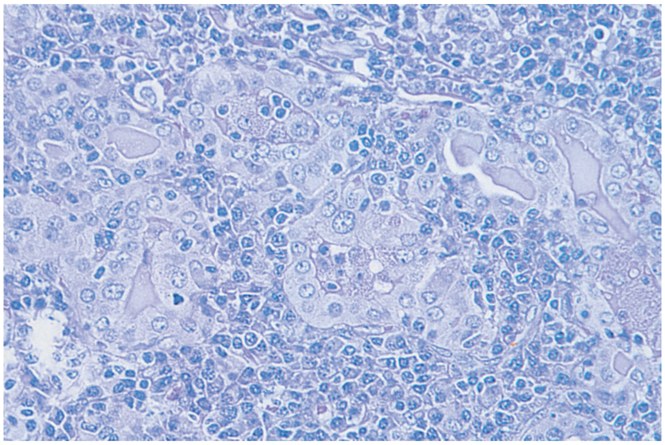

FIG 70.7 Lymphocytic infiltration of the thyroid in a patient with autoimmune hypothyroidism.

cells (APCs) and release cytotoxic and lytic factors, which result in thyrocyte death. Thyroid follicular cells have themselves been demonstrated to express HLA class II molecules, suggesting that they may also have a direct role in antigen presentation.

The humoral immune response is also important in AH. More than 90% of individuals with AH have detectable TPO antibodies. Autoantibodies directed against Tg and, to a lesser degree, the TSH-R are also commonly detected. *In vitro,* TPO antibodies can fix complement and directly induce cell damage.[17] Their presence within thyroid follicles in AH patients suggests they may have the same effect *in vivo,* although the thyrocyte destruction found in the *Rag1*-deficient mouse suggests TPO antibodies are not necessary for AH. Interestingly, the epitopes toward which TPO antibodies are directed in both GD and AH overlap, and there is no disease specificity for the targeted TPO domain.[17] TSH-R autoantibodies found in rare patients with AH are likely to exert a blocking or antagonist effect, thus inducing hypothyroidism. As thyroid hormone secretion falls, increasing thyrocyte stimulation by elevation of serum TSH may induce or augment thyroid autoantigen expression (*e.g.*, TPO, Tg), thereby perpetuating the autoimmune response.

Clinical Presentation

Hypothyroidism can result in changes in almost every organ system in the body (Table 70.3). Initially, the signs and symptoms may be subtle and nonspecific, including tiredness, cold sensitivity, and constipation. Hypothyroidism is frequently diagnosed incidentally following blood tests for another problem. The typical goiter palpable in Hashimoto thyroiditis is moderate in size and firm with a finely granular surface. Individuals often report a gradual increase in size over a number of years. However, rapid growth is unusual. In atrophic AH, the size of the thyroid gland is reduced.

Investigation and Diagnosis

Hypothyroidism is detected biochemically by a raised serum TSH with reduced fT_4. AH is differentiated from other forms of hypothyroidism by the presence of circulating autoantibodies, including TPO and Tg. On ultrasound scanning, the thyroid gland appears finely heterogeneous and hypoechoic, a change that predates serum autoantibody positivity in some. Fine-needle aspiration (FNA) demonstrates lymphocytes and Hürthle cells, but this investigation is generally only indicated if a discrete nodule is present.

TABLE 70.3 Common and Rare Clinical Manifestations of Hypothyroidism

Common	Rare
Neuropsychiatric	
Lethargy	Cerebellar ataxia
Impaired cognitive function	Deafness
Slow speech	Psychosis
Depression	
Gastrointestinal	
Anorexia	Ascites
Weight gain	
Constipation and bloating	
Abnormal liver function tests	
Cardiorespiratory	
Shortness of breath on exertion	Pericardial effusion
Reduced exercise tolerance	
Bradycardia	
Diastolic hypertension	
Cardiomegaly	
Low-voltage electrocardiogram	
Peripheral edema (nonpitting)	
Genitourinary	
Oligomenorrhea, amenorrhea, menorrhagia	
Reduced libido	
Early fetal loss	
Impotence	
Cutaneous	
Cold intolerance	
Skin dryness and thickening	
Malar flush	
Edema of the face, hands, and feet	
Change in face shape	
Pallor	
Nail abnormalities	
Alopecia	
Musculoskeletal	
Bradykinesia	
Joint and muscular pains	
Delayed relaxation of tendon reflexes	
Miscellaneous	
Goiter (in Hashimoto thyroiditis)	
Reduced basal metabolic rate	
Increased sensitivity to exogenous insulin	
Abnormal lipid metabolism	

Reflecting the effects of hypothyroidism on multiple organ systems, many biochemical and hematological abnormalities, such as mild anemia, hyponatremia, or elevated serum creatine kinase, transaminases, lactate dehydrogenase, and low-density lipoprotein (LDL) cholesterol, are also commonly detected in patients with AH.

Management

AH requires lifelong treatment with thyroid hormone replacement therapy. The most commonly prescribed is synthetic thyroxine, levothyroxine (L-T_4), which is widely available and inexpensive.

Except for individuals with known heart disease or the very old, a full, weight-related replacement dose (≈1.6 μg/kg/day) should be started. Once the patient is on a stable dose, thyroid function should be assessed annually to ensure that the patient continues to receive the appropriate dose. Some commonly prescribed medications, such as calcium and iron supplements, and proton pump inhibitors interfere with the absorption of L-T_4, and patients should be advised to take these at least 4 hours before or after their L-T_4 to ensure maximum absorption.

Subclinical Hypothyroidism

Although the need to treat individuals with overt AH is universally accepted, it is unclear whether thyroid hormone replacement is beneficial in individuals with persistent subclinical hypothyroidism (serum TSH raised, but fT_4 and fT_3 within the normal reference range on at least two separate occasions). Progression to overt hypothyroidism from this state occurs in about 2% of individuals per year who are TPO antibody negative, rising to 5% per year if antibodies are present. Persistent subclinical hypothyroidism has been associated with a number of markers of cardiac and vascular dysfunction in observational studies, including left ventricular diastolic dysfunction, increased vascular resistance, and atherosclerosis. A randomized controlled study is now underway to determine whether thyroid hormone replacement can be used to improve cardiovascular outcomes in patients with persistent subclinical hypothyroidism.[28]

CLINICAL PEARLS

Management of Persistent Subclinical Hypothyroidism

- If thyroid-stimulating hormone (TSH) is elevated, immediate treatment should be offered:
  - In pregnancy
  - Preconception, if planning a pregnancy
- If TSH is elevated but <10 mIU/L, a trial of treatment can be offered:
  - To individuals with convincing symptoms of hypothyroidism
- If TSH is >10 mIU/L, treatment should be offered:
  - To individuals under the age of 70 years
  - To individuals over the age of 70 years if there is a clear history of hypothyroid symptoms or there are significant risk factors for cardiovascular disease.

FUTURE DEVELOPMENTS

The genetics of AH remain understudied considering its frequency as the commonest autoimmune disease in humans. Considerable work remains to be done on whether treatment of subclinical hypothyroidism is beneficial. Given the insidious nature of the development of AH, it remains a good target for a preventative immunotherapeutic intervention, if a safe and economic treatment can be found.

OTHER FORMS OF THYROIDITIS

The term *thyroiditis* relates to conditions resulting in inflammation of the thyroid gland. A number of etiologies have been described, including infection, radiation exposure, drugs, and autoimmune factors. A common pattern to the natural history of several thyroiditides is frequently seen, involving an initial thyrotoxic phase of 1–3 months, followed by a rapid drop in serum thyroid hormones and a transient hypothyroid phase, often lasting another 1–4 months. During the thyrotoxic phase, preformed thyroid hormone stores are released from the thyroid follicles, leading to thyrotoxicosis, which may be severe. The hypothyroid phase follows when these preformed stores are exhausted and the thyroid has become depleted of hormones. In about 90% of cases this hypothyroidism is transient, but in some cases, it never resolves.

POSTPARTUM THYROIDITIS

Postpartum thyroiditis (PPT) is a common endocrine condition that manifests within 1 year following pregnancy.[29] It affects between 5% and 10% of women in the general population. PPT is classically a biphasic disorder, consisting of a period of transient thyrotoxicosis (median onset 12–14 weeks post partum) followed by a period of transient hypothyroidism (median onset 18–20 weeks post partum); however, a monophasic (thyrotoxicosis or hypothyroidism alone) or reversed biphasic (hypothyroidism followed by thyrotoxicosis) pattern can also occur. During pregnancy, there is a state of relative immune tolerance, followed by a rebound in immune function following delivery, coinciding with the occurrence of PPT. The presence of thyroid autoantibodies and a lymphocytic infiltrate on thyroid biopsy supports an autoimmune basis for this condition.[29]

Clinically, the thyrotoxic phase of PPT is often mild, resulting in symptoms of fatigue and irritability, which can be misdiagnosed as postnatal depression. If the thyrotoxic episode is short, it may even go unnoticed. Neck pain is not a feature. Women with PPT who are thyrotoxic may benefit from a beta-blocker, such as propranolol, for symptom relief. Antithyroid drugs are not effective, as the thyrotoxicosis is caused by release of preformed thyroid hormones. Following the episode of thyroid dysfunction, 10–20% of women remain permanently hypothyroid.[29] In women who have had PPT and then recovered, an annual assessment of thyroid function is recommended, as their risk of long-term hypothyroidism is considerable.[29] In those women who return to being euthyroid, there is a 75% risk of PPT in subsequent pregnancies and a 50% risk of permanent hypothyroidism at 7 years.[30]

TRANSLATIONAL RESEARCH

ON THE HORIZON

New Approaches to Therapy of Graves Disease

- Novel immunotherapeutic agents for Graves orbitopathy
- Anti–thyroid-stimulating hormone receptor (TSH-R) blocking antibodies for control of hyperthyroid Graves disease
- Small molecule TSH receptor antagonists for management of hyperthyroidism in Graves disease

The major challenge of the next 5–10 years is to take novel immunotherapeutic agents, including "biologicals" that have been developed for rheumatic disorders into the clinical arena for autoimmune thyroid diseases. The primary target of these efforts should be GO, which remains a disfiguring condition, often with substantial functional impairment of vision and associated low quality of life. Two randomized controlled trials of B-lymphocyte–depleting agents have yielded conflicting results, and therefore other powerful agents need to be investigated as this remains a disorder with no wholly satisfactory treatment. Early diagnosis of GO and development of markers that predict progressive or severe disease will also be helpful in identifying patients for early intervention. The development of anti–TSH-R–blocking antibodies as a therapeutic agent for hyperthyroid GD seems likely. These agents might have a role in patients unlikely to gain medical remission from thionamide antithyroid drugs or in those for whom rapid control of hyperthyroidism is desirable. Small-molecule TSH-R antagonists may also come to the clinic, with a similar role.

MULTIPLE-CHOICE QUESTIONS

1. When assessing an individual with thyrotoxicosis, which feature is NOT consistent with a diagnosis of Graves disease?
   - **A.** Increasing severity of symptoms over weeks to months
   - **B.** Grittiness of the eyes and blurred vision on waking in the morning
   - **C.** Neck pain
   - **D.** A family history of autoimmune hypothyroidism and pernicious anemia
   - **E.** Relief of symptoms with beta-blocker medication
2. Which of the listed clinical features is in keeping with a diagnosis of postpartum thyroiditis (PPT)?
   - **A.** Proptosis of the eyes
   - **B.** Pretibial myxedema
   - **C.** Previous history of Graves disease
   - **D.** Goiter with a bruit
   - **E.** Onset of symptoms 4 months after delivery
3. In moderate to severe Graves ophthalmopathy (GO), the following treatments are evidence based and effective except:
   - **A.** Oral selenium supplements
   - **B.** Topical lubricants
   - **C.** Systemic glucocorticoids
   - **D.** Orbital radiotherapy
   - **E.** Orbital decompression surgery

Type 1 Diabetes

Leonard C. Harrison

Diabetes is not a single disease but a metabolic syndrome in which different mechanisms lead to deficiency of insulin and/or impaired insulin action and persistent hyperglycemia. The American Diabetes Association classified diabetes into four categories based on etiology rather than age of onset (juvenile-onset versus adult-onset) or requirement for insulin therapy (insulin-dependent versus noninsulin-dependent).[1] The vast majority of cases, approximately 10% and 90%, respectively, are attributed to type 1 and type 2 diabetes. This chapter focuses mainly on type 1 diabetes, which results from an absolute deficiency of insulin secondary to the loss of pancreatic β cells. Type 1 diabetes is classified as 1A (immune-mediated) or 1B (idiopathic), primarily depending on the presence or absence, respectively, of pancreatic islet autoantibodies. However, as discussed below, type 1A diabetes (T1DA) and type 1B diabetes (T1DB) also differ in their natural history and clinical features.

Diabetes is diagnosed on the basis of the following criteria[1]: symptoms in association with a casual plasma glucose ≥200 mg/dL (11.1 mmol/L) OR fasting plasma glucose ≥126 mg/dL (7.0 mmol/L) OR 2-hour plasma glucose ≥200 mg/dL (11.1 mmol/L) in an oral glucose tolerance test (OGTT; 75 g glucose in water). Without symptoms, the diagnosis of diabetes must rest on confirmation of a raised plasma glucose concentration. A further diagnostic criterion introduced by the World Health Organization (WHO) in 2011, in particular for the diagnosis of type 2 diabetes, is a confirmed blood glycated hemoglobin (HbA$_{1c}$) ≥48 mmol/mol (6.5%). Because HbA$_{1c}$ is an integrated measure of glycemia over many weeks, it is not suitable for diagnosing children or in the following circumstances: suspected type 1 diabetes; symptoms of diabetes for <2 months; acute illness; medication that may increase blood glucose (*e.g.,* steroids, antipsychotics); and pregnancy. The criteria for diagnosing gestational diabetes are stricter: fasting plasma glucose ≥101 mg/dL (5.6 mmol/L) or 2-hour plasma glucose in an OGTT ≥140 mg/dL (7.8 mmol/L).

The classic symptoms and signs of T1DA, because of high concentrations of blood glucose, are polyuria, polydipsia, and unexplained weight loss; others include fatigue, increased hunger, impaired visual acuity as a result of changes in the refractive index of vitreous humor, tingling or numbness in the hands or feet resulting from sensory nerve changes, and vaginal irritation caused by *Candida* infection. If diabetes is undiagnosed or untreated, failure to metabolize glucose will result in the breakdown of fat, leading to ketonemia and ketoacidosis, which may be accompanied by nausea and hyperventilation before life-threatening ketoacidotic coma. In children presenting with the classic symptoms, T1D can be diagnosed clinically. However, in Caucasians, the diagnosis can be confirmed and in older individuals and less clear-cut cases may be clearly established by detecting circulating autoantibodies to islet antigens. These autoantibodies to insulin (IAAs), glutamic acid decarboxylase 65 000 mol. wt. isoform (GADA), insulinoma-like antigen-2 (IA-2A), and zinc transporter-8 (ZTA) are markers of β-cell autoimmunity that appear many months to years before symptoms and therefore denote high risk for clinical disease.[2-5] They are present in at least 90% of Caucasian children with T1DA (compared with ≈1% of the background population) but in only ≈50% of Hispanic American and African American children, an increasing number of whom have T2D and, in some cases, T1DB. Negative results for islet autoantibodies in children with diabetes should also alert to the possibility of monogenic maturity-onset diabetes of the young (MODY) and sulfonylurea receptor syndromes.

The hallmark of T1DA is progression to absolute insulin deficiency within several years after diagnosis. The connecting peptide in proinsulin (C-peptide) is secreted in an equimolar ratio to insulin and is used as a surrogate for insulin to evaluate residual β-cell function in the face of exogenous insulin or IAAs, or insulin antibodies induced by exogenous insulin. The plasma C-peptide in response to a mixed meal tolerance test is the gold standard. Although children with T1DA have lost most of their β-cell function at diagnosis, the measurement of plasma C-peptide is not a reliable way of distinguishing T1D, especially at diagnosis. Hyperglycemia impairs β-cell function, and when corrected by rehydration and insulin replacement, it may be followed by a "honeymoon phase" of partial recovery of β-cell function and a decreased requirement for exogenous insulin that may last many months. By several years after diagnosis, most young children display little residual β-cell function; however, in older children and adults, residual C-peptide secretion has been observed for many years and is believed to be associated with better glycemic control.

Classically, T1DA was considered a disease of "juvenile onset" in normal-weight individuals in contrast to type 2 diabetes with onset in middle-aged, overweight individuals. However, this view requires reappraisal.[6] First, 5–10% of adults who present with diabetes diagnosed initially as T2D and are typically overweight, have evidence of low-grade islet autoimmunity manifest by the presence of GADAb, and occasionally IA-2Ab or ZTAb.[7] If we accept that they have a slowly progressive form of autoimmune β-cell destruction, that was termed *latent autoimmune diabetes in adults* (LADA), their number doubles the prevalence of T1DA.

Second, the “obesity epidemic” has impacted on the T1D and T2D stereotypes. “Hybrid” types with β-cell autoimmunity and insulin resistance (“double diabetes”) are becoming increasingly common, characterized by weaker immune and genetic markers (lower avidity autoantibodies predominantly to GAD and lower risk human leukocyte antigen [HLA] alleles). Low-grade innate immune inflammation, associated with insulin resistance in obesity, could promote and uncover latent β-cell autoimmunity in individuals with lower-risk genes for T1DA.

T1DB excludes known specific causes of β-cell dysfunction, such as monogenic diabetes. It encompasses forms of ketosis-prone diabetes initially described in West Africans and African Americans[8] and subsequently in other ethnic groups, but rarely seen in Caucasians. Obesity and relatively well-preserved residual β-cell function were features of the African cases. T1DB also includes fulminant diabetes initially described in Japan, where it may account for 15–20% of new-onset T1D, and subsequently elsewhere in Asia.[9,10] Fulminant diabetes is associated with widespread mononuclear cell infiltration of both the exocrine and endocrine pancreas, and elevated concentrations of serum pancreatic amylase, elastase, and lipase, in individuals with HLA susceptibility genes for T1D.[10] Case reports have associated it with acute viral infection and drug hypersensitivity reactions, but its etiology remains unclear. In Caucasians, T1DB includes T1D, in which islet autoantibodies are undetectable, but the latter may reflect assay insensitivity on a particular occasion. A classification of diabetes that hinges on the presence or absence of islet autoantibodies is clearly not ideal. β cell–specific T cells, not islet autoantibodies, are the effectors of β-cell damage, and reciprocal relationships between autoantibodies and autoreactive T cells to islet antigens have been reported.[11] In addition, the more recent discovery of autoantibodies to ZT8 suggests the possibility that autoantibodies to islet antigens remain to be discovered and might be markers of particular subtypes of T1D. For example, in fulminant diabetes, the clinical picture suggests that if autoimmunity is involved, it targets the exocrine pancreas. Furthermore, in contrast to T1DA, in which there is an extended preclinical history of islet autoimmunity, autoantibodies may not be present at the time when fulminant diabetes presents acutely.

CLINICAL PEARLS

- The type 1 diabetes (T1D) stereotype of the thin juvenile now overlaps with the type 2 diabetes (T2D) stereotype of the obese, insulin-resistant adult.
- In Caucasian children, the diagnosis of T1D can be made on the basis of classic clinical features.
- The presence of islet autoantibodies confirms the diagnosis of type 1A diabetes (T1DA).
- Islet autoantibodies are present in more than 90% of Caucasian children but in only about 50% of Hispanic or African American children, some of whom have T2D.
- Islet autoantibodies can be detected in the first 3 years of life in the majority of Caucasian children who go on to develop T1DA.
- The risk for T1DA increases with the number and titer of islet autoantibodies.

EPIDEMIOLOGY AND NATURAL HISTORY OF T1DA

The incidence of T1DA varies widely across the globe, being highest among Caucasians of northwestern Europe and countries to which they have emigrated (Fig. 71.1). This, in part, reflects the population distribution of specific-risk HLA genes, which account for up to 50% of the lifetime risk for T1DA. However, the incidence of T1DA is rising in many countries on a background of lower-risk HLA alleles. In Western societies, the incidence in childhood has more than doubled since the 1980s and has been rising at ≈3% annually, particularly among younger children.[12] The same trend is also occurring in other countries, such as Kuwait and Saudi Arabia, and some parts of India and China, where Western lifestyles have been adopted but where the prevalence of high-risk HLA genotypes for T1DA is much lower. Just as in T2D, environmental factors may increase the penetrance of risk genes for T1DA. In the case of HLA genes in Caucasians, the increasing incidence of T1DA is accounted for by children with intermediate-risk (DR 4,4 or DR 3,3) or low-risk (DR 4,X or DR 3,X) phenotypes, not the highest-risk HLA phenotypes (DR 3,4; DQ 2,8).[13] These lower-risk phenotypes are also the ones seen in non-Caucasians and adults with T1DA. The greatest number of children with diabetes will soon be found in the most populous regions of the world, that is, India and China. The impact of the modern Western environment on T1DA is discussed further below.

T1DA affects both sexes equally in childhood, with a slight excess of males in early adult life. Of newly diagnosed cases, no more than 10–15% have a family history of T1DA. However, studies of affected families have provided major insights into the genetics and natural history of T1DA. In relatives with T1DA, the rate of progression to clinical diabetes is positively associated with the number and titer of islet autoantibodies,[2,3,5] the number of HLA class 2 risk alleles (DR3, DR4) and specific HLA class I alleles (A24),[14] and the degree of insulin resistance[15] and is negatively correlated with age. The specificity of autoantibodies is also important. IAAs are more often the first sign of islet autoimmunity in children who are followed up from birth and, of all the autoantibodies, has the highest predictive value.[2-5] In Europe, North America, and Australia, birth cohort studies of children who have a relative with T1DA have shown that the development of diabetes by the age of 18 years is almost always associated with the appearance of islet autoantibodies in the first few years of life.[5] Of children with ≥2 islet autoantibodies before the age of 3 years, 57% (95% confidence interval [CI] 51.7–62.3%) and 74.8% (95% CI 69.7–79.9%) progressed to diabetes by 6 and 10 years of age, respectively. With a single islet autoantibody, 14.5% progressed to diabetes by 10 years of age.

Men with early-onset T1DA are more likely to transmit diabetes to their offspring compared with women (Fig. 71.2), but it is not clear whether this results from genomic imprinting of a gene expressed only from a paternally inherited allele or other possible reasons. The risk is also greater in later-born offspring. The peak age of incidence in children is at the cusp of puberty, a time when the body’s requirement for insulin increases along with an increase in insulin resistance. Like the seasonal autumn–winter peak in diagnosis that is attributed to viral infections, this is likely to be “the straw that breaks the camel’s back” on a background of longer-standing autoimmune β-cell dysfunction.

PATHOGENESIS: NATURE AND NURTURE

The model for the staged natural history of T1DA, arising from the seminal studies of Eisenbarth,[16] is illustrated in Fig. 71.3. Although the pattern and rate of β-cell loss is depicted as linear, it is more likely to be episodic, reflecting direct (*e.g.*, virus, chemical toxin) or indirect (*e.g.*, diet, pollutants, microbiome)

interactions between the environment and β cells. In addition, evidence suggests that immune activation and β-cell destruction may be accelerated in the late preclinical stage. The appearance of predictive islet autoantibodies in the first years of life[5] means that the stage for developing T1DA is set very early, even before birth, on a background of genetic susceptibility. These early years must provide clues to environment–gene interactions that lead to immune dysfunction and disease.

It is generally agreed that β-cell destruction in T1DA is mediated by autoreactive T cells, the ultimate effectors being CD8 cytotoxic T cells (Fig. 71.4). The evidence for this is unequivocal in the inbred nonobese diabetic (NOD) mouse model of T1DA, which shares several key features with T1DA in outbred humans (Table 71.1) despite 65 million years of evolutionary distance. The molecular mechanisms of β-cell death, gleaned mostly from the NOD mouse, encompass a combination of both apoptosis induced by activation of extrinsic (*e.g.*, tumor necrosis factor [TNF] receptor or Fas ligation) or intrinsic (*e.g.*, endoplasmic reticulum [ER] stress) pathways and necroptosis induced by cytotoxic CD8 T-cell granule components (granzymes and perforin), reactive oxygen species (ROS), or ischemia.

The evidence from human studies is obviously less compelling, as access to human pathology is limited. Studies of pancreas biopsies and organ-donor pancreas, more recently from the

FIG 71.4 Immune mechanisms of β-cell destruction in type 1A diabetes.

Network for Pancreatic Organ Donors with Diabetes (nPOD; www.jdrfnpod.org), have not revealed the florid immune cell infiltration of islets (insulitis) seen in NOD mice but rather patchy insulitis predominantly caused by CD8 T cells and macrophages. A further observation, confirming earlier observations,[17] is hyperexpression of HLA class I by islets, in association with immunoreactive interferon-α (IFN-α), even in atrophic islets lacking insulin, which can be taken as presumptive evidence for persisting virus. A key question is: why are β cells specifically targeted? The answer may lie in insulin itself. Central to the concept of autoimmune disease is the notion that the pathology is driven by loss of immune tolerance to self-antigens. In the case of T1DA, considerable evidence, direct in the NOD mouse, identifies (pro)insulin as a key disease-initiating self-antigen (Table 71.2).

GENES

The concordance for T1D in monozygotic twins, who are almost totally genetically identical, approaches 50%, indicating that both genetic and environmental–epigenetic mechanisms contribute to disease. Large case/control studies and more recently genome-wide

TABLE 71.1 The Nonobese Diabetic (NOD) Mouse as a Model of Human Type 1A Diabetes

Feature	NOD Mouse	Human
Preclinical stage	Yes	Yes
Gender	F > M	M > F after puberty
Genetic susceptibility		
MHC class II fi57 non-Asp	Yes (I-Ag^7)	Yes (HLA-DQ8)
Polygenic non-MHC	Yes	Yes
Environmental influence on gene penetrance	Yes	Yes
Disease transmission via bone marrow	Yes	Yes
Mononuclear cell infiltration of islets (insulitis)	Marked	Moderate
Other organs	Yes	Sometimes
Impaired immune regulation	Yes	Yes
Autoantigens:		
(Pro)insulin	Yes	Yes
Glutamic acid decarboxylase (GAD)	Yes	Yes
Clinical response to autoantigen-specific therapy	Yes	Not yet shown

TABLE 71.2 Evidence for the Key Role of Proinsulin as Primary Autoantigen in Type 1A Diabetes (T1DA)

- β cell–specific (except for thymus)
- Second strongest genetic locus in humans (*IDDM2*) = VNTR 5′ of INS allelism correlates with proinsulin transcription in the thymus
- Early target of autoimmunity in humans and nonobese diabetic (NOD) mice
- Main target of T cells isolated from islets of NOD mice and humans with T1DA

Genetic manipulation in the NOD mouse:

- Transgenic expression of proinsulin (but not glutamic acid decarboxylase [GAD]) in antigen-presenting cells (APCs) prevents insulitis/diabetes
- Transfer of hematopoietic stem cells (HSCs) or myeloid progenitors encoding proinsulin in APC progeny prevents diabetes
- Knockout of proinsulin II (expressed in thymus) accelerates diabetes
- Induction of mucosal tolerance to (pro)insulin prevents diabetes

association (GWA) studies have identified over 40 chromosomal loci associated with risk for T1DA[18,19] (Fig. 71.5). Many are weak associations defined only by single nucleotide polymorphisms (SNPs), and the genes with which the SNPs are in linkage and/or their functional contribution to pathogenesis are not known. It is likely that different combinations of genes/susceptibility loci in different environmental contexts lead by different routes to the final outcome of β-cell destruction and account for phenotypic–clinical heterogeneity in T1D. Nevertheless, what is clear across populations globally is the dominance of the HLA locus (IDDM1) as the single most important genetic contributor to T1D risk (see Table 71.1), accounting for about half the lifetime risk. The highest risk HLA haplotypes in Europeans are DR3 (*DRB1*03:01-DQA1*05:01-DQB1*02:01*) and DR4 (usually *DRB1*04:01* or **04:04* with *DQA1*03:01-DQB1*03:02*). It should also be noted that the HLA DQ6 haplotype *DQA1*01:02-DQB1*06:02,* which is in linkage with DR15 (*DRB1*15:01*), is dominantly protective for T1DA but denotes susceptibility for a subtype of multiple sclerosis and for narcolepsy. The second most important contribution is from the insulin gene (*INS*) locus (IDDM2), which maps to a variable number of tandem repeats (VNTR) 5’ of the coding sequence. Apart from the HLA locus, IDDM2 is still the only locus for which genome-wide association is reflected by linkage, which might be explained by disease heterogeneity. Long (class III) and short (class I) variable number tandem repeat (VNTR) alleles are associated, respectively, with higher and lower transcription of proinsulin messenger RNA (mRNA) in medullary thymic epithelial cells (mTECs) under the control of the autoimmune regulator gene (*AIRE*)[20] and with lower and higher T1DA risk.[21] This leads to the inference that IDDM2 controls the extent of deletion of proinsulin-specific T cells during their intrathymic development and predicts that the long VNTR would be associated with less proinsulin-specific T cells in the periphery; there is evidence for and against this, perhaps because of the difficulty of measuring islet antigen-specific T cells in human blood. The *INS* polymorphism is unique to humans. Mice, instead, have two insulin genes; *INSI* is expressed in the β cell and *INSII* in the thymus, and expression of the latter is impaired in the NOD mouse. In summary, IDDM2 provides a genetic mechanism for autoimmunity targeting proinsulin and the β cell.

Many of the other candidate genes are involved in immune function and are associated with other autoimmune diseases. For example, a nonsynonymous gain-of-function (GOF) polymorphism in *PTPN22* (lymphoid tyrosine phosphatase) results in enhanced T-cell suppression, which may impair negative selection of autoreactive T cells in the thymus and decrease the number and function of natural regulatory T cells (nTregs). Polymorphisms around *IL2RA* (interleukin-2 [IL-2] receptor α chain; CD25) and *IL2* are associated with impaired IL-2 signaling, which in both humans and NOD mice impairs the generation and maintenance of nTregs. Polymorphisms involving the *VDR* (vitamin D receptor) and *CYP27B1* (25-hydroxyvitamin vitamin D3 1-α-hydroxylase) and *IFIH1* (IFN-induced with helicase C domain 1; which enhances the type I IFN response to virus infection) are clues to gene–environment interactions in T1DA.

β CELLS

Why are β cells selectively destroyed by immune inflammation that involves the whole islet, which also contains a minority of glucagon-secreting α cells and other endocrine cells? First, cytotoxic CD8 T cells recognize autoepitope peptides (*e.g.,* from insulin) presented by hyperexpressed HLA class I proteins on β cells. Second, because of their unique metabolic wiring, β cells may contribute to their own death at the hands of the immune system. Evidence for the hypothesis of “assisted suicide” is compelling.[22] Studies of rodent islets, mainly *in vitro,* have indicated that β cells lack efficient antioxidant and free radical scavenging mechanisms and are especially sensitive to mitochondrial oxidative and ER stress in response to cytokines and granzymes,[22] although more recent studies of human islets do not support this view.[23] Third, many of the candidate T1D genes identified in GWA studies are transcribed in β cells (see Fig. 71.4) and encode proteins that interact with the immune system.[23] Finally, in response to inflammation, human islets generate hundreds of RNA splice variants for proteins, which, translated as neoantigens, may not be subject to immune tolerance.

Although it is still unclear whether human β cells are more sensitive than other autoimmune target cells to immune

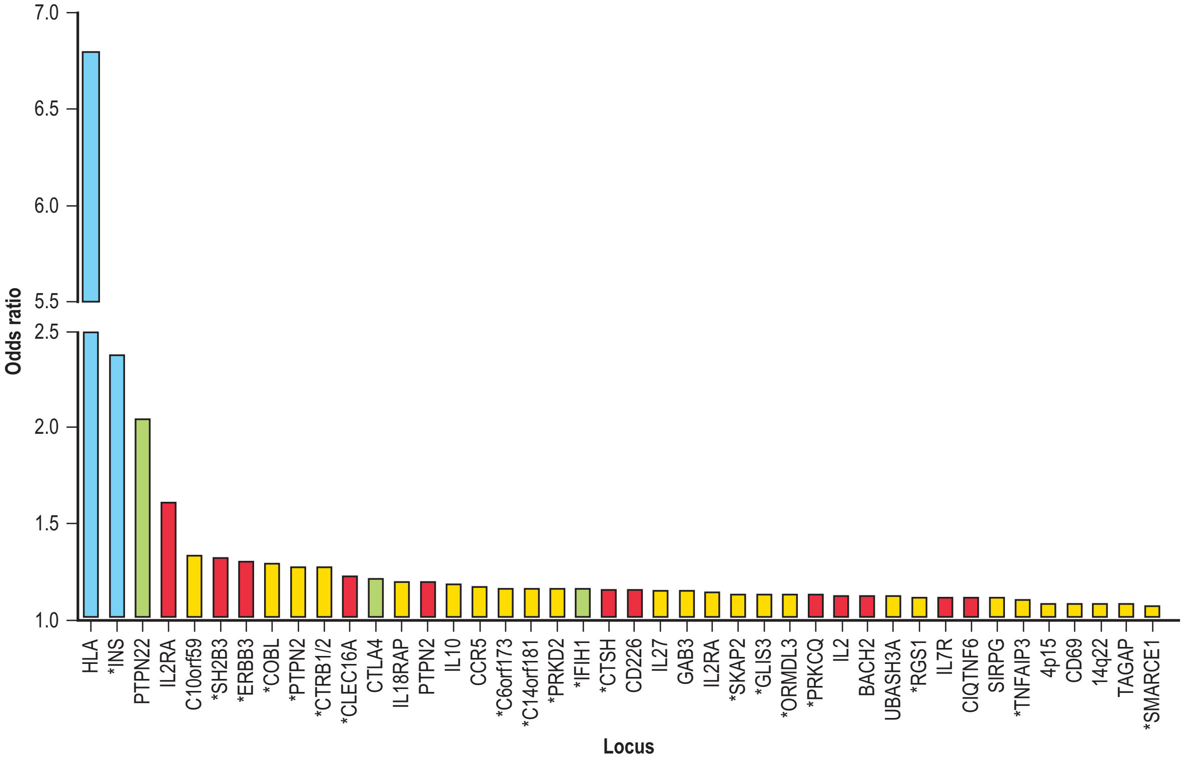

FIG 71.5 Candidate genes in type 1A diabetes (T1DA). The *y*-axis shows the odds ratio for risk alleles at each of the loci on the x-axis.[18] The majority of the known genes are involved in immune responses, and many (marked *) are expressed in islets. Colors indicate era of identification: blue 1970–2000; green 2001–2006; red 2007–2008; yellow 2009–2010.

effectors, what is clear is that having undergone apoptotic or necrotic death, β cells are not restorable in the face of autoimmune memory.

KEY CONCEPTS

Type 1A Diabetes Is an Autoimmune Disease

- Genetic and familial clustering, as well as association with other autoimmune diseases, including autoimmune polyendocrinopathy syndromes (*e.g.,* APS-1 due to mutations in *AIRE*)
- Presence of autoantibodies and T cells reactive with islet cell antigens
- Strong association with specific human leukocyte antigen (HLA) alleles and haplotypes
- Transfer of disease by bone marrow or development of disease in normal pancreas transplanted from identical twin without diabetes to the twin with diabetes
- Neonatal onset with loss of natural regulatory T cells with mutations in *FOXP3* (immune dysfunction/polyendocrinopathy/enteropathy/X-linked [IPEX] syndrome)

ENVIRONMENT—OUTSIDE AND INSIDE

The environment in its various manifestations may impact on β-cell function in several possible ways: by activating innate immune cells (macrophages) in the islets to release cytokines (*e.g.,* IL-1β, TNF) that elicit mitochondrial oxidative ER stress; by driving adaptive immunity to β cells in people with T1D risk genes, either generally or specifically by inducing posttranslational modifications in β-cell proteins that render them immunogenic; and by promoting obesity and insulin resistance and thereby increasing the workload of the β cell.

The environment in Western societies has changed dramatically in many ways during the last century (Fig. 71.6), and some of these changes have been associated epidemiologically or in animal studies with development of T1DA.[6] An index of the modern "exposome" is the ongoing rise in the prevalence of obesity. When children at increased genetic risk for T1DA (with an affected first-degree relative) were monitored from birth, weight gain in the first 2–3 years of life was shown to be a risk factor for islet autoimmunity.[24] When such at-risk children developed islet autoantibodies and were then followed up over time, those with insulin resistance progressed most rapidly to clinical diabetes.[15] Whether insulin resistance is a risk factor for the development of islet autoimmunity is an open question that should be answered by ongoing pregnancy–birth cohort studies.[25] If insulin resistance synergizes with impaired insulin secretion to promote T1DA, then lifestyle factors must be considered in the efforts to forestall or prevent T1DA.

Excessive energy consumption leading to obesity is part of a complex interplay of related factors that promote low-grade inflammation and insulin resistance. These include a poor-quality diet and lack of physical exercise, sunlight (vitamin D), and sleep. The highly processed fast-food "Western" diet lacks diversity of components, lacks plant-derived prebiotics and complex carbohydrates (starches and fiber), is high in saturated fats and in sucrose and fructose sugars, and has added artificial preservatives, emulsifiers, and sweeteners. All of these alter the composition of the gut microbiome and reduce its diversity, which is a feature

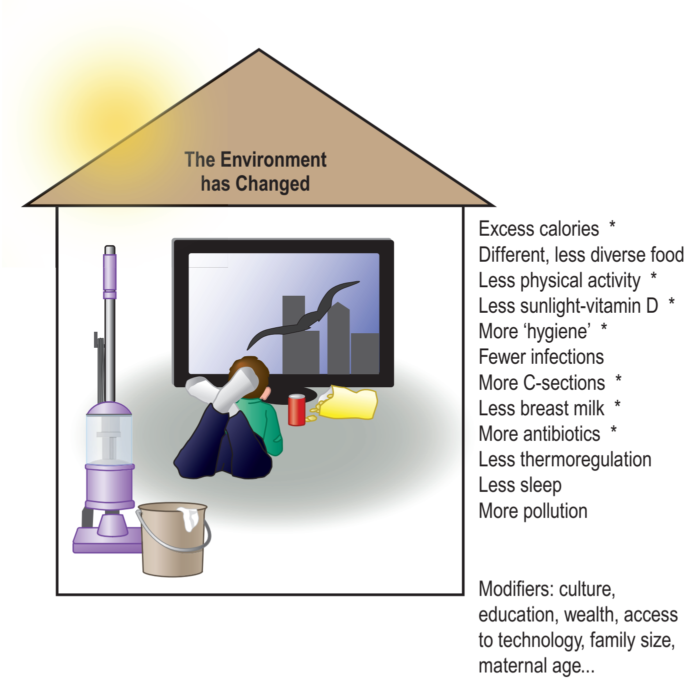

FIG 71.6 Changes in the modern environment. Those that have been associated with an increased risk for type 1A diabetes (T1DA) in humans or nonobese diabetic (NOD) mice are indicated (marked *).

found in children at risk for T1DA.[26] Diets containing a diverse range of plant products (cereals, fresh fruits, and vegetables) provide complex carbohydrates for fermentation by colonic bacteria to short-chain fatty acids (SCFAs), which are antiinflammatory.[27] The dramatic influence of the environment is seen in the comparison between the highly developed Finland and the nearby undeveloped Russian Karelia. Finland has the highest incidence of T1DA in the world, currently 57.6 cases/100 000 population ≤14 years of age (www.diabetesatlas.org). In 2005, there was a sixfold difference in the incidence of T1DA between Finland and Karelia despite overlap in ethnic background and a similar distribution of HLA-DQ risk genotypes.[28] This difference could reflect a relatively lower rate of infections (in Finland), in keeping with the “hygiene hypothesis.”[29]

However, viral infections have long been considered triggers of T1DA, but the evidence remains inconclusive.[30,31] Viral infection is circumstantially associated with the onset of T1DA, but given the long presymptomatic stage of the disease, this may simply represent a nonspecific inflammatory insult that precipitates clinical presentation. Viral mechanisms in T1DA could be direct or indirect (*e.g.,* infection of β cells, infection of the exocrine pancreas with bystander death of β cells, mimicry between T-cell epitopes in a viral protein and β-cell autoantigens, or activation of endogenous retroviruses in β cells by environmental agents). If an exogenous virus was clearly identified, then protective vaccination early in life would be an approach to primary prevention. Interest in viral triggers of T1DA was initiated by the observation that a minority of children with congenital rubella developed insulin-dependent diabetes[32] and were found to have a higher frequency of what was later recognized as the T1D susceptibility haplotype HLA-A1 B8-(DR3-DQ2). Clearly, this may have been an anomaly because congenital rubella has been virtually eliminated by vaccination and yet the incidence of T1D has continued to climb. Much circumstantial evidence exists for enteroviruses in T1DA[31] but has not been consolidated in follow-up studies. Even if a particular enterovirus strain were shown directly to be diabetogenic, vaccination would be elusive because among the many thousands of strain variants, the only one for which a vaccine exists is poliovirus. Mumps virus epidemics have been associated with T1DA onset after 2–4 years, and introduction of a mumps vaccine was associated with a plateau in the rising incidence of T1D in Finland, but this was temporary, and mumps vaccination has clearly not prevented T1D. It must be emphasized that there is no scientific evidence that any form of vaccination itself triggers T1DA.

Rotavirus is the commonest cause of gastroenteritis in young children. The discovery of strong sequence similarities between T-cell epitopes in the VP7 protein of rotavirus and the IA2 and GAD islet antigens in autoantibody-positive children led to speculation that mimicry of rotavirus might contribute to islet autoimmunity. Subsequently, in the Australian BabyDiab Study, rotavirus infection was associated over time with the first appearance of or an increase in islet autoantibodies in children before they developed diabetes.[33] Moreover, rotavirus has been shown to infect β cells in islets from mice, pigs, and monkeys and cause transient involution of the pancreas and hyperglycemia in a Toll-like receptor 3 (TLR3)–dependent manner in mice.[34] Ubiquitous rotavirus infections that drive cross-reactive immunity to islet autoantigens are unlikely to be diabetogenic but could complement and sustain the immune response to direct infection of β cells. As with rubella and mumps, it will be interesting to observe if recently introduced rotavirus vaccines have any effect on the incidence of T1DA.

The microbiome—the trillions of microorganisms (bacteria, fungi, archaea, protozoa, and viruses; Chapter 14) and their millions of genes and proteins that reside within the human mucosae, skin, and secretions—has gained increasing attention as a bellwether of health and disease (“dysbiosis”). Most microbiome analyses are based on DNA extraction and polymerase chain reaction (PCR) amplification of regions of the 16S ribosomal RNA (rRNA) gene that are conserved among bacteria. Although other internal regions of the 16S gene are variable and enable taxonomic classification from the phylum to genus level, 16S sequencing does not have the sensitivity to distinguish individual species and their strains. Direct metagenomic sequencing of all species, as well as analysis of their transcriptomes, epigenomes, and functions, is required to fully comprehend the role of the microbiome in T1DA and other chronic immune–inflammatory diseases. The marked difference in the incidence of T1DA between Finland and neighboring Karelia was found to be associated in Finnish children having decreased bacterial diversity overall, a dominance of the phylum Bacteroidetes, and lack of butyrate-producing bacteria.[26] These changes were seen after the appearance of autoantibodies, suggesting that they followed, rather than preceded, the disease process. However, in a further small study in Finnish children, metagenomic sequencing identified a relative abundance of *Bacteroides dorei,* which peaked around 7–8 months of age with the introduction of solids and preceded the appearance of islet autoantibodies. Gut *Bacteroides* species are abundant in Finnish children, including *B. dorei,* which produces a lipopolysaccharide (LPS) endotoxin that inhibits the immunostimulatory activity of *Escherichia coli* LPS, known to protect against development of diabetes in NOD mice. These findings suggest that an approach to lowering the environmental contribution to T1DA will be intervention with prebiotics, probiotics, or other means to favorably alter the composition of the gut microbiome.

KEY CONCEPTS

Type 1A Diabetes: Epidemiology, Environment, and Genes

- Incidence is increasing as a result of the impact of environment.
- Environment factors enable increasing penetrance of lower-risk human leukocyte antigen (HLA) alleles.
- Environmental factors are multifactorial but generally "pro-inflammatory" and impact via microbiome dysbiosis and epigenetic modifications on polygene expression to cause immune dysregulation in early life.

TREATMENT AND PREVENTION

Treatment of the metabolic syndrome of T1D is focused on optimizing blood glucose control with various modes of insulin delivery to prevent the short- and long-term complications of hyperglycemia. Refinements and advances over the past 30 years in insulin delivery and improved control of blood glucose and blood pressure have greatly improved the lives and prognosis of individuals with T1DA. Nevertheless, despite the introduction of pure, recombinant forms of human insulin, which have varied kinetics of action and can be injected via a syringe or continuously infused via a pump, and blood glucose self-monitoring, which can now be done continuously in real time, those with T1DA have not been rescued from a life sentence, and their blood glucose control remains less than physiological. The "cure" of T1DA requires the transplantation of insulin-secreting cells or their progenitors or the regeneration of β cells *in situ,* in conjunction with approaches to prevent allograft rejection and/or recurrence of autoimmunity (there will be no cure for T1DA without prevention). Currently, in some economically developed societies, allografts of whole pancreas or isolated islets are offered on a limited scale and at considerable cost to individuals with T1DA and life-threatening complications, in particular lack of awareness of hypoglycemia that is unresponsive to conventional treatment. However, shortage of donor tissue, cost, and the need for life-long immune suppressive agents militate against this solution. Longer-term, genetically engineered pig islet xenografts may overcome the tissue supply barrier. Stem cells, in particular autologous induced pluripotent stem cells (iPSCs), remain the great hope, but early proof-of-concept results in rodents await scale-up and translation to humans.

The incidence of spontaneous autoimmune diabetes in inbred NOD mice is decreased by many immune and other (including environmental) interventions introduced early in the disease course, although various interventions are often only effective in a proportion of mice, sometimes only delay disease onset, and sometimes have no effect (and are therefore not reported). Nevertheless, these findings in the NOD mouse suggest that T1DA is potentially preventable in outbred humans. On the basis of the key role of proinsulin in driving β-cell autoimmunity, the NOD mouse has provided "proof-of-concept" for the efficacy of antigen-specific vaccination strategies.[35] In humans, it has been convenient to classify prevention into primary (before the onset of islet autoimmunity), secondary (after the onset of islet autoimmunity), and tertiary (after the onset of clinical disease) prevention. Of course, real prevention is primary prevention—identifying those at genetic risk and intervening to avert islet autoimmunity. Neonatal screening based on HLA genotyping to identify at-risk individuals would be a basis for primary prevention, but even in countries with a high incidence of T1DA, this would have only modest predictive value, and intervention could be justified if it was practical and safe, if not efficacious. The mandate *Primum non nocere* ("first do no harm") dictates that many immune modulating agents are off limits for either primary or secondary prevention in T1DA. Options (*e.g.,* to modification of the diet or microbiome or of forms of vaccination) are greatly restricted. Agents that are effective in other autoimmune diseases are more likely to be effective in the early asymptomatic stage of T1DA, not after clinical presentation when most β cells have been destroyed. Indeed, clinical trials of tertiary prevention with more than 70 different agents since the early 1980s have failed to unequivocally demonstrate sustained preservation of residual β-cell function.[36,37] Interestingly, the number of trials reporting a positive outcome decreased from the 1980s, together with a shift in the primary outcome measure away from clinical remission to the more rigorous measure of residual insulin (stimulated C-peptide) secretion.

Is there a potential solution to the "off limits" dilemma? Classically, T1DA is regarded as a metabolic disorder diagnosed at clinical presentation with symptoms and signs of hyperglycemia. However, based on pathology, T1DA is an immune disease—autoimmune β-cell disorder (ABCD)—and only becomes a metabolic disorder at the end stage of its pathology. Accepting this reality would amount to a paradigm shift that could profoundly change the approach to and outcome of secondary prevention. Consider the situation in other autoimmune diseases. In rheumatoid arthritis, the pathology and clinical features (painful swollen joints) appear concomitantly when effective disease-sparing treatment with newer biological agents is initiated, *not* at the end stage of pathology when the joints are irreversibly deformed. A further benefit of diagnosing of T1DA early in the asymptomatic stage, based on evidence of underlying pathology, is that it would markedly reduce the risk of life-threatening ketoacidosis associated with the classic symptomatic presentation.

In health, immune responses to autoantigens are regulated to prevent development of autoimmune diseases. Autoantigen-specific immunotherapy aims to boost or restore autoantigen-specific immunoregulatory mechanisms. Its parallel, allergen-specific immunotherapy, has been shown in randomized trials to be effective in allergic asthma and rhinitis. Such "negative vaccination" can be achieved in several ways: by administering antigen via a "tolerogenic" route (mucosal, dermal), cell type (resting dendritic cell), mode (with blockade of costimulation molecules), or form (as an "altered peptide ligand"). Mechanisms of antigen-induced tolerance include deletion and/or anergy of effector T cells and induction of regulatory T cells (iTregs). Of clinical importance is the ability of iTregs to exert antigen nonspecific "bystander" suppression. Thus by direct cell contact and/or the release of soluble immunosuppressive factors, such as IL-10, iTregs impair the function of antigen-presenting DCs to elicit effector T-cell responses to the same or other antigens presented locally in the lesion or draining lymph nodes. Bystander suppression does not require that the "tolerizing" antigen is necessarily the primary driver of pathology. Its clinical importance is that it obviates specificity restrictions imposed by polymorphisms in the HLA and human T-cell receptors.

In NOD mice, administration of insulin, proinsulin peptides, or proinsulin DNA via oral or nasorespiratory routes, acting locally on the mucosal immune system, induces Tregs and decreases the incidence of diabetes. Results of randomized secondary prevention trials of insulin or GAD in relatives at risk for T1DA (ClinicalTrials.gov) have been summarized elsewhere.[35-37] In the DPT-1 oral insulin trial, relatives with a 5-year diabetes risk of 25–50% received 7.5 mg human insulin or placebo daily for a median of 4.3 years. There was no effect overall, but posttrial hypothesis testing revealed a significant delay in diabetes onset in participants with significant IAA at entry.[38] This outcome has led to an ongoing follow-up international trial by NIH-TrialNet using the same dose of 7.5 mg daily, which is not optimal because on a body-weight basis this dose is very small compared with that required to induce protective iTregs in the NOD mouse.

Apart from the dose, other variables have not been systematically tested in humans, in part because of the expense and duration of prevention trials. These variables include route of administration, form of the antigen, combinations of antigen with antigen-nonspecific agents, and the nature of induced immune responses. Unfortunately, surrogate markers of a potential therapeutic response have not been included in most trials and, in the case of antigen-specific T cells in blood, are not universally accepted as being sufficiently robust and reproducible. Oral delivery might not be optimal because proteins are degraded after ingestion, and the concentration or form of peptide reaching the upper small intestine may be variable and unpredictable. T-cell responses that were observed after nasorespiratory administration of a peptide have not been observed after oral administration. In a randomized trial of nasal insulin in individuals with recent-onset T1D not initially requiring insulin treatment, participants in the nasal insulin arm had markedly blunted insulin antibody responses after subsequent subcutaneous insulin.[39] This was the first demonstration, in humans, of immune regulation induced by mucosally administered exogenous autoantigen. Although this result provides a rationale for further disease endpoint trials, a Finnish study[40] suggested that this result cannot be extrapolated to endogenous "autoantigenic" insulin. Nasal insulin (1 unit/kg daily) did not alter the rate of progression to diabetes in islet autoantibody-positive children <3 years of age. However, these children were at very high risk, and many appeared to have had borderline β-cell function. As in the oral insulin trial, markers of an insulin bioeffect and evidence of immune tolerance were not reported. In the ongoing Intranasal Insulin Trial II (INIT II) in Australia, New Zealand, and Germany, higher doses of nasal insulin (44 or 440 IU) are being administered weekly for a year to relatives with T1D who have autoantibodies to at least two islet antigens (≈40% risk of diabetes over 5 years). The primary outcome is clinical diabetes; secondary outcomes are measures of metabolic and immune function. In INIT II, the insulin dose is substantially higher than in the Finnish study, the participants are older and have less advanced subclinical disease and therefore are at lower risk. The promise of antigen-specific therapy, therefore, has yet to be realized in humans. If a balance between pathogenic and protective T cells is deterministic for disease development, then antigen-specific therapy is most likely to be effective as a primary preventive strategy. Once disease has been initiated, insulin-specific or other antigen-specific approaches may require complementary therapy with other agents to inactivate or delete the burden of pathogenic effector cells.

ON THE HORIZON

- Closed-loop insulin delivery—blood glucose monitoring devices will become more refined, cheaper, and widely available.
- "Linking the -omes" (exposome–microbiome–metabolome–epigenome) across time in early life will provide new insights into how environment–gene interactions lead to immune dysregulation and type 1A diabetes (T1DA).
- Manipulation of the gut microbiome via scientifically formulated probiotics and prebiotics will be used for primary prevention of T1DA.
- T1DA is primarily an immune disease—autoimmune β-cell disorder (ABCD)—and only secondarily a metabolic disorder. Recognition of these disease components will expand the therapeutic possibilities for secondary prevention.

MULTIPLE-CHOICE QUESTIONS

1. Type 1 diabetes (T1D):
   - **A.** Is a genetic disease in which environment plays little or no role
   - **B.** Is classified as type 1A or type 1B, depending on evidence for an autoimmune basis (*i.e.*, the presence of absence respectively of islet autoantibodies)
   - **C.** Cannot be diagnosed on the basis of clinical features alone
   - **D.** Is associated with increased diversity of gut bacterial microbiota

2. In T1DA:
   - **A.** The dominant genetic contribution remains to be established.
   - **B.** The incidence has increased along with increased penetrance of lower-risk genetic alleles.
   - **C.** Most newly diagnosed cases have a first- or second-degree relative with the disease.
   - **D.** Most children who develop the disease have islet autoantibodies after 5 years of age.

3. In T1DA:
   - **A.** The absence of islet autoantibodies excludes the diagnosis.
   - **B.** Blood glycated hemoglobin (Hb_{A1c}) can be used to make the diagnosis children.
   - **C.** Immune-modulating agents have been successful in stabilizing or reversing β-cell failure for at least 2 years after the diagnosis.
   - **D.** Strict blood glucose control in pregnancy prevents fetal complications.

Immunological Lung Diseases

Joyce S. Lee, Andrew P. Fontenot

The lung serves as an interface between the environment and the sanctuary of the body. The defense systems of the upper airways clear the majority of inhaled particulates. Those that evade the upper airway defenses are combated by the innate and acquired immune responses. Essentially all autoimmune diseases are dependent on the inappropriate activation of autoreactive CD4 T cells as well as autoreactive B cells responsible for pathogenic autoantibodies. Immunological lung diseases develop when the normal mechanisms of immune self-tolerance fail. This chapter deals with the pulmonary manifestations of these disorders.

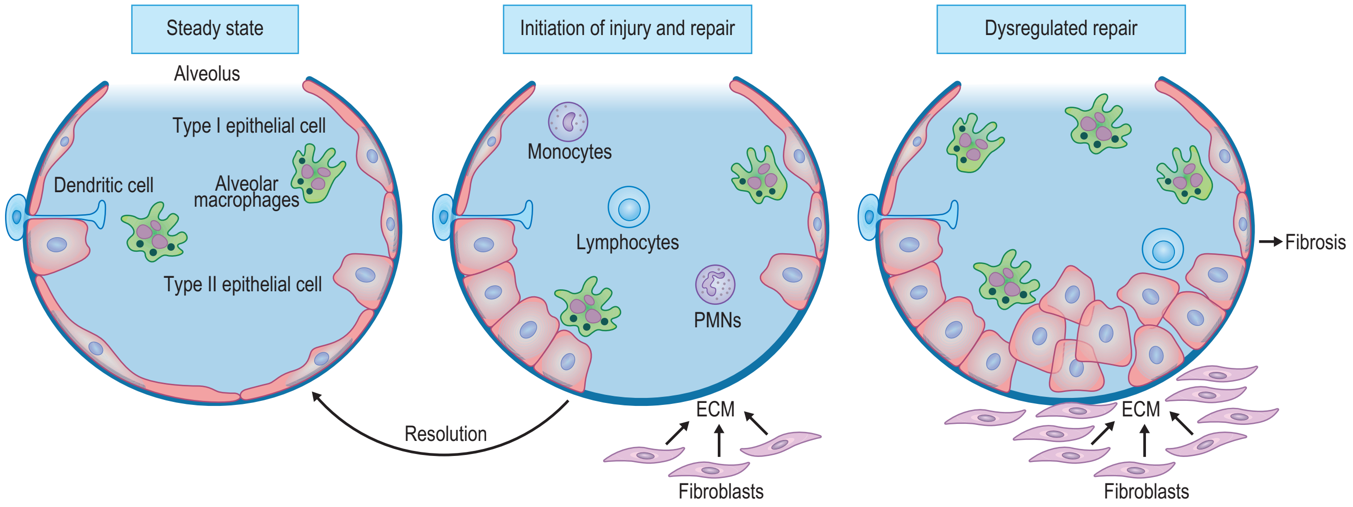
INFLAMMATION IN THE PATHOGENESIS OF INTERSTITIAL LUNG DISEASE

In the normal host, the resident alveolar macrophage is the predominant cell type in fluid from bronchoalveolar lavage (BAL). Resident alveolar macrophages function to ingest and degrade the inhaled antigenic load, to clear pulmonary surfactant, and to tonically suppress the development of inappropriate immune responses. Relatively few lymphocytes are present in the normal lung parenchyma. However, after stimulation by the relevant antigen in the lung-draining lymph nodes, antigen-specific lymphocytes migrate to the lung and participate in the inflammatory response. In addition to lymphocytes, other inflammatory and immune cells, including neutrophils, eosinophils, and other mononuclear cells, accumulate in the lung of patients with immunological lung disease, depending on the underlying disease. Within the normal alveolus, the major cellular constituents are alveolar macrophages and epithelial cells. Resident dendritic cells (DCs) also project dendrites through the tight junctions of the alveolar epithelium to sample the alveolar space. An initial insult typically involves the alveolar epithelial cell. Damage to type I alveolar epithelial cells results in release of chemokines that recruit and activate inflammatory cells, allowing for resolution of inflammation and repair of injured tissue (Fig. 72.1). With either prolonged exposure or failure to adequately clear an inhaled antigen, persistent inflammation results in extracellular matrix (ECM) deposition, culminating in tissue remodeling, progressive collagen deposition, and pulmonary fibrosis. Impaired ventilation and gas exchange occur as a consequence of lung fibrosis, resulting in patient morbidity and mortality. With destruction of type I alveolar epithelial cells, exposure of the underlying basement membrane can cause further inflammation. Proper restoration of the epithelial barrier is critical for resolution of lung inflammation. Type II alveolar epithelial cells can serve as progenitor cells that migrate and differentiate into type I alveolar epithelial cells to reestablish an intact lung epithelium.

Macrophages and lymphocytes have also been localized to areas of pulmonary fibrosis in patients with immunological lung diseases, including idiopathic pulmonary fibrosis (IPF), systemic sclerosis, and rheumatoid arthritis (RA).[1] In the lung, macrophages can be divided, according to their location, into alveolar or interstitial macrophages. Resident alveolar macrophages are yolk-sac–derived cells that are dependent on interleukin-34 (IL-34), colony-stimulating factor 1 (CSF-1), and the transcription factor PU.1 for their development.[2-4] These yolk-sac–derived macrophages are self-renewing,[5] maintained at a stable number throughout life, and are localized on epithelial surfaces and lining fluid of the alveoli and airways. With relatively poor antigen-presenting ability, they function to remove inhaled particles and bacteria. Conversely, interstitial macrophages are derived from hematopoietic stem cells (HSCs)[6] and are located in the tissue spaces between the alveoli. In the context of lung injury, interstitial macrophages greatly increase in number. Although interstitial macrophages have less phagocytic activity than alveolar macrophages, they have increased ability to present antigens to T cells. Upon activation, these macrophages express a variety of cytokines, including tumor necrosis factor-α (TNF-α) and monocyte chemotactic protein-1 (MCP-1). In addition to antigen presentation to T cells, macrophages are important for lung fibrosis and tissue remodeling in immunological lung diseases through secretion of specific growth factors, such as transforming growth factor-β (TGF-β), insulin-like growth factor-1 (IGF-I), platelet-derived growth factor (PDGF), and fibroblast growth factor (FGF).

T cells are also associated with lung fibrosis. For example, T cells have been located in areas of interstitial fibrosis and honeycombing with relatively fewer in areas of normal lung in patients with IPF.[7] In connective tissue disease–associated interstitial lung disease (ILD), T cells are diffusely distributed throughout the lung and within focal lymphoid aggregates.[8] In animal models, depending on their phenotype, T cells can be either profibrotic or antifibrotic. γδ T cells decrease lung inflammation and fibrosis in multiple mouse models.[9] CD8 T cells have been found in high proportion in BAL and surgical lung biopsy samples from patients with IPF, as well as patients with systemic sclerosis, but their role in these immunological lung diseases is not well understood.

Different subsets of CD4 T cells (Chapter 16) have been implicated in the pathogenesis of immunological lung diseases. T-helper type 1 (Th1) cells express interferon-γ (IFN-γ). Although IFN-γ is a potent proinflammatory cytokine, it has antifibrotic effects through inhibiting fibroblast proliferation and collagen expression. Th2 cells are defined by expression of IL-4, IL-5, and



1. Denudation of barrier
2. Cytokine/chemokine expression
3. Recruitment of inflammatory cells
4. Proliferation of type II epithelial cells
5. DC maturation
6. Fibroblasts express ECM

FIG 72.1 Pathogenesis of Interstitial Lung Disease. In the healthy lung, the alveoli maintain an antiinflammatory state to prevent unwanted inflammation. The predominant cells in the healthy alveolus are macrophages and types I and II epithelial cells. Upon injury, there is denudation of the epithelial barrier, resulting in the expression of cytokines/chemokines, recruitment of inflammatory cells, proliferation of type II epithelial cells, dendritic cell (DC) maturation, and expression of extracellular matrix (ECM) by fibroblasts. This inflammatory milieu leads to the resolution of inflammation and repair of lung injury. Conversely, in the presence of either prolonged antigen exposure or an inability to clear antigen, persistent inflammation ensues, resulting in extracellular matrix deposition with subsequent tissue remodeling, fibrosis, and permanent lung dysfunction.

IL-13. In contrast to IFN-γ, Th2 cytokines have been shown to promote lung fibrosis. Therefore the balance between Th1 and Th2 T cells through expression of different cytokines affects the development of pulmonary fibrosis.[10] Th17 cells express IL-17A and IL-17F, which are potent inflammatory cytokines important for the recruitment of neutrophils to areas of inflammation. Th17 cells have been implicated in the development of lung fibrosis in murine models.[11,12] Conversely, regulatory T cells (Tregs) suppress pathogenic T-cell responses that promote inflammation (Chapter 18). In patients with IPF, Tregs may be less able to suppress expression of cytokines by Th1 and Th2 cells, suggesting that Tregs are important in regulating ILD and pulmonary fibrosis.[13]

IDIOPATHIC INTERSTITIAL PNEUMONIAS

Idiopathic interstitial pneumonias (IIPs) are a group of diffuse inflammatory and/or fibrotic lung disorders that include IPF, acute interstitial pneumonitis (AIP), desquamative interstitial pneumonitis (DIP), respiratory bronchiolitis–associated interstitial lung disease (RB-ILD), nonspecific interstitial pneumonia (NSIP), cryptogenic organizing pneumonia (COP), lymphocytic interstitial pneumonia (LIP), and idiopathic pleuroparenchymal fibroelastosis (IPPFE).[14] The diagnosis of IIPs requires the exclusion of connective tissue diseases (CTDs), drug toxicity, and environmental exposures, and a thoracoscopic lung biopsy is often required. In addition, some patients with IIPs have clinical features suggesting an underlying autoimmune disorder. However, these subjects do not meet established criteria for a CTD. A joint European Respiratory Society and American Thoracic Society Task Force recently proposed the term “interstitial pneumonia with autoimmune features” (IPAF) as well as classification criteria for

KEY CONCEPTS

Classification of the Idiopathic Interstitial Pneumonias

- The idiopathic interstitial pneumonias comprise a group of eight histologically distinct disorders.
- The distinction is important since response to treatment and prognosis differs:
    - Idiopathic pulmonary fibrosis (IPF) with histopathology labeled as usual interstitial pneumonitis (UIP): the pathology of UIP can occur in other diseases such as connective tissue diseases
    - Acute interstitial pneumonitis (AIP)
    - Desquamative interstitial pneumonitis (DIP)
    - Respiratory bronchiolitis–associated interstitial lung disease (RB-ILD)
    - Nonspecific interstitial pneumonia (NSIP)
    - Lymphocytic interstitial pneumonia (LIP)
    - Cryptogenic organizing pneumonia (COP)
    - Idiopathic pleuroparenchymal fibroelastosis (IPPFE)
- To differentiate between these diseases, a thoracoscopic lung biopsy is often required.

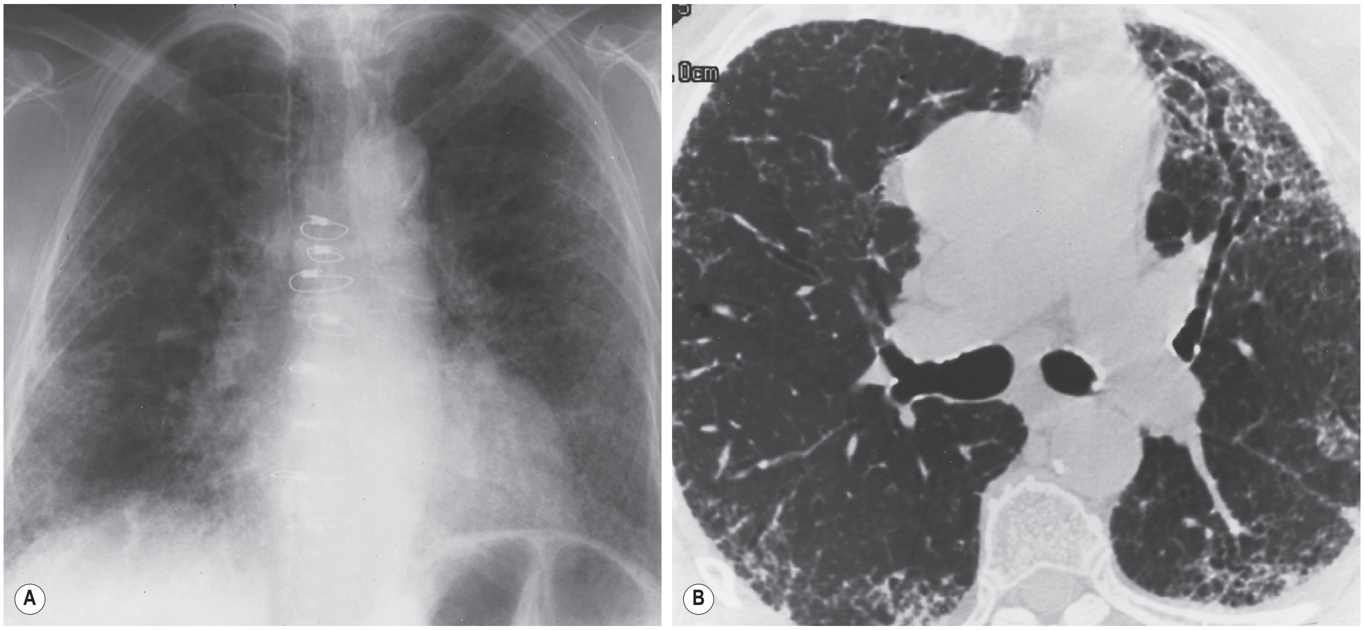


FIG 72.2 Radiographic Manifestations of Idiopathic Pulmonary Fibrosis. (A) Chest radiograph in a patient with idiopathic pulmonary fibrosis showing diffuse, coarse reticular opacities with a lower lung zone predominance. Cystic radiolucencies, consistent with honeycombing, are evident. (B) High-resolution computed tomography shows peripheral reticular opacities, honeycombing, and traction bronchiectasis.

these subjects.[15] Importantly, the distinction between these various disorders is of clinical relevance, since response to treatment and outcome differs.

Idiopathic Pulmonary Fibrosis

IPF, also known as *cryptogenic fibrosing alveolitis,* is the most common diffuse parenchymal lung disease of unknown etiology.[16] It is characterized by progressive clinical deterioration despite available therapy. Although IPF has characteristic clinical, radiographic, and histological appearances, other ILDs, including the CTDs, drug reactions, and environmental exposures, can mimic these findings.

Clinical Manifestations

CLINICAL PEARLS

Idiopathic Pulmonary Fibrosis (IPF)

- IPF is one of the most common causes of diffuse parenchymal lung disease of unknown etiology and is characterized by insidious onset of cough and dyspnea.
- The histopathological pattern of IPF is usual interstitial pneumonitis.
- A confident diagnosis of IPF based on high-resolution computed tomography can only be made in one-third of cases.
- IPF is generally a fatal disorder, characterized by relentless progression and a 5-year survival of 30–50%.
- Pirfenidone and nintedanib appear to slow disease progression in IPF.

The incidence and prevalence of IPF are uncertain, although prevalence rates for men and women of 20.2 per 100 000 and 13.2 per 100 000, respectively, have been reported.[17] Both the incidence and prevalence of IPF increase with age, with most patients presenting between 50 and 70 years of age. Although the clinical features of IPF are variable, most patients present with the insidious onset of exertional dyspnea and a dry, nonproductive cough. Physical examination reveals dry, end-inspiratory crackles with clubbing present in 25–50% of patients.

Chest radiography typically shows diffuse reticular opacities, predominantly in the peripheral lower lung zones. Ground-glass opacities, small cysts (honeycombing), and reduced lung volumes may also be seen (Fig. 72.2A). These radiographic changes often precede the onset of symptoms, and serial chest radiographs usually reveal progressive loss of lung volume. High-resolution computed tomography (HRCT) findings include bibasal peripheral reticular opacities (see Fig. 72.2B). Honeycombing, traction bronchiectasis, and subpleural fibrosis can also be present.

The typical physiological abnormalities in IPF are those of a restrictive lung disease with a low diffusing capacity for carbon monoxide and severe gas exchange abnormalities exacerbated by exercise.

Histopathology

The gross appearance of the lungs in IPF shows a nodular pleural surface, and histopathological examination reveals usual interstitial pneumonitis (UIP).[18] UIP is characterized by nonuniform and variable distribution of the interstitial changes. At low magnification, alternating zones of interstitial fibrosis, inflammation, honeycombing, and normal lung can be seen (Fig. 72.3A). At higher magnification, derangement of alveolar walls with edema, fibrinous exudate, fibroblast proliferation, and fibrosis occur. *Honeycomb change* refers to enlarged airspaces lined by metaplastic bronchial epithelium and surrounded by walls thickened with collagen (see Fig. 72.3B). The earliest finding in UIP is the fibroblast focus, a lesion consisting of distinct clusters of fibroblasts and myofibroblasts in a loose connective tissue matrix within the alveolar wall, with minimal interstitial inflammation or intraalveolar macrophage accumulation (see Fig. 72.3C).[18]

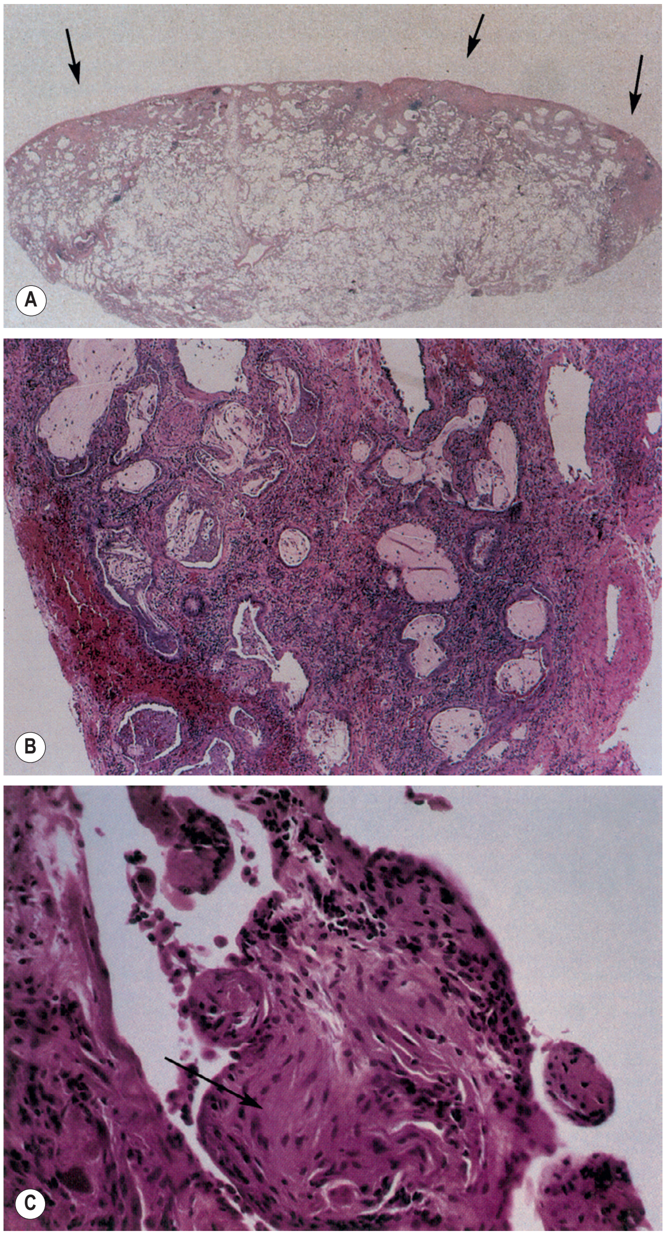

FIG 72.3 **Histopathology of Usual Interstitial Pneumonitis (UIP).** (A) Low-magnification photomicrograph of UIP showing the variegated appearance from one field of view to the next with areas of dense subpleural fibrosis (arrows) separated from other areas of normal lung. (B) High-magnification photomicrograph of UIP showing honeycomb change characterized by enlarged airspaces filled with mucin and separated by fibrosis. (C) Fibroblast focus in UIP is characterized by clusters of spindle-shaped fibroblasts (arrow) in a loose connective tissue matrix within the alveolar wall.

Tables 72.1 and 72.2 compare the clinical and pathological features of UIP, DIP, RB-ILD, and NSIP.

Pathogenesis

The pathogenesis of IPF is poorly understood, but current evidence suggests that fibrosis results from aberrant wound healing in response to repetitive injury and is mediated through an interplay between immunological, genetic, environmental, and viral factors (Fig. 72.4).[16] Some cases of IPF are familial, inherited as an autosomal dominant trait with variable penetrance. Recently, dysregulated expression of a mucin gene, *MUC5B,* has been associated with development of familial IPF.[19] Mutations in the telomerase ribonucleoprotein complex associated with telomere shortening have also been linked with familial IPF.[16] In addition, surfactant protein C mutations have been rarely associated with IPF.

In the normal lung, the interstitium is thin and delicate with few lymphoid cells and fibroblasts. Following the initiation of the inflammatory process, damage to the alveolar epithelial cell occurs, followed by vascular leak, fibroblast activation and proliferation, ECM synthesis, and activation of the innate immune system.[16] The release of danger-associated molecular patterns from dead or dying cells results in macrophage activation. Following activation, alveolar macrophages secrete IL-1, IL-8, tumor necrosis factor-α (TNF-α), PDGF, and IGF-1. This cytokine milieu promotes the activation and recruitment of neutrophils and lymphocytes to the area of alveolitis.

T lymphocytes, which accumulate in the alveolar space and interstitium, express an activated phenotype, including the expression of human leukocyte antigen D-related (HLA-DR) and IL-2 receptor. Following activation, CD4 T cells evolve into three major subsets distinguished by the cytokines produced (Chapters 9 and 16). In IPF, T cells expressing a Th2-type phenotype predominate, producing IL-4, -5, and -13. In addition, the Th17 cytokine, IL-17A, has been linked to the development of bleomycin-induced lung injury and collagen deposition.[11,12] Evidence also suggests that patients with IPF have oligoclonal CD4 T-cell expansions that proliferate in response to antigens present in diseased tissue.[20] Treg function may be impaired in patients with IPF.[13] In addition, immune complexes have been identified in the serum and lungs of patients with IPF.[21]

In addition to their role as scavengers, alveolar macrophages are vital in the repair phase of inflammation. However, the distinguishing feature between a self-resolving inflammatory process and a fibrotic response, as seen in IPF, is the accumulation of collagen. Evidence suggests that the fibrotic process in IPF is a consequence of dysregulation of both collagen synthesis and degradation. Macrophage-derived growth factors, including TGF-β, PDGF, and IGF-1, stimulate fibroblast proliferation and collagen deposition.[22] Adequate resolution of an inflammatory process requires matrix degradation. Matrix metalloproteases (MMPs) produced by macrophages and fibroblasts are involved in matrix degradation, and control of metalloprotease production involves substances known as *tissue inhibitors of metalloproteases* (TIMPs). TIMPs are elevated in the lungs of patients with IPF. In addition, TGF-β can markedly augment TIMP production. Thus there appears to be a loss of balance between the events mediating resolution and those mediating perpetuation of the inflammatory response, setting the stage for lung injury, tissue remodeling, and the development of irreversible pulmonary fibrosis.

Diagnosis

The diagnostic evaluation of a patient with diffuse parenchymal lung disease includes a thorough history and physical examination with particular attention to symptoms and signs that could indicate a CTD, occupational and environmental exposures, or medication and drug use. A careful family history is also important.

TABLE 72.1 Clinical Features of the Idiopathic Interstitial Pneumonias

	UIP	DIP	RB-ILD	AIP	NSIP
Mean age (years)	57	42	36	49	49
Childhood	No	Rare	No	Rare	Occasionally
Onset	Insidious	Insidious	Insidious	Acute	Subacute, insidious
Mortality (mean survival)	68% (5–6 years)	27% (12 years)	0%	62% (1–2 months)	11% (17 months)
Response to steroids	Poor	Good	Good	Poor	Good
Recovery possible	No	Yes	Yes	Yes	Yes

KEY CONCEPTS

Pathogenesis of the Idiopathic Interstitial Pneumonias (IIPs)

- Although the inciting event(s) is unknown in the different diseases, a common result is a dysregulated fibroproliferative response (similar to wound healing), which leads to excessive extracellular matrix (ECM) production and lung remodeling.
- A genetically determined inability to repair and reepithelialize the denuded basement membranes adequately may be a contributing factor and may relate to the familial occurrence of some cases of idiopathic pulmonary fibrosis (IPF).
- The presence of a chronic stimulus (autoantigen), as is seen in the pneumoconioses, may result in a persistent inflammatory and immune response and lead to a failure in the normal healing process.
- The release of transforming growth factor-β (TGF-β) following epithelial injury stimulates collagen synthesis and the prevention of apoptosis of proliferating fibroblasts in the lung and may impair collagen degradation by inhibiting the production of metalloproteases.
- A predominant T-helper type 2 (Th2) response in the lung and the absence of interferon-γ (IFN-γ) favor the development of a fibrotic response.

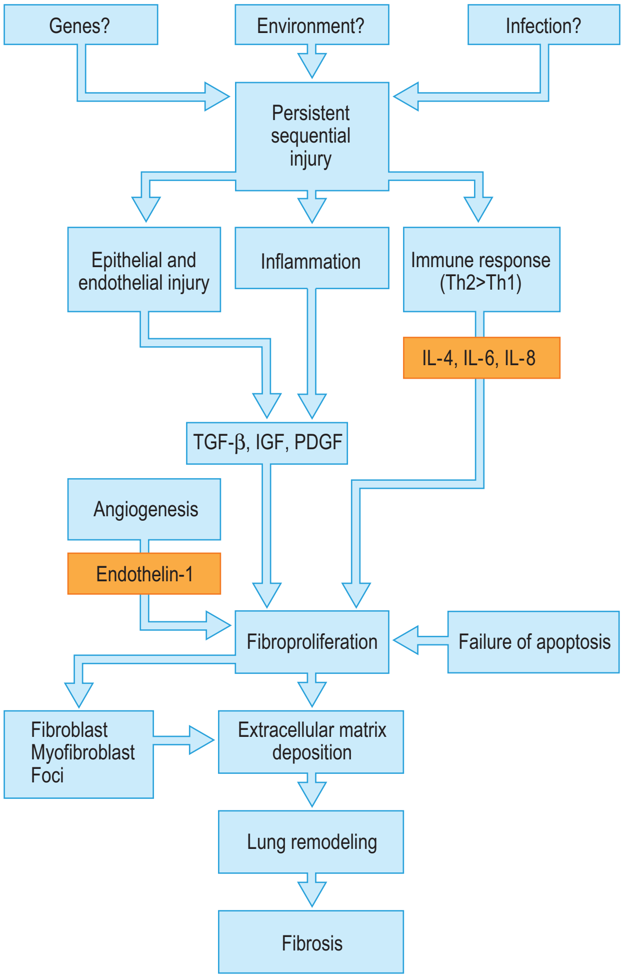

FIG 72.4 Events Hypothesized to Be Involved in the Pathogenesis of Idiopathic Pulmonary Fibrosis. The initiating event(s) leading to persistent lung injury remains poorly understood. The interaction between genetic factors, environmental exposures, and infectious agents leads to epithelial and endothelial injury, resulting in the secretion of macrophage-derived growth factors, including transforming growth factor-β (TGF-β), insulin-like growth factor-1 (IGF-1), and platelet-derived growth factor (PDGF). This cytokine milieu stimulates fibroblast proliferation and collagen deposition. In addition, the resulting T-helper type 2 (Th2) immune response stimulates extracellular matrix production and fibroblast proliferation, resulting in lung remodeling and, eventually, lung fibrosis.

The history and physical findings in IPF are nonspecific. However, extrapulmonary involvement does not occur; the presence of fever, arthralgias, myalgias, or pleuritis should suggest a connective tissue disorder. Antinuclear antibodies (ANAs) and rheumatoid factor are present in 10–20% of patients with IPF, but titers greater than 1 : 320 should suggest an alternative diagnosis.

The majority of patients with IPF have abnormal chest radiography results at the time of presentation. Basal peripheral reticular opacities are the characteristic radiographic findings. A confident diagnosis of IPF from HRCT of the lung requires the presence of patchy, peripheral bibasal reticular abnormalities with honeycombing.[23] The presence of extensive ground-glass opacities on HRCT should suggest an alternative diagnosis, such as DIP, hypersensitivity pneumonitis, bronchiolitis obliterans organizing pneumonia (BOOP), or NSIP.

A surgical lung biopsy is recommended in patients with suspected IPF without a definitive HRCT appearance and who do not have contraindications to the procedure. This is especially important in patients with atypical clinical or radiographic findings, which could suggest the possibility of one of the other histological patterns of the IIPs and an improved prognosis. Biopsy may be omitted in older patients with cardiovascular disease, or those with evidence of extensive honeycomb change. Biopsy through video-assisted thoracoscopy (VATS) is the preferred surgical technique and has been associated with less morbidity and a decreased length of hospital stay compared with open lung biopsy.

Treatment and Outcome

The usual course of IPF is relentless progression without spontaneous remission, commonly with a fatal outcome. The most common cause of death in patients with IPF is progression of the underlying disease with two-thirds of deaths caused by respiratory failure or cardiovascular complications. Other causes of death in IPF include bronchogenic carcinoma, infection, and pulmonary embolism. Recent studies in patients with biopsy-proven IPF indicate a poor prognosis (30–50% 5-year survival).[24] Previously, there was no evidence to support the use of any specific therapy in the management of IPF. However, recent clinical trials have shown decreased decline in forced vital capacity (FVC) after use of either pirfenidone[25] or nintedanib.[26] Thus for the first time, there are two drugs approved by the US Food and Drug Administration (FDA) for the treatment of IPF, with multiple other phase II and III clinical trials scheduled for completion in the near future. Finally, lung transplantation should be considered in patients who have progressive clinical and physiological deterioration and who meet established criteria.

Acute Interstitial Pneumonia

AIP is a fulminant form of IIP. Although it was previously thought to represent an acute phase of UIP, some studies have suggested that it is a distinct entity.[18] However, patients with documented UIP/IPF experiencing acute exacerbations can have the pathology of AIP superimposed on UIP.[27]

Clinical Manifestations

AIP presents with the abrupt onset of dyspnea followed by rapid progression to respiratory failure. The clinical, radiographic, physiological, and histological features are identical to those of the acute respiratory distress syndrome (ARDS) but without any identifiable cause. Most patients are previously healthy individuals over 40 years of age. Men and women are equally affected. A viral prodrome is common, with symptoms that include fever, nonproductive cough, and dyspnea. Laboratory studies are nonspecific. Chest radiography and HRCT show diffuse airspace opacities and ground-glass attenuation, respectively. A similar presentation may occur as the initial manifestation of a CTD.

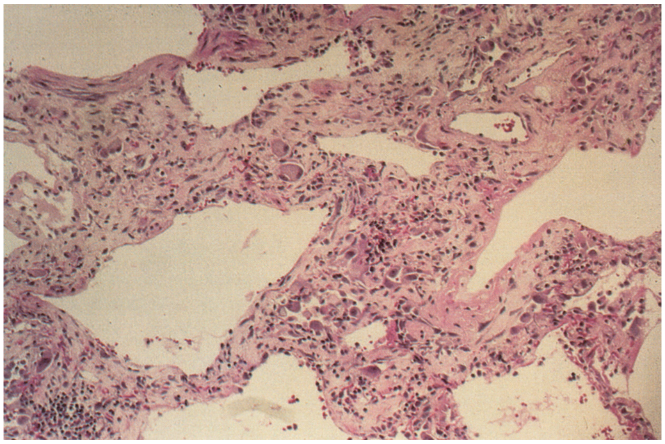

FIG 72.5 Histopathology of Acute Interstitial Pneumonitis. Diffuse thickening of the alveolar septum with an infiltration of mononuclear cells is the characteristic abnormality. The temporal uniformity of this process is also apparent.

Histopathology

AIP is characterized by diffuse interstitial fibrosis that is temporally uniform (Fig. 72.5).[28] The changes are identical to the organizing phases of diffuse alveolar damage, as seen in ARDS. Within the thickened interstitial space, there is active, diffuse fibroblast proliferation similar to the focal fibroblast foci seen in UIP. If this is progressive, honeycomb change occurs. Other features of acute lung injury, which are frequently seen in AIP, are intra-alveolar hyaline membranes.

Diagnosis

The diagnosis of AIP is based on a clinical syndrome of idiopathic ARDS and the presence of organizing diffuse alveolar damage on lung biopsy. Lung biopsy is occasionally performed to establish the diagnosis and exclude other causes of acute ILD.

Treatment and Outcome

No effective therapy exists for patients with AIP. Glucocorticoids are utilized in most cases, but no survival benefit has been shown. Overall, the prognosis of patients with AIP is poor, with mortality rates in the range of 50–88%. Half the patients die within 6 months of disease onset. However, those who survive may have complete recovery of lung function, and AIP rarely recurs in survivors.

Desquamative Interstitial Pneumonitis

DIP represents fewer than 3% of all cases of interstitial lung disease.[29] However, it is a distinct clinicopathological entity that differs substantially from UIP.

Clinical Manifestations

DIP affects individuals in their fourth to fifth decades of life with a male predominance. It predominantly occurs in cigarette

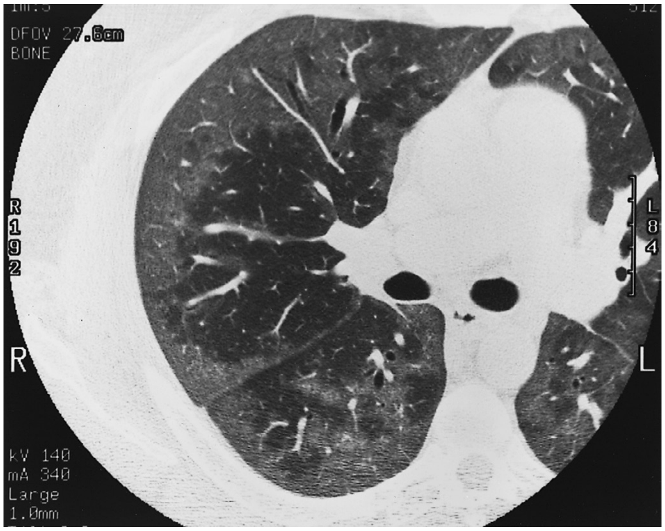

FIG 72.6 Radiographic Manifestations in Desquamative Interstitial Pneumonitis. High-resolution computed tomography scan in a patient with desquamative interstitial pneumonitis shows ground-glass attenuation in the periphery of the upper and lower lung fields.

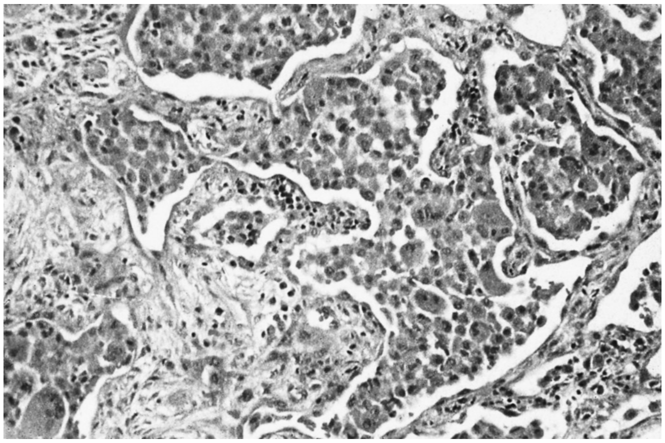

FIG 72.7 Histopathology of Desquamative Interstitial Pneumonitis. A high-magnification photomicrograph of desquamative interstitial pneumonitis shows the uniform, diffuse accumulation of macrophages within the alveolar space with associated thickening of the alveolar septum. These aggregates of macrophages almost completely fill the alveolar spaces.

smokers. Clinically, most individuals present with subacute onset of a dry, nonproductive cough and dyspnea. Clubbing is present in approximately 50% of patients with DIP. Laboratory evaluation is usually nonspecific.

Although the chest radiography results can be normal in up to 20% of symptomatic individuals, it typically shows nonspecific bibasilar ground-glass opacities. Reticulonodular interstitial infiltrates have also been reported. HRCT confirms the presence of ground-glass attenuation in the periphery of the lower lung zones (Fig. 72.6). Pulmonary function testing shows a restrictive defect with hypoxemia and a decrease in diffusion capacity.

Histopathology

DIP is a misnomer. It was initially thought that the intraalveolar cells represented sloughed or desquamated alveolar epithelial cells. However, DIP is pathologically characterized by uniform, diffuse accumulation of macrophages in the alveolar space (Fig. 72.7). At low magnification, the overall appearance is one of uniformity from one field of view to the next as opposed to the variegated appearance of UIP. In addition, there is scant interstitial inflammation with varying degrees of fibrosis of the alveolar septum.

Diagnosis

The diagnosis of DIP requires tissue confirmation of the pathological lesion. This is important since DIP has a better prognosis and response to therapeutic intervention compared with IPF. A DIP-like pattern is frequently seen in other IIPs as well as in pulmonary Langerhans cell histiocytosis, CTDs, and drug reactions. Thus the diagnosis of DIP requires careful correlation of pathological findings with clinical and radiological findings.

Treatment and Outcome

The primary intervention in DIP is smoking cessation. Since this is a rare condition with relatively few published cases, it is unclear whether glucocorticoids alter the natural history of this disease. A mortality rate of 28% with a mean survival of 12 years has been reported compared with a 30–50% 5-year survival in UIP.[24] Of note, 22% patients improved spontaneously, and 60% responded to glucocorticoid therapy. This picture is dramatically different from that of IPF, in which spontaneous improvement rarely, if ever, occurs. However, a significant minority of patients with DIP fail to respond to treatment and progress to respiratory failure secondary to advanced fibrosis.

Respiratory Bronchiolitis–Associated Interstitial Lung Disease

RB-ILD is a distinct clinical entity that occurs in current or former cigarette smokers. It is unclear whether RB-ILD and DIP represent different diseases or different ends of the spectrum of the same disease process.[29] DIP occurs predominantly and RB-ILD occurs exclusively in cigarette smokers, suggesting a common pathogenesis related to cigarette smoke exposure.

Clinical Manifestations

The mean age at presentation with RB-ILD is 36 years. Males are more often affected, and all individuals with RB-ILD are cigarette smokers. Symptoms include a dry, nonproductive cough and dyspnea. Clubbing is absent in RB-ILD, whereas it is frequently present in DIP. Laboratory evaluation is nonspecific.

Chest radiography typically shows diffuse, fine reticular or nodular interstitial opacities with normal lung volumes. Additional findings include bronchial wall thickening and a prominent peribronchovascular interstitium. HRCT may reveal ground-glass opacification and emphysema.

Pulmonary function tests most commonly reveal a mixed restrictive–obstructive pattern with a reduced diffusing capacity and mild hypoxemia. The residual volume may be increased, with no change in other spirometric parameters.

Histopathology

The pathology of RB-ILD is similar to that of DIP. However, in RB-ILD, the intraalveolar macrophages accumulate primarily

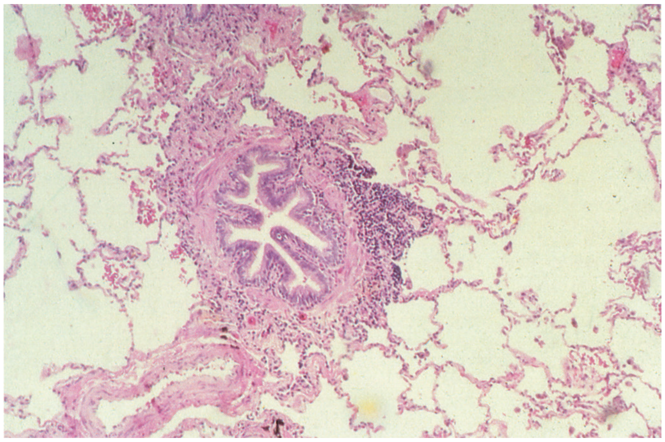

FIG 72.8 Histopathology of Respiratory Bronchiolitis–Interstitial Lung Disease. An ectatic bronchiole with a thickened wall is shown, with a mononuclear infiltrate extending into the immediately surrounding alveoli.

within the peribronchiolar airspaces and are associated with thickening of the alveolar septum in these areas (Fig. 72.8). The differentiation of this lesion from DIP requires sparing of distal airspaces with the lesion confined to the peribronchiolar airspaces in RB-ILD.

Diagnosis

RB-ILD should be suspected in young individuals who have a history of cigarette smoking and complain of cough and dyspnea with chest radiography or HRCT showing nodular and/or reticular interstitial opacities. The diagnosis requires tissue confirmation of the pathological findings noted above.

Treatment and Outcome

The key therapeutic intervention in RB-ILD is cessation of smoking. The use of glucocorticoids has been associated with favorable results. At present, the clinical course and prognosis of patients with RB-ILD are unknown. In most clinical series, patients either improved or stabilized, and mortality is uncommon.[29,30]

Nonspecific Interstitial Pneumonitis

The term NSIP was first used to describe cases of interstitial pneumonia that did not demonstrate a pattern of UIP, AIP, or DIP. Currently, the term NSIP is applied to an IIP or to a similar histological pattern that occurs in CTD, hypersensitivity pneumonitis, infection, or drug-induced lung disease. Thus the diagnosis of NSIP should prompt investigation for a causative agent.[18] In fact, 16% of patients in the original description of NSIP had one of the CTDs.[31]

Clinical Manifestations

Idiopathic NSIP occurs in middle-aged individuals, with a slight female predominance. A dry, nonproductive cough and exertional dyspnea are the most common symptoms, although fever is present in 25% of patients. Symptoms are usually present for 6–10 months before diagnosis. As in other IIPs, the laboratory evaluation is nonspecific.

Chest radiography usually shows bilateral interstitial infiltrates, and sometimes the result can be normal in a symptomatic patient. HRCT characteristically shows bilateral, patchy ground-glass attenuation indistinguishable from DIP or RB-ILD.[23]

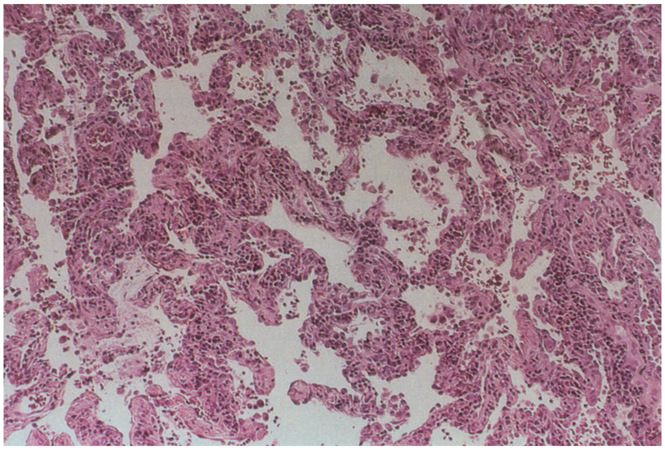

FIG 72.9 Histopathology of Nonspecific Interstitial Pneumonitis. Low-magnification photomicrograph of cellular nonspecific interstitial pneumonitis shows diffuse uniform thickening of the alveolar septum as a result of the presence of a lymphoplasmacytic infiltrate.

Histopathology

NSIP is characterized by varying, but temporally uniform, degrees of fibrosis and inflammation of the alveolar septum, without the histopathological features indicative of UIP, AIP, or DIP (Fig. 72.9). NSIP has been divided into three groups, depending on the presence or absence of interstitial fibrosis: interstitial lymphoplasmacytic inflammation (48% of cases); inflammation and fibrosis (38%); and fibrosis (14%). Although the changes are temporally uniform, they may be patchy with intervening areas of normal lung.

This temporal uniformity is in contrast to the variegated pattern seen in UIP. Fibroblast foci, the earliest lesions seen in UIP, are found in 20% of patients with NSIP, making it difficult to differente fibrotic NSIP from UIP. The key feature in this circumstance is the temporal uniformity of the lesions in NSIP.

Treatment and Outcome

Unlike patients with UIP, individuals with NSIP have a favorable prognosis. In the original description of the disease, 45% of subjects completely recovered, and the condition of another 42% remained stable or improved.[31] Only 11% of patients died, with a mean survival of 16 months. All of the individuals with an aggressive course were in the fibrotic group. Ten-year survival in the cellular group was 90%, compared with 35% in patients with the fibrotic pattern. Despite the worse prognosis of NSIP with a fibrosing pattern, this is still significantly better than the 15% 10-year survival rate for patients with UIP.[32]

Cryptogenic Organizing Pneumonia

COP is a specific clinicopathologic disorder of unknown etiology characterized by excessive proliferation of granulation tissue within the lumen of distal airspaces.[33] The term COP is reserved for cases demonstrating bronchiolitis obliterans organizing pneumonia (BOOP) without an obvious cause, since this histological appearance occurs in a variety of inflammatory lung disorders, including CTDs, malignancy, infections, and those caused by medications.

Clinical Manifestations

The onset of disease is usually in the fifth to sixth decades of life; men and women are equally affected. Most individuals have symptoms for less than 2 months before diagnosis. The initial presentation is usually with a dry, nonproductive cough and flu-like symptoms, including fever, sore throat, and malaise. This is followed by progressive dyspnea, and routine laboratory evaluation is nonspecific.

Chest radiography shows diffuse, often patchy alveolar opacities in the setting of normal lung volumes (Fig. 72.10A). These opacities can be migratory and usually have a peripheral distribution similar to those seen in chronic eosinophilic pneumonia. Rarer radiographic manifestations include linear or nodular interstitial opacities and honeycombing. The presence of a pleural effusion or pleural thickening should suggest an associated CTD. HRCT shows patchy airspace consolidation, especially in the lung periphery with a lower-lung zone predominance (see Fig. 72.10B). Other findings include ground-glass attenuation, small nodular opacities, and bronchial wall thickening.

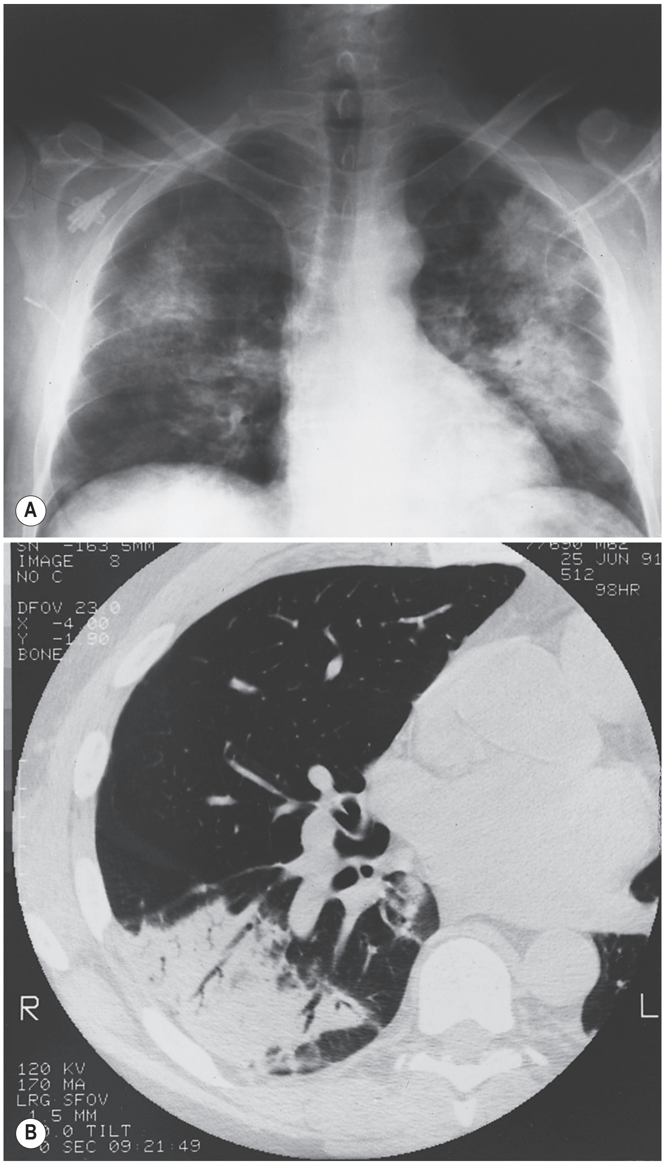

FIG 72.10 **Radiographic Findings in Cryptogenic Organizing Pneumonia.** (A) Chest radiograph in a patient with cryptogenic organizing pneumonia shows bilateral patchy alveolar opacities with a peripheral distribution in the setting of normal lung volumes. (B) Chest computed tomography shows a dense right lower lung consolidation with the presence of air bronchograms.

As in other ILDs, a restrictive ventilatory defect is the most common pulmonary function abnormality. Gas exchange abnormalities are common and are accompanied by decreased diffusing capacity, widening of the alveolar–arterial gradient, and exercise-induced hypoxemia.

Histopathology

The histopathology of COP is characterized by excessive proliferation of granulation tissue in the small airways and alveolar ducts with associated chronic inflammation in the alveolar walls (Fig. 72.11).[33] The intraluminal fibrotic buds (Masson bodies) consist of loose collagen-embedding fibroblasts and myofibroblasts and have a tendency to extend from one alveolus to the next, giving a characteristic "butterfly" pattern. The lesions are patchy in nature and have a uniform temporal appearance at low magnification, with preservation of the underlying lung parenchyma. This pattern has been described as the prototypical healing response of the lung to a variety of insults.

Diagnosis

The presence of BOOP in a lung biopsy does not necessarily represent COP, since COP is a diagnosis of exclusion. Organizing pneumonia is a nonspecific response to many lung injuries and can occur in conjunction with another pathological process or as a component of other primary pulmonary disorders, such as infections, irradiation, CTD, hypersensitivity pneumonitis, granulomatosis with polyangiitis, or chronic eosinophilic pneumonia (Table 72.3).

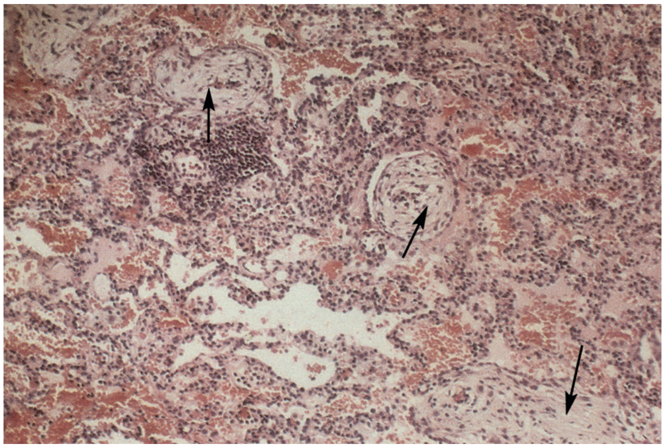

FIG 72.11 **Histopathology of Cryptogenic Organizing Pneumonia.** A photomicrograph of cryptogenic organizing pneumonia shows intraalveolar fibroblast proliferation (arrows) and early collagen production. In addition, thickening of the alveolar septa with a lymphoplasmacytic infiltrate consistent with cellular nonspecific interstitial pneumonitis is present.

TABLE 72.3 Disorders Associated With a Bronchiolitis Obliterans Organizing Pneumonia (BOOP) Pattern

Idiopathic BOOP (cryptogenic organizing pneumonia)
Connective tissue diseases
- Systemic lupus erythematosus
- Rheumatoid arthritis
- Polymyositis/dermatomyositis
- Sjögren syndrome

Hypersensitivity pneumonitis
Chronic eosinophilic pneumonia
Drug-induced
- Gold
- Penicillamine
- Amiodarone
- Bleomycin
- Sulfa drugs

Granulomatosis with polyangiitis (wegener granulomatosis)
Bone marrow transplantation
Lung transplantation/rejection
Inhalational injury
Neoplasms
Lung irradiation
Virus-associated
- Human immunodeficiency virus (HIV)
- Influenza virus
- Adenovirus

TABLE 72.4 Pleuropulmonary Manifestations of Connective Tissue Diseases

	SLE	RA	SSc
Pulmonary hypertension	+	+	+++
Vasculitis	+	±	±
Pleural disease	+++	+++	+
Bronchiolitis obliterans	±	++	+
Aspiration pneumonia	–	–	++
Diaphragmatic dysfunction	++	–	–
Lung nodules	–	++	–
Diffuse alveolar damage	+	±	±
BOOP	±	+	±
UIP	+	++	+
Capillaritis	++	+	±
LIP	+	+	+
NSIP	+	++	++

BOOP, bronchiolitis obliterans organizing pneumonia; LIP, lymphocytic interstitial pneumonia; NSIP, nonspecific interstitial pneumonia; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SSc, systemic sclerosis; UIP, usual interstitial pneumonitis.

Treatment and Outcome

Treatment with glucocorticoids usually offers dramatic clinical and radiographic improvement within days to weeks.[33] Complete clinical, physiological, and radiographic recovery occurs in two-thirds of cases. In the remainder, persistent disease progresses to fibrosis. It is common for relapses to occur with glucocorticoid tapering, followed by improvement with reintroduction of treatment; consequently at least 6 months of therapy is recommended. The 5-year survival rate in COP is 73%, compared with 5-year survival rates of 44% in patients with BOOP resulting from other causes (*e.g.,* CTD) or 30% for IPF.

LUNG INVOLVEMENT IN CONNECTIVE TISSUE DISEASES

CTDs are a heterogeneous group of systemic autoimmune diseases that frequently involve the lungs. The pleuropulmonary manifestations of these diseases are diverse, affecting all parts of the respiratory tract (*i.e.,* airways, alveoli, blood vessels, and pleura) (Table 72.4). Although pulmonary complications generally occur in patients with well-established disease, occasionally the lung involvement is the first manifestation of the autoimmune disorder. This section discusses the pleuropulmonary manifestations of systemic lupus erythematosus (SLE), RA, and systemic sclerosis (SSc) (for a discussion of other manifestations in these diseases, see Chapters 51, 52, and 55).

Systemic Lupus Erythematosus

SLE is a disease of unknown etiology characterized by the presence of autoantibodies directed against various nuclear antigens. These autoantibodies and the resultant immune complexes mediate many of the manifestations of SLE (Chapter 51). This disease mainly affects young women (female-to-male ratio >8 : 1) and may involve virtually every organ system. Pleuropulmonary involvement occurs at some point in the disease course in 38–89% of cases.[34] Thus the respiratory system is affected more commonly in SLE than in any other CTD. However, infectious pneumonia remains the commonest cause of pulmonary disease and death in these patients. Thus in patients with SLE presenting with a febrile illness and pulmonary infiltrates, a community-acquired or opportunistic infection must be promptly excluded.

Acute Lupus Pneumonitis

Acute lupus pneumonitis is an uncommon pulmonary manifestation of SLE, occurring in fewer than 5% of cases.[34] The clinical presentation mimics that of an infectious pneumonia with the abrupt onset of fever, cough, and dyspnea. Serum complement levels are often low, and chest radiography typically shows diffuse alveolar opacities. Acute lupus pneumonitis can be accompanied by pericarditis and often pleuritis and pleural effusion.

It can be difficult to distinguish acute lupus pneumonitis from an infectious pneumonia. BAL followed by thoracoscopic lung biopsy is recommended before instituting corticosteroid therapy. The histopathology varies and includes diffuse alveolar damage, BOOP, NSIP, or a combination of these.

There are no controlled trials of therapy for acute lupus pneumonitis. Treatment includes high-dose glucocorticoids (1–2 mg/kg/day) with or without accompanying cytotoxic drugs, such as cyclophosphamide. Mortality rates as high as 50% have been reported. In those patients who fail to respond to treatment, respiratory failure is the usual cause of death.

Diffuse Alveolar Hemorrhage

DAH occurs in fewer than 5% of patients with SLE, and it represents the initial manifestation of disease in 11–20% of those cases.[34] However, most cases develop in individuals with well-established diagnoses of SLE, usually with preexisting lupus nephritis.

The symptoms of DAH mimic those of infectious pneumonia and acute lupus pneumonitis.[34] Hemoptysis is present in 42–66%

of patients at presentation. Therefore the absence of hemoptysis does not exclude the diagnosis, particularly in the setting of a falling hematocrit, diffuse pulmonary infiltrates, and blood-stained BAL fluid. DAH in SLE most often results from pulmonary capillaritis, but it can also be caused by diffuse alveolar damage. Immunofluorescence studies show granular deposits of immunoglobulin G (IgG) and C3 along alveolar walls, interstitium, and capillary endothelial cells.

There are no controlled trials for the treatment of alveolar hemorrhage in SLE. Glucocorticoids, cytotoxic drugs, and plasmapheresis have been used in various combinations. The mortality rate associated with DAH is approximately 50%. Poor prognostic factors include the need for mechanical ventilation, presence of infection, and prior treatment with cyclophosphamide.

Lupus Pleuritis

The pleura are the most common site of respiratory involvement in SLE, with pleurisy and pleural effusions occurring in 50–80% of patients. Lupus pleuritis can be the presenting manifestation of disease, but more commonly, it develops in patients with established SLE. It is often recurrent. The clinical manifestations include chest pain, fever, and dyspnea, and chest radiography typically shows bilateral pleural effusions. The pleural fluid is serous or serosanguineous and exudative in nature. Compared with effusions in RA, the glucose is higher, and the lactate dehydrogenase level is lower. The most helpful measurement is a pleural fluid ANA titer greater than 1:160. Examination of the pleura reveals infiltration with plasma cells and lymphocytes, accompanied by pleural thickening and fibrosis. Treatment with nonsteroidal antiinflammatory drugs (NSAIDs) and/or glucocorticoids is usually effective for relief of pleural discomfort.

Interstitial Lung Disease

The presence of ILD in SLE is uncommon, especially compared with SSc or RA. However, minor interstitial abnormalities can be found on HRCT in approximately one-third of patients with SLE who have normal results of chest radiography and physiological testing. The significance and natural history of these subclinical findings are uncertain. The presence of anti-SSA (Ro) has been noted in approximately 80% of patients who have lupus with interstitial changes. In addition, the prevalence of ILD is increased in a subset of patients with SLE who have sclerodermatous skin changes.

The diagnosis of SLE is usually well established in patients who develop the insidious form of ILD. The disease course is characterized by progressive dyspnea and cough; chest radiography shows reduced lung volumes and reticular interstitial infiltrates. A restrictive lung function pattern with reduced diffusing capacity and exercise-induced hypoxemia are typical. The histopathology of chronic interstitial disease in SLE resembles NSIP, although cases of BOOP, LIP, and UIP have been described. Response to therapy depends on the underlying histopathology, with the UIP-like form being least responsive.

Pulmonary Vascular Disease

Although previously thought to be unusual, the development of pulmonary hypertension has been increasingly noted in SLE, with an incidence ranging from 0.5–14%. Pulmonary hypertension in SLE has been associated with the presence of Raynaud syndrome, serositis, digital vasculitis, and antiphospholipid antibodies.[35] Dyspnea and fatigue, despite normal results on chest radiography, is the most common presentation. Most of the patients with SLE who have pulmonary hypertension are female, with 3- and 5-year survival rates of 45% and 17%, respectively, representing a worse prognosis compared with that for patients with idiopathic pulmonary hypertension. The vascular changes of SLE-associated pulmonary hypertension are similar to those seen in idiopathic pulmonary hypertension with intimal hyperplasia, smooth muscle hypertrophy, and medial thickening. Several pathological mechanisms have been proposed for the development of pulmonary hypertension, including vasoconstriction, in addition to vasculitis and thrombosis associated with antiphospholipid and anticardiolipin antibodies. Serum endothelin levels are elevated in patients with SLE-associated pulmonary hypertension and correlate with pulmonary arterial pressures.

As the pulmonary hypertension advances, the central pulmonary arteries enlarge. Pulmonary function testing shows an isolated decrease in the diffusing capacity for carbon monoxide. Patients with SLE-associated pulmonary hypertension may respond to immunosuppressive therapy. In a small study, five of 12 patients with SLE responded to monthly intravenous bolus doses of cyclophosphamide in addition to systemic glucocorticoids. A positive response was indicated by sustained hemodynamic improvement after at least 1 year of treatment without the need for additional pulmonary hypertension–specific therapies. Patients who responded to immunosuppression could be maintained on azathioprine or mycophenolate mofetil to avoid potential adverse effects of cyclophosphamide. Patients with SLE who were treated with bosentan did not have clinical worsening and showed an improvement in 6-minute walk distance.[36] Overall, the long-term survival of patients with SLE-associated pulmonary hypertension is poor,[37] and the optimal treatment regimen for SLE-associated pulmonary hypertension remains unknown.

Respiratory Muscle Dysfunction

The shrinking lung syndrome is caused by diaphragmatic weakness as well as weakness of other respiratory muscles. This entity accounts for the findings of dyspnea without evidence of interstitial infiltrates or pulmonary vascular disease. It occurs in 25% of patients with SLE. Chest radiography typically shows elevated diaphragms and basilar atelectasis. The pathogenesis of respiratory muscle weakness is unknown, but it is not associated with generalized muscle weakness. Glucocorticoids are frequently ineffective in the treatment of this syndrome. Improvement has been noted with inhaled β-agonist and theophylline therapy. Despite a variable response to therapy, it is unusual for this manifestation of SLE to be progressive.

Rheumatoid Arthritis

RA is an autoimmune disease associated with autoantibodies directed against citrullinated antigens and characterized by the presence of a symmetrical, inflammatory polyarthritis (Chapter 52). It occurs more frequently in women, with a female-to-male ratio of 2:1. Disease onset is most commonly in the fourth to fifth decades of life. The pleuropulmonary complications of RA occur more commonly in individuals with subcutaneous nodules, high titers of rheumatoid factor, and more severe chronic articular involvement. Although RA itself is more common in women, the pleuropulmonary manifestations have a higher incidence in men. The pleuropulmonary complications of RA are numerous, but the treatment-related lung toxicity and pulmonary infections are difficult to differentiate from the primary pleuropulmonary manifestations of the disease.

Pleuritis and Pleural Effusions

As in SLE, pleural abnormalities are one of the most common pulmonary complications of RA. Pleural effusion is clinically evident in approximately 5% of patients, and this can occur before the development of arthritis. Pleural disease is often discovered as an incidental finding on routine chest radiography, but nonspecific chest pain, dyspnea, and fever are not unusual. The effusion can be unilateral or bilateral and can coexist with ILD.

Typically, the effusion is an exudate, with a glucose level less than 30 mg/mL in 70–80% of cases. The mechanism underlying the low pleural fluid glucose is impaired membrane transport of glucose. A low pleural fluid pH is thought to occur secondary to impaired carbon dioxide exit from the pleural space. If the effusion is chronic, the cholesterol concentration can be increased, and the pleural fluid can have a milky appearance (pseudochylothorax). Cytological examination reveals multinucleated giant cells, spindle-shaped macrophages, and necrotic debris.

Most rheumatoid effusions are small and asymptomatic, thus requiring no treatment. They resolve over several months without complications. The use of glucocorticoids for active articular disease hastens the resolution of the pleural process.

CLINICAL PEARLS

Lung Involvement in Rheumatoid Arthritis (RA)

- RA is more common in women, but pleuropulmonary complications occur more frequently in men.
- Factors associated with pleuropulmonary complications of RA include more severe articular involvement, subcutaneous nodules, and high levels of rheumatoid factor.
- Pleural effusions are the most common complication, characterized by an exudate and a low glucose and low pH.
- The differentiation of rheumatoid nodules from malignant lesions can be difficult.
- The rapid growth of a nodule should prompt aggressive investigation for a malignant cause.

Rheumatoid Nodules

Rheumatoid or necrobiotic nodules are the only pleuropulmonary manifestation specific for RA. These nodules are most commonly seen in men with active articular disease, high rheumatoid factor titers, and subcutaneous nodules. Most individuals are asymptomatic and are diagnosed on routine chest radiography. Radiographically, these nodules can be singular or multiple with an upper to midlung zone predominance. Cavitation occurs in approximately 50% of cases. HRCT indicates a higher frequency of nodules than previously thought. Rarely, subpleural necrobiotic nodules can erode into the pleural space, resulting in a pneumothorax with a complicating bronchopleural fistula. It can be difficult to differentiate these nodules from malignant lesions, and open-lung biopsy is frequently necessary. Evidence of rapid growth on chest radiography should prompt an aggressive diagnostic evaluation.

Caplan syndrome refers to the rapid development of pulmonary nodules predominantly in the upper lung zone. This syndrome was originally described in Welsh coalminers with RA. Histologically, these nodules are identical to necrobiotic nodules. Other occupational dust exposures have also been associated with this syndrome.

Airway Disease

Airflow limitation is a common finding in patients with RA, being present in approximately one-third of patients. The mechanism(s) responsible for airway disease is poorly understood. The interplay of cigarette smoking and RA may play a role.

A life-threatening complication of RA is upper airway obstruction, resulting from synovitis of the cricoarytenoid joint. Common presenting complaints include a sore throat, hoarseness, and fullness in the throat. It can progress to inspiratory stridor and upper airway obstruction. This complication occurs more commonly in women, particularly in those with advanced RA. Seventy-five percent of patients were found to have cricoarytenoid abnormalities when screening with direct or indirect laryngoscopy and computed tomography (CT) was utilized. The treatment of cricoarytenoid arthritis includes antiinflammatory medications.

Bronchiolitis obliterans is a progressive form of obstructive lung disease that is being increasingly recognized as a complication of RA.[38] This entity was thought to develop secondary to the use of penicillamine in the treatment of RA, but most cases occur in the absence of this therapy. The histopathological lesion of bronchiolitis obliterans is constrictive bronchiolitis, which is characterized by concentric submucosal and peribronchiolar fibrosis resulting in extrinsic compression and obliteration of the bronchiolar lumen. The typical clinical presentation is insidious onset of cough and dyspnea, with a normal or hyperinflated chest on radiography. This complication occurs more commonly in women than in men. Pulmonary function studies show airflow limitation with hyperinflation and a reduced diffusing capacity. Expiratory HRCT shows multiple areas of air trapping (mosaic pattern). Some individuals respond to high-dose glucocorticoids and cytotoxic drugs, but in most patients, bronchiolitis obliterans progresses to respiratory failure.

Bronchiectasis occurs at an increased frequency in RA, usually in individuals with long-standing articular disease. Productive cough and dyspnea are the most common respiratory symptoms. In most patients, bronchiectasis is not clinically significant. Recurrent pneumonia and respiratory failure are potentially fatal complications of this problem.

Interstitial Lung Disease

Although ILD is a common complication of RA, the incidence is difficult to determine, since different methods of detection have been employed and dissimilar populations of patients have been studied. However, clinically significant ILD occurs in approximately 14% of patients.[39] The development of ILD in relation to the onset of arthritis is variable. Most often, the ILD develops subsequent to arthritis, but in approximately 20% of patients, the lung disease precedes the onset of arthritis and is associated with cigarette smoking, presence of the shared HLA-DR4 epitope, and RA-specific anticitrullinated protein antibodies.

The most common histopathologies identified in this patient population are UIP, LIP, NSIP and BOOP. The clinical manifestations of ILD in RA resemble those seen in idiopathic disease and include a dry, nonproductive cough and dyspnea on exertion. Chest radiography and HRCT show increased reticular markings with a predilection for the peripheral lower lung zones. Often, pleural abnormalities accompany the interstitial changes. With advanced disease, progression to honeycomb lung occurs. LIP usually occurs in cases of RA complicated by Sjögren syndrome;

the presence of keratoconjunctivitis sicca and xerostomia in a patient with RA and ILD should suggest this histological type.

In general, ILD in RA appears more indolent than in the IIPs. Thus because of uncertain treatment benefits and possible adverse effects, the decision to institute therapy should be based on clinical, radiographic, and physiological deterioration.

Drug-Induced Lung Disease

Methotrexate and gold are the two main anti-RA drugs capable of causing lung injury. Methotrexate administered weekly (10–20 mg/week) is associated with the development of interstitial changes in 1–5% of patients with RA. No correlation with age, sex, disease duration, or cumulative dose has been identified. The clinical presentation is subacute, with fever, cough, and dyspnea occurring 1–5 months after initiation of the drug. Chest radiography shows mixed interstitial–alveolar infiltrates. Nonspecific laboratory abnormalities include leukocytosis, sometimes with mild eosinophilia, and an elevated erythrocyte sedimentation rate (ESR). In most cases, BAL reveals a lymphocytosis. Histologically, cellular NSIP is seen with areas of organizing pneumonia. Noncaseating, granulomatous inflammation similar to that seen in hypersensitivity pneumonitis may also be present. The primary treatment of methotrexate-induced pneumonitis is withdrawal of methotrexate, as well as appropriate supportive care.

Gold-induced pneumonitis occurs in fewer than 1% of patients with RA who are treated with gold. Dyspnea and cough usually begin after 4–6 weeks of therapy; eosinophilia occurs in a minority of patients. Chest radiography typically reveals mixed alveolar–interstitial opacities with a predilection for the upper lung zone. The histology is similar to that seen in patients with RA-associated ILD. Thus the differentiation of gold-induced pneumonitis from RA-associated ILD can only be established when discontinuation of the medication results in remission.

Systemic Sclerosis (Scleroderma)

SSc is characterized by excessive deposition of ECM in the skin and internal organs, and vascular involvement (Chapter 55). The degree of visceral organ involvement determines morbidity and mortality. Pulmonary involvement occurs in 70–100% of patients with SSc. There is no correlation with the degree of extrapulmonary disease. ILD is the most common pulmonary manifestation of SSc. Of note, with the improved mortality associated with renal involvement in SSc, lung disease has become the most important cause of morbidity and mortality.

Interstitial Lung Disease

The incidence of ILD in SSc depends on the method of detection. Autopsy studies have reported an ILD incidence of 60–100% of cases, whereas studies based on chest radiography have noted interstitial changes in 14–66% of cases. Cough and dyspnea on exertion are the most common symptoms. Physical examination reveals bibasilar rales. Radiographic findings include basal reticulonodular infiltrates, enlargement of pulmonary arteries, and progressive volume loss. Pulmonary function testing reveals restrictive lung disease, preservation of flow rates, and decreased diffusing capacity. A disproportionate decrease in diffusing capacity compared with lung volume changes should suggest pulmonary hypertension, especially in individuals with limited scleroderma (calcinosis, Raynaud phenomenon [RP], esophageal dysmotility, sclerodactyly, telangiectasia [CREST] syndrome). The predominant histopathologic abnormality is NSIP. Rarely, LIP may complicate cases of SSc associated with Sjögren syndrome. Although the 5-year survival for patients with SSc and ILD is 38–45%, it is better than that of patients with IPF.

Pulmonary Vascular Disease

Pulmonary hypertension is a frequent complication of SSc, occurring in approximately 30% of patients with diffuse scleroderma and in 10–50% of those with limited scleroderma (Chapter 55). It is a major cause of morbidity and mortality in systemic sclerosis and has also become part of the diagnostic criteria for the disease.[40] Pulmonary hypertension can either be associated with interstitial fibrosis or result from involvement of small and medium-sized arteries and arterioles with smooth-muscle hyperplasia, medial hypertrophy, and intimal proliferation (plexogenic). Direct involvement of the pulmonary circulation is more common with limited scleroderma, whereas pulmonary hypertension in patients with diffuse scleroderma is more likely associated with ILD.

The clinical presentation is characterized by the insidious onset of fatigue and dyspnea on exertion. Physical examination and chest radiography show signs typical of pulmonary hypertension, whereas a decreased diffusing capacity is seen on pulmonary function testing. Risk factors for developing SSc-associated pulmonary hypertension include limited skin involvement, duration of disease greater than 10 years, onset of SSc at older age, and severity and duration of RP.

The pathogenesis of SSc-associated pulmonary hypertension is poorly understood. Vascular changes occur at an early stage in SSc and include apoptosis, endothelial cell activation with increased expression of cell adhesion molecules, inflammatory cell recruitment, intimal proliferation, and adventitial fibrosis leading to vessel obliteration. Endothelial injury is reflected by increased levels of soluble cell adhesion molecules, disturbances of angiogenesis with increased levels of circulating vascular endothelial growth factor (VEGF), and the presence of angiostatic factors. To what extent dysregulated angiogenesis in SSc-associated pulmonary hypertension is driven by an inflammatory process or other as yet unidentified mechanisms remains unclear.

Treatment of SSc-associated pulmonary hypertension has been disappointing, with no therapy showing a significant survival benefit. Calcium channel blockers are not usually indicated for patients with SSc-associated pulmonary hypertension, although often used at lower doses for RP. Continuous intravenous epoprostenol improves exercise capacity and hemodynamics.[41] Randomized clinical trials with phosphodiesterase inhibitors, including sildenafil, showed a modest effect on exercise capacity, hemodynamic parameters, and functional class after 12 weeks of treatment. Carefully selected patients may be considered for heart–lung transplantation but are often excluded because of the risk of postoperative complications arising from SSc-related gastroesophageal reflux disease (GERD) and renal dysfunction.

CONCLUSIONS

ILDs comprise a diverse group of disorders ranging from idiopathic etiologies to those related to an underlying autoimmune condition. There is likely a complex interplay between the innate and adaptive arms of the immune system and the profibrotic pathways that lead to the development of these various disease states. Future work should focus on better understanding this relationship and, more importantly, translating these findings to the clinical setting. The role of standard immunosuppressive approaches with the ongoing discovery of novel approaches to

ON THE HORIZON

- Our understanding of the idiopathic interstitial pneumonias (IIPs) and autoimmune-related interstitial lung diseases (ILDs) has evolved over time. With increased emphasis being placed on diagnosis, because of the implications for treatment and prognosis, we are more accurately phenotyping the diseases. This has led to a better understanding of genetic associations, biological pathways, as well as more accurate identification of risk factors for disease development and progression.
- However, there are still many areas in need of further understanding and research. In the future, determining whether risk factor identification and modification can lead to primary and/or secondary prevention strategies in the treatment of immunological lung diseases will be essential.
- Testing if the novel antifibrotic therapies approved for idiopathic pulmonary fibrosis (IPF) are more broadly applicable to other forms of ILDs, including autoimmune-related ILD, will be important.
- Other therapies that target the immune system also need to be more carefully studied in diseases outside of IPF.

targeting the immune system as well as novel antifibrotic therapies will need to be determined.

MULTIPLE-CHOICE QUESTIONS

1. The most common pulmonary manifestations of systemic lupus erythematosus (SLE) is:
   A. Interstitial lung disease (ILD)
   B. Diffuse alveolar hemorrhage (DAH)
   C. Pleural effusion
   D. Pulmonary hypertension

2. Idiopathic pulmonary fibrosis (IPF) is characterized by:
   A. The pathological lesion of usual interstitial pneumonitis
   B. A relentless progression and a poor prognosis despite therapeutic intervention
   C. The presence of interstitial opacities in a basilar and peripheral distribution
   D. All of the above

3. Which of the following statement regarding systemic sclerosis (SSc) is correct?
   A. Renal involvement and renal crisis remain the predominant cause of mortality in SSc.
   B. Pulmonary hypertension is a newly added diagnostic criteria for SSc.
   C. The most common lung pathological lesion in SSc is lymphocytic interstitial pneumonitis (LIP).
   D. Calcium channel blockers are indicated for patients with SSc-associated pulmonary hypertension.

Sarcoidosis

Edward S. Chen, David R. Moller

Sarcoidosis is a systemic inflammatory disorder characterized by the presence of noncaseating granulomas and lymphocyte inflammation.[1,2] The disease most frequently involves lungs and thoracic lymph nodes, although any organ system can be involved (Table 73.1). The manifestations and clinical course of sarcoidosis vary greatly.[3] An estimated 30–60% of patients with sarcoidosis are asymptomatic, usually with isolated bilateral hilar adenopathy, and clearly some of these patients remain unidentified. Symptomatic manifestations most frequently involve the respiratory system, with symptoms of cough, dyspnea, and chest discomfort. Löfgren syndrome is a distinct presentation of acute sarcoidosis, with polyarthritis, bilateral hilar adenopathy, erythema nodosum, and often uveitis. This form of sarcoidosis usually resolves completely. Other clinical manifestations depend on the range and extent of extrapulmonary involvement. More than one-third of patients will experience chronic active disease, which is associated with considerable risk of long-term morbidity resulting from progressive organ dysfunction and complications of immunosuppressive treatment. Given the lack of validated biomarkers of disease activity, the management of sarcoidosis involves serial assessment of symptoms, radiographic imaging, and objective measurement of organ function.

EPIDEMIOLOGY

Sarcoidosis is found worldwide, although there are striking differences in the prevalence of the disease in different geographical areas and racial groups.[4] In Europe and North America, the estimated prevalence ranges from 10 to 64 cases per 100 000, with higher rates in African-American populations. Although it can occur at any age, over 80% of cases are diagnosed between 20 and 50 years of age, with a further peak after age 50 years.[4,5] Globally, there is a slight female preponderance. Sarcoidosis may present differently in men and women,[6] and it presents differently in older people, complicating case identification.[7] Recent studies have supported prior observations of worse outcomes in African American women compared with other demographic groups in the United States.[8,9]

The frequency of clinical manifestations and disease severity varies among different groups. Löfgren syndrome has a particularly high frequency in the Scandinavian countries and in Ireland but occurs in <5% of African American patients with sarcoidosis. Lupus pernio, a disfiguring nodular facial condition associated with chronic sarcoidosis, is more frequent in patients of African descent. Cardiac involvement occurs in >50% of Japanese patients with sarcoidosis, but in only 10–25% of European and North American patients. Retrospective studies suggest that sarcoidosis is the direct cause of death in 1–6% of cases, usually from pulmonary, cardiac, or neurological involvement.[10]

GENETICS

There is substantial evidence for a genetic predisposition to sarcoidosis, including higher concordance among monozygotic twins than among dizygotic twins and familial clustering in 5–16% of patients. A US-based multicenter study compared 706 newly diagnosed cases of biopsy-proven sarcoidosis to age-, sex-, and race-matched relatives and found an approximate fivefold increased relative risk in siblings and parents of individuals with sarcoidosis.[11]

Major histocompatibility complex (MHC) class II alleles are major contributors to disease susceptibility across different ethnic populations.[12] Human leukocyte antigen–D related 3 (HLA-DR3) is associated with increased sarcoidosis risk in Scandinavian and European populations, whereas HLA-DR1 and HLA-DR4 alleles are associated with disease protection. A significant association was found with HLA-DRB1*11:01 in African Americans and Caucasians, whereas HLA-DRB1*15:01 was a risk factor only in Caucasians. Residues forming pocket 4 of HLA-DR and pocket 9 of HLA-DQ seem to influence sarcoidosis risk, which suggests specific antigenic peptides are involved in causing sarcoidosis. HLA class I alleles (B*07, A*03) also confer risk for sarcoidosis, independently from HLA class II alleles. Together, these HLA associations with sarcoidosis may reflect the effects of an 8.1 ancestral haplotype (*A1, B8, DR3, DQ2*) that is linked to several other immune-related diseases; larger studies will be necessary to determine the independent risks associated with each allele.

HLA class I and II alleles are associated with clinical course. HLA DRB1*03:01 and DQB1*02:01 are associated with favorable outcomes, whereas DR14 and DR15 are associated with severe, chronic disease in European and Japanese populations, as are the closely linked alleles DRB1*1501:01 and DQB1*06:02.

Studies of non-HLA polymorphisms have yielded few clues to the genetic basis of sarcoidosis. A meta-analysis found polymorphism of the gene for tumor necrosis factor-α (TNF-α) associated with a 1.5-fold increased risk of developing sarcoidosis.[13] Associations were reported between sarcoidosis and the CC chemokine receptors CCR2 and CCR5 and the receptor for

TABLE 73.1 Major Clinical Features of Systemic Sarcoidosis

Organ System (Approx. % Involvement)	Major Clinical Features
Pulmonary (90)	Bilateral hilar adenopathy, restrictive and obstructive disease, fibrocystic disease, bronchiectasis, mycetomas
Upper airway (5–10)	Hoarseness, laryngeal or tracheal obstruction, nasal congestion, sinusitis, saddle nose deformity
Ocular (25)	Anterior and posterior uveitis, chorioretinitis, conjunctivitis, optic neuritis, glaucoma, lacrimal gland enlargement
Skin (20–30)	Cutaneous and subcutaneous nodules and plaques, erythema nodosum, lupus pernio, hypopigmented macules
Hepatic (10)	Hepatomegaly, pruritus, jaundice, cirrhosis
Cardiac (10–15)	Arrhythmias, heart block, cardiomyopathy, sudden death
Central nervous system (5–10)	Cranial neuropathies (*e.g.,* Bell palsy), aseptic meningitis, brain mass, seizures, obstructing hydrocephalus, myelopathy, polyneuropathy, mononeuritis multiplex, small-fiber neuropathy
Salivary and parotid gland (<10)	Salivary and parotid gland enlargement, sicca syndrome
Hematologic (30–50)	Lymphadenopathy, splenomegaly, hypersplenism, anemia, lymphopenia, thrombocytopenia
Joints/ musculoskeletal (10–20)	Polyarthritis, bone cysts, Achilles tendonitis, dactylitis, heel pain, myopathy
Endocrine (<10)	Hypercalciuria (more common), hypercalcemia, hypopituitarism, diabetes insipidus
Renal (<5)	Renal calculi, nephrocalcinosis, renal failure, epididymitis, testicular mass

advanced **g**lycation **e**nd products (RAGE), but wider confirmation is lacking. Although strongly associated with early-onset sarcoidosis in children, NOD2/CARD15/IBD1 has not been linked with sarcoidosis in adults.[14] No association has been found between sarcoidosis and serum angiotensin-converting enzyme (ACE), vitamin D–converting enzyme, or the *NRAMP1* gene (linked to tuberculosis).

Genome-wide association studies (GWAS) in both familial and sporadic cases of sarcoidosis have identified chromosomal regions both inside and outside the MHC region, which contribute to sarcoidosis susceptibility. The butyrophilin-like 2 (*BTNL2*) gene within the MHC locus is associated with sarcoidosis risk in Caucasians and, to a lesser extent, African Americans.[15] Despite its proximity to the MHC locus, the *BTNL2 rs206530* allele can confer increased risk for chronic active sarcoidosis in patients without Löfgren syndrome.[16,17] *BTNL2* belongs to the immunoglobulin (Ig) gene superfamily and is costimulatory for T-cell activation, providing a hypothetical link with sarcoidosis. The gene encoding annexin A11 has also been associated with sarcoidosis, potentially affecting granuloma formation through its involvement in apoptosis and cellular proliferation.[18] A gene interaction network analysis suggested that T-helper 1 (Th1) and Th17 signaling pathways are involved in sarcoid immunopathogenesis.[19]

ENVIRONMENTAL FACTORS

Environmental factors have been implicated in the etiology of sarcoidosis with reports of time–space clustering and a higher incidence of disease in the springtime months. Health care workers, military personnel, and firefighters may also have a higher incidence of sarcoidosis.

The largest study of sarcoidosis etiology found weak positive associations (odds ratio [OR] ≈1.5) with workplace exposure to insecticides, mold, mildew, and musty odors.[3] Sarcoidosis was not associated with exposure to heavy metals, wood dusts, or rural residence, but smoking appeared to be protective. Studies of rescue workers and others exposed to the heavy dust burden from the World Trade Center terror attack found an increased incidence of a sarcoidosis-like granulomatous pulmonary disease.[20] A significant proportion of these patients had extrapulmonary manifestations, including chronic nonerosive polyarthritis, suggesting that they fall within the spectrum of systemic sarcoidosis.[21]

Role of Infectious Agents

Since the initial descriptions of sarcoidosis, investigators have looked for evidence of microbial infections in sarcoidosis because of its clinical similarities to other infectious diseases, most notably tuberculosis. Polymerase chain reaction (PCR) studies have shown microbial DNA in sarcoidosis tissues consistent with prior exposure to mycobacteria. Overall mycobacterial DNA was detected 10–20-fold more often in sarcoidosis versus control tissue.[22] The Kveim reaction also suggests a transmissible agent—intradermal inoculation with an extract from sarcoidosis tissue induces epithelioid granulomas indistinguishable from those in sarcoidosis biopsies.[23] Several groups have now demonstrated lung and blood CD4+ and CD8+ T-cell responses to multiple mycobacterial antigens in sarcoidosis, including mKatG, *Mycobacterium tuberculosis* ESAT-6, Ag85, superoxide dismutase, and heat shock proteins.[24,25] These studies suggest that mycobacterial organisms trigger sarcoidosis in a subgroup of patients.

Studies from Japan report the presence of *Propionibacterium acnes* or *P. granulosum* genomes in 80–98% of sarcoidosis tissues from Japan and Europe but also in up to 60% of control tissues.[26] In animal models, *P. acnes* proteins have been shown to induce Th1-driven granulomatous inflammation, partly via Toll-like receptor 9 (TLR9) stimulation. Given that these are commensal organisms on normal skin and upper airways, their pathogenic role remains undefined.

Although direct demonstration of an infectious etiology remains unproven, most investigators favor the hypothesis that certain classes of microbial organisms trigger sarcoidosis in those with genetic susceptibility.

AUTOIMMUNITY

Patients with sarcoidosis often have low-titer autoantibodies that may be part of the generalized hypergammaglobulinemia observed in many patients as a result of T-cell activation.[27] No disease-specific autoantibodies have yet been identified, so it remains unknown whether autoimmunity plays a role in sarcoidosis.

IMMUNOLOGY/PATHOGENESIS

KEY CONCEPTS

Immunopathogenesis of Sarcoidosis

- Noncaseating epithelioid granulomas
- Genetic susceptibility primarily involving major histocompatibility complex (MHC) genes
- Oligoclonal expansion of T-cell receptor specific T cells consistent with antigen-driven inflammation
- T-helper 1 (Th1) polarization at sites of disease
  - Decrease in regulatory T-cell (Treg) function contributes to Th1-mediated inflammation
  - Potential role of interferon (IFN)-γ–expressing Th17.1 cells
  - Potential role of classical Th17 effector cells
- Etiology involves microbial triggers
  - Mycobacterial or propionibacterial organisms most commonly implicated
- Role of innate immunity in macrophage activation and granuloma formation
- Progressive accumulation of serum amyloid A (SAA) within granulomas may drive chronic disease
  - Nidus for granuloma formation
  - Feed-forward amplification of local Th1 responses in part through Toll-like receptor 2 (TLR2)

The histological hallmark of sarcoidosis is the presence of discrete, compact noncaseating granulomas (Fig. 73.1). The dominant cell in the central core is the epithelioid cell, thought to be a differentiated mononuclear phagocyte. CD4+ T cells and mature macrophages are interspersed throughout the epithelioid core, whereas CD4+ and CD8+ T cells are seen around the periphery of the granuloma. Multinucleated giant cells are scattered throughout the inflammatory locus. In the lung, granulomas tend to form along areas that are rich in lymphatic vessels, such as the bronchovascular, bronchial submucosal, and interlobular septal regions.[28]

Prior to the 1980s, sarcoidosis was thought to be a disease of immune depression with blood lymphopenia and cutaneous anergy. Subsequently, bronchoalveolar lavage (BAL) studies in pulmonary sarcoidosis showed that there were, in fact, enhanced cell-mediated immune processes at sites of granulomatous inflammation with activated CD4 BAL lymphocytes. These BAL T cells are $CD4^+$ with a $CD45RO^+$ "memory" phenotype expressing high levels of activation molecules DR and VLA-1 (very late antigen-1, CD49a). Direct evidence that sarcoidosis is an antigen-driven disorder comes from studies of T-cell receptor (TCR) gene expression. These studies document the expansion of oligoclonal populations of T cells expressing specific α/β or γ/δ TCR in BAL, blood, or skin (Kveim biopsy). The most compelling data were derived from HLA-DRB1*03:01-positive Swedish patients who have greatly increased numbers of $AV2S3^+$ Th1 cells in the lung. The expanded oligoclonal $\alpha\beta^+$ T-cell subsets in sarcoidosis often contain shared amino acid motifs in the CDR3 region of their $V\beta$ or $V\alpha/J\alpha$ genes, consistent with an antigen-driven T-cell response. The antigenic specificities of these expanded T-cell clones remain to be identified.

Th1 Polarization in Sarcoidosis

T cells at sites of disease show a highly polarized Th1 cytokine profile at the time of diagnosis (Fig. 73.2).[29] BAL studies have demonstrated expression of interferon-γ (IFN-γ) and tumor necrosis factor (TNF) in pulmonary sarcoidosis. Consistent with a polarized type 1 process, Th1-promoting cytokines interleukin-12 (IL-12), -18, -2, -15, and -27 are upregulated in sarcoidosis-affected tissues. Chemokines and chemokine receptors that are typically associated with Th1 responses, such as CXCR3, CCR5, MCP-1, RANTES, MIP-1, MIG, and osteopontin (early T-lymphocyte activation protein), are upregulated in sarcoidosis, as are the Th1-differentiation transcription factor signal transducer and activator of transcription 1 (STAT1) and its phosphorylated form. Th1-associated gene expression signatures in sarcoidosis tissues have linked CXCL9 with chronic disease activity.[30]

Other evidence of the importance of polarized Th1 immunity in sarcoidosis comes from clinical experience with biological therapies with Th1-promoting effects, such as IFN-α, IFN-γ, and IL-2, which have been associated with new or recrudescent

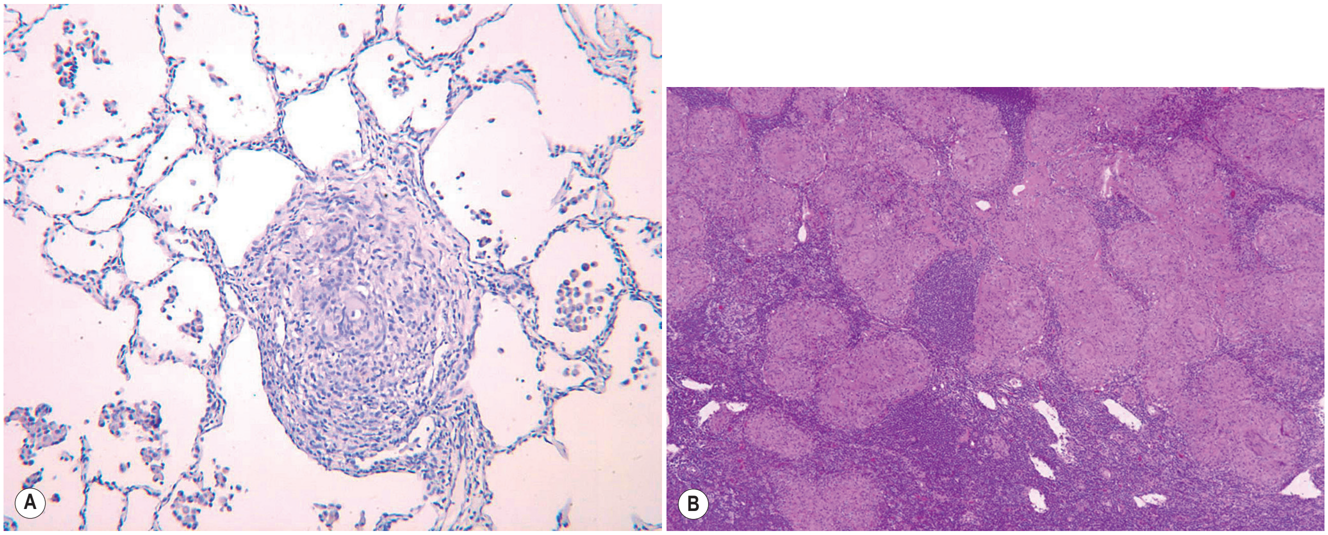

FIG 73.1 (A) Open lung biopsy showing typical noncaseating epithelioid granuloma, giant cells, and lymphocytic infiltrates in lung parenchyma in sarcoidosis. (B) Lymph node biopsy showing extensive replacement with well-defined epithelioid granulomas in a patient with sarcoidosis.

3. Misfolded/aggregated SAA "seeds" further SAA accumulation and release of soluble SAA peptides
4. SAA induces feed-forward amplification of local Ag-specific Th1 responses to trapped Ags
Inability to clear SAA and Ags leads to chronic inflammation and fibrosis
Clearance of SAA and Ags allows remission

FIG 73.2 Conceptual Model of the Immunopathogenesis of Sarcoidosis. Granuloma formation in sarcoidosis results from stimulation by poorly soluble antigens that evoke a hyperimmune T-helper 1 (Th1) response with stimulation of interferon (IFN)-γ, along with tumor necrosis factor (TNF), interleukin (IL)-12, IL-10, and other cytokines from mononuclear phagocytes and dendritic cells. As a consequence of this response, misfolded serum amyloid A (SAA) aggregates in an amyloid-like process to provide a persistent poorly soluble nidus and a template for further SAA aggregation within sarcoidosis granulomas. SAA and SAA peptides released from the granulomas stoke a feed-forward stimulation of macrophages and T cells that amplifies polarized Th1 responses to local tissue antigens. This course continues to progress unless there is removal of stimulating antigen(s) and clearance of SAA, allowing remission of Th1-driven granuloma formation. The model depicts mycobacterial organisms as the etiological trigger, although other microbes or environmental agents might trigger a similar pathogenic pathway.

sarcoidosis. Conversely, low or undetectable levels of IL-4, IL-5, and Th2-associated chemokines and chemokine receptors are found in the sarcoidosis lung.[31] Sarcoidosis has also been described in patients with 5q-myelodysplasia with deletion of Th2 genes.

Th17 effector responses may drive the granulomatous response in sarcoidosis, although they are a minority of CD4 effector T cells. Most IFN-γ–producing cells in BAL from patients with sarcoidosis bear a Th17 phenotype termed *Th17.1*, although their transcriptional profile remains to be studied.[32] BAL cells from patients with Löfgren syndrome strongly express transcriptional regulators of Th1 (T-bet$^+$) and Th17 (RORγT$^+$).[33] Further work is needed to assess whether and how a Th1/Th17 permissive environment affects clinical outcomes in sarcoidosis.

CD4+ regulatory T cells (Tregs) show reduced numbers and function in sarcoidosis.[34,35] This suggests that Treg deficiency contributes to the imbalanced Th1 (and Th17) responsiveness in these patients. CD4$^+$CD25$^{\text{bright}}$FOXP3$^+$ T cells (natural Tregs) accumulate at the periphery of sarcoidosis granulomas, in BAL fluid, and in the peripheral blood of patients with active disease but are functionally deficient, with reduced ability to inhibit granuloma formation *in vitro*.[34] Nebulized vasoactive intestinal peptide (VIP) has been shown to significantly reduce TNF production by lung cells in sarcoidosis and increased the frequency of lung CD4$^+$CD127$^-$CD25$^+$ Tregs, possibly by converting naïve CD4$^+$CD25$^-$ T cells to Tregs, suggesting that inhaled VIP might be a treatment for sarcoidosis.[36] Longitudinal studies will be necessary to confirm the relationship between T-cell subsets and the clinical course of sarcoidosis. Other studies find a reduced number of immunoregulatory CD1d-restricted Vα24$^+$ natural killer T (NKT) cells in the blood of patients with nonremitting sarcoidosis, suggesting that lack of these cells may play a role in chronicity.

Innate Immunity in Sarcoidosis

Far fewer studies have looked at innate immune mechanisms, but evidence is mounting that TLRs and other innate immune receptors may be involved in sarcoidosis. For example, enhanced responses to TLR2 stimulation, including induction of TNF, have been observed in the lung and blood cells of patients with sarcoidosis.[37] TLR2 interacts with innate ligands as a heterodimer with other TLR subunits. Analysis of the TLR10–TLR1–TLR6 gene cluster on chromosome 4 has suggested that the absence of the common haplotype is associated with increased risk for developing chronic active sarcoidosis.[38]

Patients with sarcoidosis also show increased responsiveness to ligands for the TLR-2/1 heterodimer and decreased responses TLR-2/6 ligands.[37] Together, these findings support a potential role for aberrant TLR2 responsiveness in sarcoidosis.

A major conceptual challenge in sarcoidosis is understanding how pulmonary fibrosis occurs in an environment dominated by IFN-γ, which is known to inhibit collagen synthesis. Alternatively activated macrophages (M2) have been histologically associated with myofibrosis in biopsy specimens of muscular sarcoidosis.[39] Although an M2 macrophage phenotype is often associated with a Th2 cytokine environment (which has never been identified in sarcoidosis, even in late fibrotic disease), a fibrosis-promoting M2c macrophage phenotype could be induced by IL-10 or CCL18, which are present in sarcoidosis tissues.[40,41] M2 macrophages can promote fibrocyte recruitment through the expression of transforming growth factor (TGF), CCL18, and CXCL12; M2 macrophages are also capable of differentiation to fibrocyte-like cells that express collagen. It remains unclear whether M2-like macrophages result from mechanisms inherent to sarcoidosis or from generalized wound-healing responses.

Serum Amyloid A Aggregation Hypothesis

Although sarcoidosis is associated with prior exposure to mycobacterial or other microbial organisms, there is no clinical or pathological evidence of active infection or reactivation of latent microbial infection in sarcoidosis. This holds true in patients after years of corticosteroid, immunosuppressive, or anti-TNF therapy.

The physicochemical properties of the Kveim reagent closely resemble those of amyloid or prion proteins. Serum amyloid A (SAA) can be detected in epithelioid macrophages in sarcoidosis. This appears to be disease specific and several orders of magnitude greater than in other granulomatous disorders.[42,51] SAA stimulates expression of TNF, Th1-related cytokines, and IL-10 via TLR2 in the lung cells of patients with sarcoidosis. Sarcoidosis may therefore involve the induction, misfolding, and aggregation of SAA as a result of an aberrant hyperpolarized Th1 response to specific microbial triggers (see Fig. 73.2). Misfolded SAA may promote progressive self-aggregation in an amyloid-like process, with SAA and its peptides amplifying Th1 responses to pathogenic tissue antigens present within sarcoidosis granulomas. This mechanism could explain the cardinal clinical feature of chronic monophasic progressive inflammation in untreated sarcoidosis, in the absence of any tissue infection.[1]

PATIENT EVALUATION AND DIFFERENTIAL DIAGNOSIS

Pulmonary Sarcoidosis

The most common symptoms of pulmonary sarcoidosis are cough, progressive shortness of breath, and ill-defined chest discomfort of variable severity (see Table 73.1). Chronic sputum production and hemoptysis are more frequent in advanced fibrocystic disease. Typically, there are few physical findings. Lung crackles are heard in <20% of patients, and clubbing is rare. Pulmonary hypertension and cor pulmonale are important but underrecognized complications, associated with higher mortality rates.

Chest radiography (CXR) results are abnormal in over 90% of sarcoidosis patients. By convention, the chest radiograph is divided into the following stages:

0: Normal CXR
I: Bilateral hilar adenopathy
II: Bilateral hilar adenopathy + interstitial infiltrates
III: Interstitial infiltrates only (nonfibrotic)
IV: Fibrotic interstitial lung disease

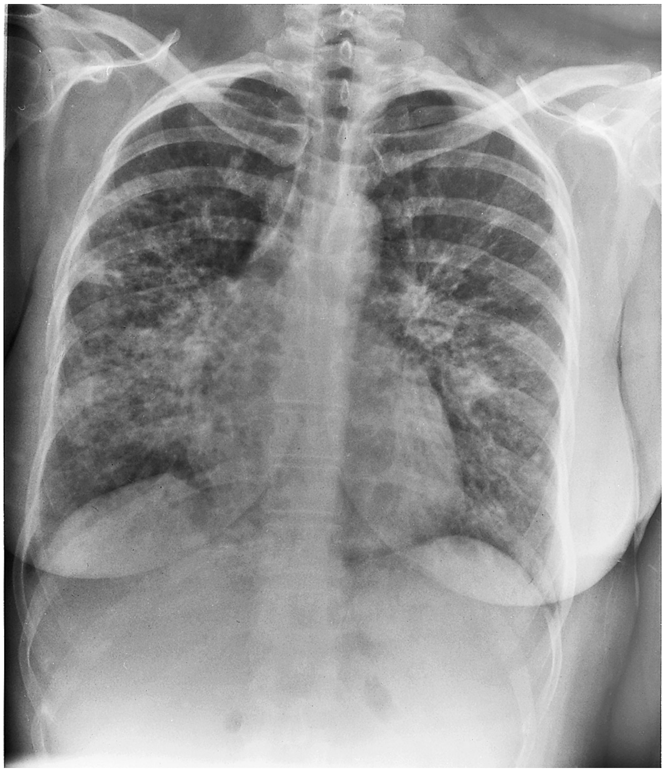

FIG. 73.3 Stage II chest radiograph with bilateral hilar adenopathy and reticulonodular infiltrates.

Stage I is initially seen in 40–50% of cases. Typically, the hilar adenopathy is discrete, symmetrical, and often accompanied by right paratracheal adenopathy. Stage II CXR, often with mid- or upper-zone infiltrates, is seen in 20–30% of presenting cases (Fig. 73.3). Stage III is seen in 10–20% of cases at presentation. Those with fibrotic changes are frequently placed in a separate subgroup, stage IV, in recognition of the poor outcome of this group of patients (Fig. 73.4). More unusual patterns of pulmonary sarcoidosis include large, well-defined, nodular infiltrates; miliary disease; or a pattern of patchy air-space consolidation with air bronchograms, termed “alveolar sarcoidosis.” Pleural effusions and pneumothorax are rare.

Computed tomography (CT) of the chest is more sensitive than plain radiography in demonstrating enlarged lymph nodes and pulmonary infiltrates. Chest CT typically demonstrates nodular infiltrates that follow central bronchovascular structures (Fig. 73.5). Studies correlating the value of the CXR stage against objective assessments of chest CT are lacking. However, in childhood sarcoidosis, longitudinal scoring of the findings on high-resolution CT (HRCT) of the chest correlates with changes in pulmonary function.[43]

Pulmonary function tests do not correlate well with CXR stage. In patients with stage I CXR, pulmonary function tests are normal in about 80% of cases or show just isolated reduction in carbon monoxide diffusing capacity (DL_{co}). When pulmonary infiltrates are present on CXR, 40–70% of cases show restrictive impairment with reduced forced vital capacity (FVC) and forced expiratory volume per second (FEV_1), and/or reduced DL_{co}. Obstructive impairment is found in 30–50% of patients with abnormal CXR results, mainly in advanced fibrocystic sarcoidosis. Bronchial hyperreactivity is present in 10–30% of patients.

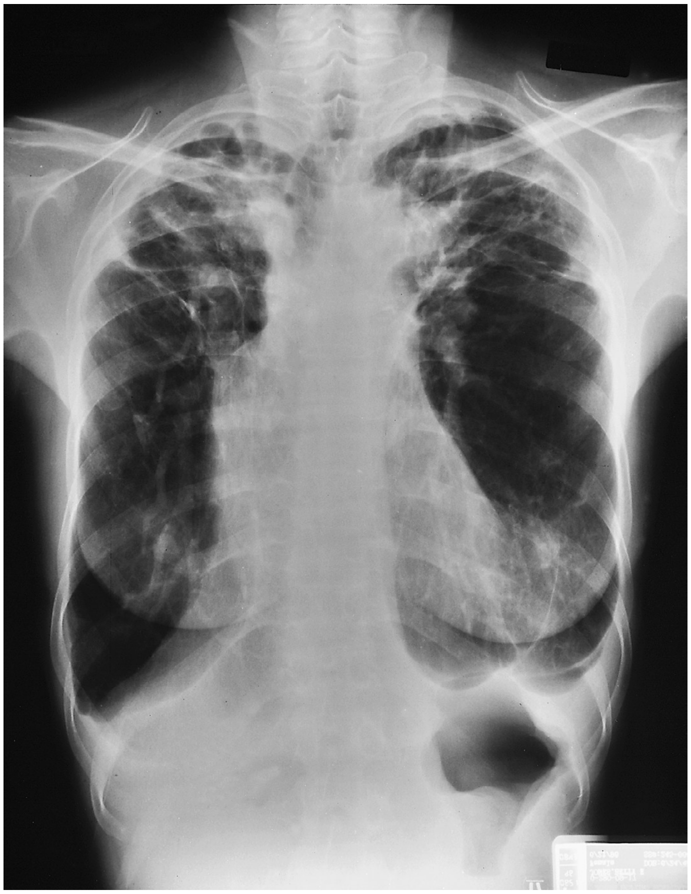

FIG 73.4 Stage IV chest radiograph of fibrocystic pulmonary sarcoidosis with typical upward hilar retraction and multiple cystic and bullous changes.

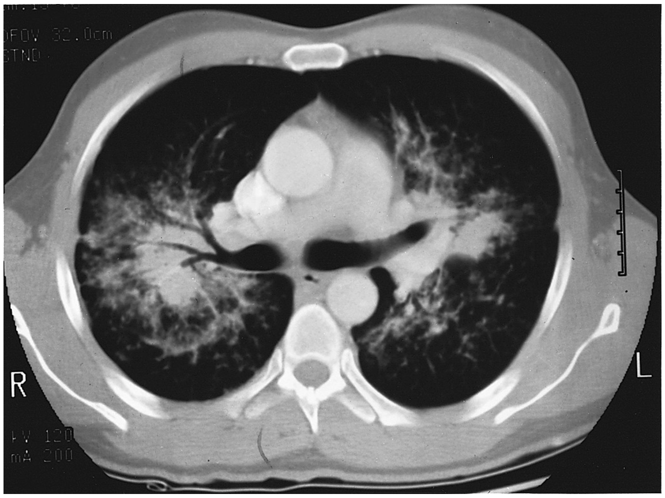

FIG 73.5 Computed tomography scan demonstrating bilateral hilar, paratracheal, and paraaortic lymphadenopathy with interstitial infiltrates in a dominantly central bronchovascular distribution.

Pulmonary hypertension is an underrecognized complication of pulmonary sarcoidosis affecting at least 5% patients and up to 50% of patients with dyspnea that is not explained by the level of pulmonary function impairment.[44] Screening for pulmonary hypertension is indicated in patients with advanced lung disease because of the associated increased mortality.

Extrapulmonary Sarcoidosis

Most patients have clinically important involvement of more than one organ, either with or without pulmonary sarcoidosis (see Table 73.1).

Sarcoidosis of the Upper Respiratory Tract

Sarcoidosis can cause nasal congestion, crusting, epistaxis, anosmia, rhinorrhea, sinusitis, or nasal septal perforation; a "saddle nose" deformity, palatal perforation, or bone erosion may occur. Laryngeal sarcoidosis occurs in 1–5% of patients, with hoarseness, dysphonia, dysphagia, dyspnea, or, rarely, stridor and acute respiratory failure.

Ocular Sarcoidosis

Unilateral or bilateral anterior uveitis is the most common manifestation of ocular sarcoidosis, often in association with bilateral hilar adenopathy. Chronic uveitis occurs in up to 20% patients with chronic sarcoidosis, more frequently in Black populations. Other manifestations include posterior uveitis, granulomatous conjunctivitis, severe chorioretinitis, or optic neuritis that can cause blindness (Chapter 74).

Cutaneous Sarcoidosis

Erythema nodosum, which is a feature of Löfgren syndrome, may recur. Chronic skin sarcoidosis usually manifests as nontender, nonpruritic plaques and subcutaneous nodules around the hairline, eyelids, ears, nose, mouth, and the extensor surfaces of arms and legs. Lupus pernio is a disfiguring form of facial cutaneous sarcoidosis, with violaceous plaques and nodules covering the nose, nasal alae, and malar areas and the area around the eyes.

Cardiac Sarcoidosis

Cardiac involvement is clinically apparent in <5–10% of patients with sarcoidosis in North America and Europe, although autopsy studies have suggested that the prevalence may exceed 25%. In Japan, cardiac involvement is more common, occurring in more than 50% of patients. Complete heart block, bundle branch blocks, ventricular arrhythmias, sudden death, cardiomyopathy, supraventricular arrhythmias, and valvular dysfunction may occur. Current advice is to screen for cardiac sarcoidosis at presentation, via assessment of symptoms (palpitations, syncope), electrocardiography (ECG), and echocardiography.[45]

Hepatic Sarcoidosis

Symptoms of hepatic sarcoidosis include fever, tender hepatomegaly, and/or pruritus. Characteristically, serum alkaline phosphatase and γ-glutamyl transferase are elevated proportionately higher than aspartate and alanine aminotransferases or bilirubin, although all patterns can occur. "Abdominal sarcoidosis" refers to a constellation of liver, spleen, and abdominal lymph node involvement, which is often associated with hypercalcemia; pulmonary involvement may not be evident.

Joints and Bones

Arthralgias are common in multisystem sarcoidosis, although joint radiographs are usually normal. Acute, often incapacitating, polyarthritis involving the ankles, feet, knees, and wrists may occur in Löfgren syndrome. Persistent joint disease with pain, swelling, and tenderness of the phalanges of the hands and feet is found in <5% of patients with chronic sarcoidosis. Joint radiographs may demonstrate "punched-out" lesions with cystic changes without erosive chondritis. Cystic lesions of the long bones, pelvis, sternum, skull, and vertebrae are rare.

Neurosarcoidosis

Neurosarcoidosis occurs in 5–15% of patients with sarcoidosis. The most common manifestation is cranial neuropathy, most frequently bilateral or unilateral seventh-nerve (facial) palsy. The palsy may resolve spontaneously or with corticosteroids but sometimes recurs years later. Optic neuritis may result in blindness. Manifestations of central nervous system (CNS) involvement include mass lesions, aseptic meningitis, obstructive hydrocephalus, and hypothalamic/pituitary dysfunction. Seizures, headache, change in mental status, confusion, and diabetes insipidus may be presenting symptoms. Myelopathy with paraparesis, hemiparesis, and back and leg pain have been described. Peripheral neuropathies account for ≈15% of cases of neurosarcoidosis, often presenting as mononeuritis multiplex or a primary sensory neuropathy. Small-fiber neuropathies with or without autonomic neuropathy are increasingly recognized in patients with sarcoidosis, particularly those with pain and chronic disease.

Salivary, Parotid, and Lacrimal Gland Sarcoidosis

Parotid or lacrimal gland enlargement and sicca syndrome may be the dominant clinical manifestations of sarcoidosis. Heerfordt syndrome, also known as *uveoparotid fever,* manifests as fever, parotid and lacrimal gland enlargement, uveitis, and bilateral hilar adenopathy, sometimes with cranial neuropathies (usually facial palsy).

Hematological Sarcoidosis

Peripheral lymph node enlargement occurs in 20–30% patients as an early manifestation of sarcoidosis but then typically remits spontaneously. Persistent, bulky lymphadenopathy occurs in <10% of patients. Splenomegaly occurs in <5% of cases. It is occasionally massive and often associated with hepatomegaly or hypercalcemia. Polyclonal hypergammaglobulinemia is present in ≥25% of patients.

Sarcoidosis Myopathy

Although random muscle biopsy specimens at autopsy have demonstrated muscle granulomas in most patients with sarcoidosis, symptomatic myopathy with weakness and tenderness is uncommon. Rarely, sarcoidosis can present as a polymyositis with profound weakness and elevated serum creatine kinase and aldolase.

Hypercalcemia, Hypercalciuria, and Renal Disease

Hypercalcemia is present in 2–5% of patients; hypercalciuria is more common. Abnormal calcium regulation may cause kidney stones or nephrocalcinosis and is thought to result from enhanced conversion of 25-OH vitamin D_3 to the active 1,25-$(OH)_2$ vitamin D_3 by macrophages and epithelioid cells in granulomas expressing 1α-hydroxylase (also known as *cytochrome p450 27B1*). Importantly, if patients with sarcoidosis are screened for vitamin D deficiency, they may have low 25-OH vitamin D_3 levels and elevated active 1,25-$(OH)_2$ vitamin D_3 levels, placing them at risk of nephrocalcinosis with renal failure if they are given vitamin D supplements.

Psychosocial Manifestations

Depression and/or fatigue have been found in 30–60% patients with symptomatic sarcoidosis. Depression is associated with female sex, lower socioeconomic status, poor access to care, and increased disease severity, but not with race.

KEY CONCEPTS

Clinical Relevance

- Multisystem disease with heterogeneous manifestations and clinical course
- Diagnosis based on consistent manifestations and biopsy showing typical pathology
    - No useful biomarkers for diagnosis or prognosis
    - Differential includes infections (mycobacterial, fungal), malignancy (*e.g.,* lymphoma), immunoglobulin G4 (IgG4)–related disease; interstitial lung diseases
- Association with T-helper 1 (Th1) –promoting therapies
    - After treatment with interferon (IFN)-α, IFN-γ, and interleukin (IL)-2 and other biologicals
    - After immune reconstitution in patients with human immunodeficiency virus (HIV) infection undergoing highly active retroviral therapy (HAART)
- Goal of treatment with immunosuppressive medications is to preserve function of affected organs while improving quality of life
    - Clinical trials needed to establish roles of individual therapies
    - Benefit of anti–tumor necrosis factor (TNF) therapies point to a role for TNF in sarcoidosis

Associated Conditions

Sarcoidosis and Pregnancy

Pregnancy usually has little effect on the course of sarcoidosis, although some patients experience spontaneous improvement. In those whose condition improves during pregnancy, exacerbations frequently follow several months after delivery. The temporary clinical improvement may relate to suppressed Th1 immunity during pregnancy.

Th1-Promoting Therapeutics

Administration of Th1-promoting therapeutics, such as IFN-α, IFN-γ, IL-2, and IFN-β, has been linked to initiation or recrudescence of sarcoidosis.

Common Variable Immunodeficiency

Sarcoidosis is associated with common variable immunodeficiency (CVID) in both adults and children. A high index of suspicion must be maintained for this in patients with sarcoidosis who have recurrent infections.

IgG4-Related Disease

This lymphoproliferative disorder involves multiple organ systems and can be mistaken for sarcoidosis, particularly when central or peripheral adenopathy are present. Distinguishing features of IgG4-related disease include the presence of dense lymphoplasmacytic infiltrates on biopsy, autoimmune pancreatitis and other autoimmune phenomena, and the presence of fibrosis in organs not commonly involved in sarcoidosis, such as the peritoneum, aorta, and thyroid gland.

Human Immunodeficiency Virus

Sarcoidosis may develop in patients infected by human immunodeficiency virus (HIV) with immune reconstitution after starting antiretroviral therapy, perhaps from reconstituted Th1 immunity. Granulomatous inflammation of skin or lungs is most often reported.

Autoimmune Disorders

Sarcoidosis has been described in association with autoimmune diseases, such as Crohn disease, ulcerative colitis, primary biliary cirrhosis, scleroderma, Sjögren syndrome, autoimmune hemolytic anemia, and autoimmune endocrinopathies. These associations could result from a common, predisposing altered Th1/Th17 immunity.

Cancer

Multisystem sarcoidosis may develop in patients with a recent history of cancer or following chemotherapy treatment, perhaps related to a rebound in immunological responsiveness following successful treatment.

Diagnosis

The diagnosis of sarcoidosis is based on a compatible clinical picture, histological evidence of noncaseating granulomas, and the absence of other known causes of this pathological response. Chronic beryllium disease and hypersensitivity pneumonitis must be excluded when there is a compatible history, and clinical findings are confined to the lung. In the absence of defined multisystem disease, sarcoidosis is a presumptive diagnosis, as local "sarcoid" reactions can occur in response to infection, tumor, or foreign material. Biopsy confirmation of sarcoidosis is not usually necessary in Löfgren syndrome, except in regions where histoplasmosis is endemic.

In general, biopsy of the easiest, most accessible abnormal tissue site is used to confirm the diagnosis. Biopsy of a skin nodule, superficial lymph node, lacrimal gland, nasal mucosa, conjunctivae, or salivary gland (lip biopsy) helps establish a diagnosis.

Biopsy by fiberoptic bronchoscopy is frequently used to diagnose pulmonary sarcoidosis because of its relative safety and high yield. The yield of transbronchial biopsy is operator dependent but approaches 50–85% of patients when pulmonary infiltrates are present. Endoscopic bronchial ultrasonography has improved the diagnostic yield of sampling intrathoracic lymph nodes in sarcoidosis. Mediastinoscopy or surgical lung biopsy is considered when lymphoma or other intrathoracic malignancy cannot be excluded and less invasive techniques have not given definitive answers. Imaging techniques, such as gadolinium-enhanced MRI, ^{18}F-fluorodeoxyglucose (FDG)-positron emission tomography (PET) scanning, or ^{67}gallium scanning, are nonspecific but may assist in assessing inflammation in the heart, brain, and bone or in directing biopsy.

Initial diagnostic evaluation of a patient with possible sarcoidosis should include tests for the presence and extent of pulmonary involvement and screening for extrathoracic disease. If cardiac symptoms are present, echocardiography and Holter monitoring should be performed. Cardiac magnetic resonance imaging (MRI) or cardiac PET have greater sensitivity in demonstrating patchy inflammation or scarring compared with gated technetium(^{99m}Tc) sestamibi scanning or echocardiography.[46] Endomyocardial biopsy is positive in <10–25% cardiac sarcoidosis cases because of the patchiness of the granulomatous inflammation, so a negative biopsy result never excludes the diagnosis. Diagnosis of cardiac sarcoidosis is usually made by histological confirmation of sarcoid at a noncardiac site in association with compatible cardiac imaging, conduction abnormalities, or arrhythmias.

CLINICAL PEARLS

Tests Recommended for an Initial Evaluation of a Patient With Sarcoidosis

- Chest radiography or chest computed tomography (CT)
- Pulmonary function tests
  - Spirometry
  - Diffusing capacity
  - Lung volumes
  - Flow–volume loop (if suspected upper airway obstruction)
- Slit-lamp examination (to exclude subclinical uveitis)
- Blood tests
  - Comprehensive metabolic panel (calcium; liver and renal functions)
  - Complete blood count, including differential and platelet count
  - Measurement of active $1,25\text{-(OH)}_2$ vitamin D_3
- Electrocardiography
- Purified protein derivative skin test or blood test for latent tuberculosis

MRI with gadolinium enhancement is the best way to detect the characteristic inflammatory lesions of CNS or spinal cord sarcoidosis, particularly in the periventricular and leptomeningeal areas. A normal scan does not exclude neurosarcoidosis, particularly for cranial neuropathies or during corticosteroid therapy. Cerebral spinal fluid characteristically demonstrates lymphocytic pleocytosis and/or elevated protein levels. Diagnosis of neurosarcoidosis is usually confirmed by biopsy of a non-CNS site (*e.g.*, lung or lymph node). Rarely, brain biopsy is needed to exclude infectious or malignant disease. In suspected cases of peripheral neuropathy or myopathy, electromyography (EMG) or nerve conduction studies should be considered. Small-fiber neuropathy can be confirmed by performing quantitative immunohistochemistry of appropriate skin biopsy specimens.

Other Diagnostic Studies

No noninvasive tests are useful in making a diagnosis of sarcoidosis. Serum ACE levels are elevated in 40–90% of patients with clinically active disease, but these are nonspecific and may be found in other inflammatory and granulomatous diseases as well.

CLINICAL COURSE AND PATIENT MANAGEMENT

The clinical course of sarcoidosis is highly variable. Overall, 50–65% of patients undergo spontaneous remission, usually within the first 2–3 years. Löfgren syndrome is associated with spontaneous remission in >70–80% of patients. Peripheral adenopathy, salivary and parotid gland enlargement, and Bell palsy generally subside spontaneously or with treatment and do not recur. Elevated serum liver function tests also may revert to normal without treatment. Remission is observed in approximately 50–80% of patients with a stage I CXR, 30–60% with a stage II CXR, and 20–30% with a stage III CXR. Patients with a stage IV CXR with fibrocystic changes rarely (<5%) experience remission.

Extrapulmonary disease that is severe at presentation tends to persist and require treatment. Overall, mortality ranges from 1–6%, with the major causes being advanced pulmonary, cardiac, and neurological involvement.[10]

The intensity of surveillance of sarcoidosis depends on the severity of clinical presentation. When sarcoidosis undergoes remission, the disease rarely recurs; exceptions often involve neurological or ocular manifestations. No biomarkers have been found to be useful in management decisions.

TREATMENT

THERAPEUTIC PRINCIPLES

Indications for Corticosteroid Therapy in Patients With Sarcoidosis

- Pulmonary involvement
  - Moderate or severe, symptomatic pulmonary disease
  - Progressive, symptomatic pulmonary disease
  - Persistent pulmonary infiltrates or abnormal lung function for 1–2 years with mild symptoms to assess reversibility
  - Advanced fibrocystic disease
- Extrapulmonary involvement
  - Threatened organ failure: severe ocular, cardiac, or central nervous system (CNS) disease
  - Posterior uveitis or anterior uveitis not responding to local steroids
  - Persistent hypercalcemia
  - Persistent renal or hepatic dysfunction
  - Pituitary disease
  - Myopathy
  - Palpable splenomegaly or evidence of hypersplenism, such as thrombocytopenia
  - Severe fatigue and weight loss
  - Painful lymphadenopathy
  - Disfiguring skin disease

Current therapies are nonspecific and largely unproven.[47] If there is no organ-threatening involvement at presentation, a period of observation is usually indicated to evaluate whether the disease will remit spontaneously.

Corticosteroids remain the mainstay of therapy for progressive organ-threatening or life-threatening manifestations of sarcoidosis. The optimal doses and duration of corticosteroid treatment have not been established by rigorous clinical studies. For pulmonary and cutaneous disease, initial treatment is usually with no more than 20–40 mg/day of prednisone for 2–4 weeks, followed by a slow tapering regimen over several months to a maintenance dose of 5–15 mg/day. Alternate-day therapy has been suggested, although it may be ineffective in a subgroup of patients who subsequently respond to daily dosing. Treatment is normally continued for at least 6–12 months, as premature tapering is likely to result in relapse. Recurrent, progressive pulmonary disease occurs in 16–74% of patients as corticosteroid therapy is tapered; patients with repetitive relapses usually need chronic suppressive therapy to minimize loss of lung function. Weight gain, hypertension, hyperglycemia, glaucoma, and osteoporosis are serious potential complications. Bisphosphonate therapy is recommended for patients on chronic corticosteroid therapy. Inhaled corticosteroids may help reduce symptoms of cough or airway irritability but are not useful as sole agents in pulmonary sarcoidosis.

Pentoxifylline, a phosphodiesterase inhibitor, was shown to be beneficial in one study of mild pulmonary sarcoidosis, although wider experience suggests only very few patients respond to it. Gastrointestinal side effects often limit the dose that is tolerated.

ALTERNATIVE CYTOTOXIC THERAPIES

Corticosteroid-sparing therapies are frequently used for chronic, progressive sarcoidosis when corticosteroid adverse effects significantly degrade quality of life.[2,47,48] Low-dose weekly methotrexate (10–20 mg/week) is recommended for pulmonary, cardiac, ocular (panuveitis), cutaneous, and neurological sarcoidosis requiring higher doses of corticosteroids. Success rates range from 50% to 70%, but it may take ≥6 months to be effective. Potential serious complications include hepatotoxicity, opportunistic infections, bone marrow suppression, and pulmonary toxicity. Azathioprine can also be useful in sarcoidosis with similar response rates to methotrexate but a slightly increased risk of infection. Mycophenolate mofetil and leflunomide have been used as steroid-sparing agents in small case series. Potential drug toxicities for all four drugs include bone marrow suppression, gastrointestinal symptoms, skin rashes, and an increased risk of malignancy. Cyclophosphamide has been used in steroid-recalcitrant sarcoidosis, particularly refractory neurosarcoidosis, but its use is severely limited because of its oncogenic potential. Calcineurin inhibitors suppress T-cell activation but do not work in sarcoidosis.

Clinical trials support the effectiveness of biological agents targeting specific immunological pathways in sarcoidosis. Infliximab (anti-TNF) had a small impact on pulmonary function over 6 months but was effective for many extrapulmonary manifestations. Case series have suggested that adalimumab may also be effective in some patients with sarcoidosis. Etanercept, golimumab (anti-TNF), and ustekinumab (anti–IL12/IL23) were ineffective in pulmonary sarcoidosis. Interestingly, there have been some case reports of successful use of rituximab (anti–B cell) in treatment-refractory sarcoidosis, particularly neurosarcoidosis, although how it may work in sarcoidosis remains unclear. Further studies are needed to define the role of biological agents (Chapter 89) in sarcoidosis, not least because these therapies carry risks of serious, life-threatening infections and malignancy.

SPECIFIC SITUATIONS

Löfgren Syndrome

Nonsteroidal antiinflammatory drugs (NSAIDs) are recommended for relief of constitutional symptoms and joint pains. For disabling arthritis or severe constitutional symptoms, corticosteroids are almost immediately effective and can generally be tapered over a few weeks to months.

Mucocutaneous and Joint Sarcoidosis and Hypercalcemia

Hydroxychloroquine is often tried as a first-line treatment for cutaneous, joint, nasal, or sinus manifestations when corticosteroids are not immediately needed. Hypercalcemia may also respond to hydroxychloroquine as maintenance therapy. Chloroquine may be effective in some patients unresponsive to hydroxychloroquine but has a greater potential for ocular toxicity and is rarely used. Minocycline and doxycycline have been effective in a small number of patients with cutaneous sarcoidosis, but wider experience shows that these drugs are rarely effective.

Ocular Sarcoidosis

Anterior uveitis is usually treated with topical corticosteroids. Oral or intravenous corticosteroids are used initially for posterior uveitis, chorioretinitis, or optic neuritis.

Pulmonary Hypertension

Small retrospective case series have suggested that pulmonary vasodilator treatment can reduce pulmonary artery pressure and improve exercise dyspnea and 6-minute walk distance in patients with sarcoidosis who have pulmonary hypertension.[49] The benefit of vasodilator therapy on survival rates remains uncertain.[50]

Cardiac Sarcoidosis

Initial treatment consists of cardiac medications (antiarrhythmic therapy, diuretics, and afterload-reducing agents) along with corticosteroid therapy that may reverse heart block, reduce arrhythmias, and improve cardiac function. Corticosteroids are recommended in moderate doses as some studies have found no difference in 5-year survival rates for patients treated with prednisone >30 mg/day versus <30 mg/day. Higher doses are often used initially for intractable arrhythmias or heart block. Cardiomyopathy may require long-term treatment, and cytotoxic drugs are often used for steroid sparing. Small case series have suggested that TNF inhibitors may be useful, but caution is advised with regard to their use, since these agents can worsen congestive heart failure in nonsarcoidosis cardiomyopathy. Automatic implantable defibrillators and/or pacemakers are indicated in patients at risk for sudden death from serious arrhythmias or heart block, although their prophylactic use remains controversial. The effectiveness of radiofrequency ablation for prevention of arrhythmias in cardiac sarcoidosis remains uncertain.

Neurosarcoidosis

High doses of oral corticosteroids (60–80 mg/day) or high-dose pulse intravenous therapy are often used for serious CNS involvement. Tapering should be performed over several months after confirming suppression of inflammation by objective criteria (*e.g.,* serial MRI scans). With the exception of cranial neuropathies, neurosarcoidosis tends to be chronic and requires long-term therapy.

Depression/Fatigue/Pain

Small case series have highlighted the existence of small-fiber neuropathy and autonomic neuropathy in sarcoidosis, particularly in patients with pain. A few case reports have suggested that anti-TNF therapies may be beneficial in small-fiber neuropathy, but their role in sarcoidosis remains undefined. Intravenous immunoglobulin (IVIG) has also been effective in a subset of patients with small-fiber neuropathy (Chapter 84). One study suggested that the stimulant dexmethylphenidate hydrochloride may be helpful in treating chronic fatigue in sarcoidosis. Therapies directed at treating depression may improve quality of life in these patients, although clinical trials are lacking.

Role of Transplantation in Sarcoidosis

Lung, heart, kidney, and liver transplantations have been performed successfully in patients with sarcoidosis. Recurrent granulomas are found in the transplanted organs of some patients but are generally responsive to increased immunosuppression. Overall, survival rates with lung and cardiac transplantations in sarcoidosis are similar to those in other organ-specific diseases.

OPPORTUNITIES FOR PROGRESS IN SARCOIDOSIS

ON THE HORIZON

- Diagnostic and prognostic tools based on:
  - Genotyping
  - Genomic/microbiome/proteomic and immunological signatures
- Improvements in imaging techniques to assist in assessment of organ involvement
- Multicenter clinical trials of immune-altering therapies for treatment of sarcoidosis

We have the necessary foundations for making rapid progress in understanding sarcoidosis. Although there is considerable clinical heterogeneity, distinct clinical phenotypes are well established, from acute sarcoidosis (Löfgren syndrome) to chronic progressive organ disease. It is known that the genetic basis of sarcoidosis predominantly resides within the MHC. Immunological hallmarks of the disease include noncaseating granulomas and highly polarized Th1 and Th17 immunity with proinflammatory cytokines, such as TNF, at sites of disease, associated with reduced Treg activity. Evidence from multiple centers suggests that mycobacterial and possibly propionibacterial organisms may trigger sarcoidosis. The recent identification of innate immune pathways, one of which involves SAA, suggests mechanisms that may explain the pathogenesis of chronic sarcoidosis in the absence of active chronic infection. The challenge for the next 5–10 years is to translate these laboratory discoveries into clinical tools to assist the clinician in providing the diagnosis and prognosis for individual patients. Newer therapies are sorely needed for the treatment of patients with sarcoidosis, particularly those who have chronic disease and generally require long-term maintenance therapy. The potential for curing this disease is suggested by a remission rate of >50%, although progress toward this goal awaits a better understanding of the mechanisms that allow remission to occur. Research that integrates assessment of clinical phenotype, genetic background, and individual immunophenotypical and environmental triggers in different subgroups of patients may offer the best chance for rapid progress.

MULTIPLE-CHOICE QUESTIONS

1. Is cardiac sarcoidosis a rare manifestation?
2. True or false, sarcoidosis rarely results in airway obstruction.
3. True or false, stage IV sarcoidosis indicates advanced, widespread, multisystem disease.
4. True or false, Sarcoidosis represents an immune deficiency state.
5. True or false, calcineurin inhibitors are useful as treatment for sarcoidosis.

74

Immunological Ocular Disease

James T. Rosenbaum, Phoebe Lin

The immune system can induce disease in virtually any portion of the eye. Examples include conjunctivitis, keratitis, keratoconjunctivitis, uveitis, scleritis, optic neuritis, and orbital inflammation. The anatomy of the eye is depicted schematically in Fig. 74.1. Uveitis is defined as inflammation of the uveal tract, which is the middle layer of the eye, divided into the anterior uvea (iris, ciliary body) and posterior uvea (choroid). The uvea is sandwiched between an outer layer (sclera) and an inner layer (retina). The anterior segment is separated from the posterior segment by the lens. Two relatively common immunologically mediated ocular diseases, discussed elsewhere in this volume, are sicca secondary to Sjögren syndrome (Chapter 54) and anterior ischemic optic neuropathy secondary to giant cell arteritis (Chapter 59). Before considering the various ocular inflammatory disorders, it is critical to review some unique considerations related to ocular immunology.

OCULAR IMMUNE PRIVILEGE

Many of the mechanisms that drive inflammation in the eye are identical to those operating at other tissue sites. The major difference between the immunopathology of intraocular inflammation and that of systemic inflammatory disease relates to the fact that the eye, like the brain and the testis, is an immunologically privileged site. During uveitis, keratitis, and scleritis, as well as following corneal transplantation, a variety of local immunosuppressive mechanisms act to limit the damage caused by infiltrating leukocytes and, consequently, to influence the patient's clinical course. One of the most important factors is the constitutive expression of Fas ligand (FasL) within the eye. In addition, normal ocular tissues produce relatively high levels of immunomodulatory cytokines and immunosuppressive neuropeptides, as well as complement. Other factors include the blood–aqueous and blood–retinal anatomical barriers, limited major histocompatibility complex (MHC) expression, a paucity of lymphatic drainage channels within the eye, and, in the case of the cornea, the complete absence of blood vessels. The term *anterior chamber–associated immune deviation* (ACAID) describes the suppression of a cell-mediated immune response when soluble antigen is directly injected into the aqueous humor. All of the above factors contribute to ACAID.

FAS LIGAND

Most immune cells, including neutrophils, monocytes, macrophages, and lymphocytes, express Fas (CD95) on their surface. The interaction between Fas and its receptor FasL (CD95L) triggers apoptosis of the Fas-bearing cell. FasL is constitutively expressed within the eye, being detected in normal cornea, anterior uvea, and retina. The importance of FasL to ocular immune privilege has been demonstrated primarily in experimental models of ocular inflammation. Corneal allografts from FasL-negative mice into recipients of normal phenotype are rejected in all cases, whereas approximately half of FasL-positive grafts survive.[1] When injected into the eyes of FasL-deficient mice, herpes simplex virus (HSV) causes a severe invasive infection. A similar procedure in normal phenotype control animals results in relatively minor inflammation. Levels of FasL in the aqueous humor during human acute anterior uveitis are capable of inducing apoptosis in Fas-positive lymphoid cells. In this self-limiting condition, as well as in relevant rodent models, apoptosis of infiltrating T cells is observed early in the course of the inflammation. In addition to FasL, the local expression of tumor necrosis factor (TNF)–related apoptosis inducing ligand (TRAIL) by corneal endothelium also contributes to enhanced apoptosis and immune privilege within the eye.[2]

CYTOKINES, NEUROPEPTIDES, AND COMPLEMENT IN THE PROMOTION AND REGULATION OF OCULAR INFLAMMATION

The aberrant immune activation that occurs in uveitis appears to be caused by a combination of environmental triggers and genetic risk factors that tip the balance away from immune regulation and toward inflammation. Inflammatory pathways of the adaptive immune system that play a role in the pathogenesis of uveitis include T-helper 1 (Th1) lymphocytes (that produce interferon-γ [IFN-γ], interleukin-2 [IL-2], and IL-12), and IL-23-responsive Th17 lymphocytes (that produce IL-17, IL-22, and IL-6).

An example of a subgroup of immune cells that keep the immune system in check are regulatory T cells (Tregs). Tregs produce antiinflammatory cytokines, such as IL-10, transforming growth factor (TGF)-β, and IL-35. Tissues in both the anterior and the posterior segments of the human eye constitutively express TGF-β. The concentration of TGF-β in the aqueous humor is sufficient to inhibit T-cell activation and proliferation in a variety of assays.[3] As might be anticipated, significantly lower levels of this activated cytokine are measured in the aqueous humor of patients with a variety of uveitis syndromes compared with levels present in normal eyes. Another antiinflammatory cytokine, IL-27, is produced constitutively by resident cells in the retina, including retinal ganglion and photoreceptor cells.[4] IL-27 is upregulated by IFN-γ and suppresses Th17 cells.[4]

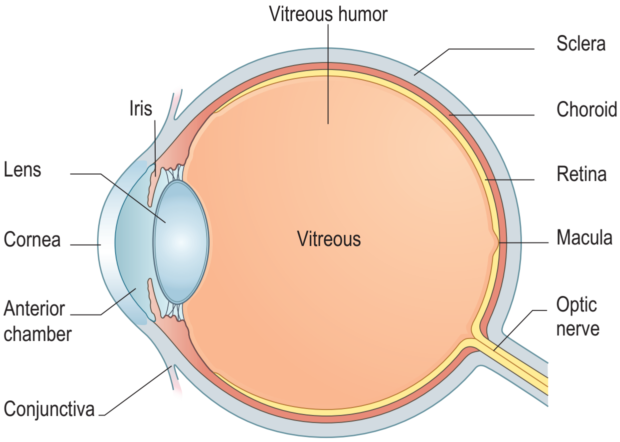

FIG 74.1 Schematic representation of the eye.

Furthermore, retinal pigment epithelial (RPE) cells are thought to play an important role in inducing Tregs through the production of retinoic acid in the presence of TGF-β.

Several cytokines, such as IFN-γ or IL-17, can be either protective or inflammatory, depending on the context in which they are produced. For example, although IL-17 is recognized as an inflammatory cytokine contributing to the pathogenesis of uveitis, one study showed that recombinant human IL-17 given systemically protected against inflammation in two different animal models of experimental uveitis.[5]

The inflammatory cytokine IL-1 has been implicated in the pathogenesis of various ocular inflammatory diseases. IL-1 receptor antagonist (IL-1Ra) is expressed in normal cornea[6] and retinal pigment epithelium, and this implies that this tissue contains a control mechanism for responses mediated by IL-1. Interestingly, topical application of IL-1Ra promotes experimental corneal allograft survival. Furthermore, the aqueous humor contains neuropeptides, including α-melanocyte stimulating hormone, vasoactive intestinal peptide, substance P, and calcitonin gene–related peptide, which inhibit T cells and macrophages.[7] Complement is active at low levels in the healthy eye, regulated by complement regulatory proteins that are expressed both on intraocular cell membranes and within the intraocular fluid; this system may participate in the destruction of pathogens invading the eye. Interestingly, iC3b, generated because of this activation, appears to contribute to immune tolerance.[8]

ANTERIOR CHAMBER–ASSOCIATED IMMUNE DEVIATION

ACAID is "a stereotypic, systemic immune response to antigens placed in the anterior chamber (of the eye) in which delayed hypersensitivity is avoided and suppressed." The culmination of cellular events in ACAID leads to the production of two different Treg populations, $CD4^+$, $CD25^+$ Tregs that inhibit the afferent immune response, and $CD8^+$ Tregs that block the efferent phase characterized by previously sensitized CD4 T cells. The molecular events that are responsible for ACAID include the following: entry of an antigen into the eye stimulates production of TNF-α, and hence the upregulation of cell adhesion molecules; antigens processed by antigen-presenting cells (APCs) in the eye migrate to the spleen and present to B cells in the marginal zone in the context of a nonconventional MHC molecule; induction of $CD8^+$ ACAID Tregs in the presence of IL-10 from $CD4^+$, $CD25^+$ Tregs, and from γδ T cells; $CD8^+$ Tregs upregulate FasL, IL-10, and TGF-β to promote FasL-mediated killing of T cells that recognize the ocular antigen; TGF-β also induces ocular APCs to secrete IL-10 during antigen processing. Apoptotic T cells from the eye pass in the bloodstream to the spleen, where they are phagocytosed and induce activation of Th2-type CD4 T cells. The Th2-type cells control Th1 function by secreting various immunomodulatory cytokines. T-cell receptor α-chain fragments from apoptotic cells are presented in the class I pathway. This event generates CD8 natural killer (NK) cells, which are capable of deleting the CD4 T cells that would otherwise mediate a delayed-type hypersensitivity response. One study demonstrated that IFN-γ appears to be important in CD8 Treg suppressive function.

Invariant natural killer T (iNKT) cells, which interact with lipid antigens presented in the context of an MHC-like molecule, Cd1d, may play a role in the induction of ACAID in the thymus and the spleen. In fact, one study showed that activation of iNKT cells could suppress experimental autoimmune uveitis.

IMMOBILITY OF DENDRITIC CELLS WITHIN THE ANTERIOR CHAMBER

The vast majority of cells that phagocytose foreign antigen within the iris fail to migrate after antigen uptake. This is clearly demonstrable by intravital microscopy and correlates with the failure of these antigen-bearing cells to migrate to the local lymph nodes.[9] The inability to migrate is consistent with the known lack of lymphatics within the eye and must mean that soluble antigen injected into the anterior chamber is not presented in the regional lymph node in a manner that is comparable with what follows antigen exposure in other peripheral tissues.

Role of the Commensal Microbiota in Ocular Immunity

Although the eye is thought to be relatively devoid of microorganisms, it is now known that there is a small number of normally residing ocular surface bacteria and viruses.[10,11] Perturbations in the ocular surface microbiota can result in infection and/or manifest as sterile inflammation. For instance, the presence of torque teno virus was very strongly associated with sterile endophthalmitis (a condition in which there is severe intraocular inflammation usually associated with infection) and was also found in some cases of culture-positive bacterial endophthalmitis.[12] Whether torque teno virus was the causal factor, merely an association, or indirectly causal via viral immune-modifying effects is unknown. Deep DNA sequencing may uncover previously unknown causes of uveitis.

UVEITIS

Uveitis as a Diagnostic Entity

Uveitis is a spectrum of different diseases that includes infections and immune-mediated diseases (Table 74.1). It is the third leading preventable cause of blindness worldwide. Inflammatory disorders of the retina (retinitis) and sclera (scleritis) frequently involve the adjacent uvea. Mechanisms contributing to uveitis include an immune response to a sequestered self-antigen, molecular mimicry, immune complex deposition, or a toxin.

The differential diagnosis of uveitis is facilitated by identifying characteristic clinical features. Uveitis can be classified by location[13]: anterior (iritis, iridocyclitis), intermediate (pars planitis, vitritis), or posterior (retinitis, choroiditis, retinochoroiditis, chorioretinitis). Some forms of uveitis involve all portions of

TABLE 74.1 Diagnostic Categories of Uveitis

Diagnostic Group		Diagnosis
Infectious causes	Viral	Herpes simplex, Herpes zoster
		Cytomegalovirus (CMV) infection
		Chikungunya
		Human T-lymphotropic virus 1 (HTLV-1) infection
		Mumps
		West Nile virus infection
		Ebola
		Zika virus infection
	Bacterial or spirochetal	Atypical *Mycobacterium* infection
		Bacterial endocarditis
		Bartonella infection
		Brucellosis
		Leprosy
		Leptospirosis
		Lyme disease
		Propionibacterium infection
		Tuberculosis
		Leprosy
		Syphilis
		Whipple disease
	Parasitical (protozoan or helminthic)	*Acanthamoeba* infection
		Cysticercosis
		Onchocerciasis
		Pneumocystis jiroveci infection
		Toxoplasmosis
		Toxocariasis
	Fungal	Histoplasmosis
		Coccidioidomycosis
		Candidiasis
		Aspergillosis
		Sporotrichosis
		Blastomycosis
		Cryptococcosis
Immune-mediated		Ankylosing spondylitis
		Behçet disease
		Crohn disease
		Drug or hypersensitivity reaction (*e.g.,* to rifabutin or cidofovir)
		Familial granulomatous synovitis with uveitis
		Interstitial nephritis
		Juvenile idiopathic arthritis
		Kawasaki disease
		Multiple sclerosis
		Psoriatic arthritis
		Reactive arthritis
		Relapsing polychondritis
		Rheumatic fever
		Sarcoidosis
		Scleritis
		Sjögren syndrome
		Sweet syndrome
		Systemic lupus erythematosus
		Ulcerative colitis
		Vasculitis
		Vogt-Koyanagi-Harada syndrome

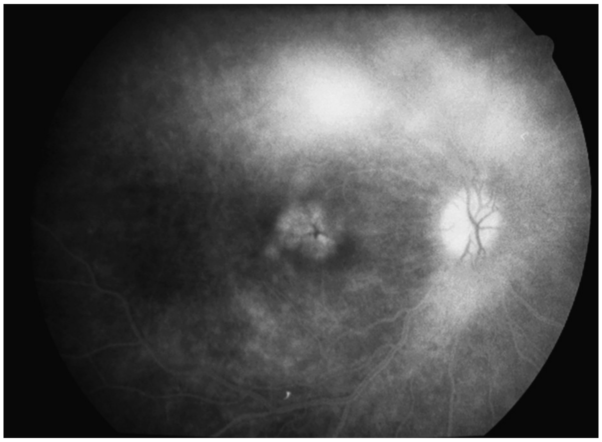

FIG 74.2 Fundus Fluorescein Angiogram Showing Cystoid Macular Edema. Fluorescein, which appears as a white stain, should be absent from the center of this photograph because the macular area is avascular.

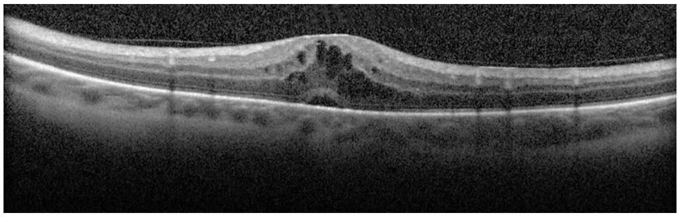

FIG 74.3 Spectral Domain Optical Coherence Tomography (SD-OCT) of Cystoid Macular Edema caused by Panuveitis. SD-OCT allows for precise quantification of macular thickening and photoreceptor damage. Note the intraretinal fluid–filled cysts resulting in distortion of the foveal contour. This patient had 20/100 visual acuity.

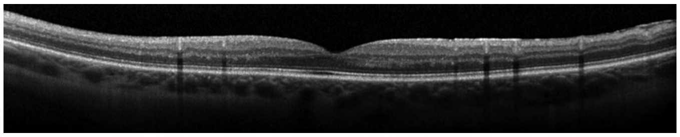

FIG 74.4 Spectral Domain Optical Coherence Tomography (SD-OCT) Image of a Normal Eye. This is the same macula as seen in Fig. 74.3, after an intravitreal steroid implant was placed. In this SD-OCT image, the macula shows a normal dimple or indentation at the normal fovea.

the uveal tract (panuveitis). Uveitis can be classified by course (self-limiting, chronic, or recurrent); by onset (sudden, insidious); by symmetry (unilateral, bilateral); by associated complications, such as glaucoma, cystoid macular edema (Figs. 74.2–74.4), synechiae (*e.g.,* adhesion of the iris to the lens) (Fig. 74.5), retinal detachment, or band keratopathy (the deposition of calcium in the epithelium of the cornea) (Fig. 74.6); and by the appearance of inflammatory keratic precipitates on the endothelium of the cornea within the eye (granulomatous, nongranulomatous) (Fig. 74.7). Granulomatous diseases with large cellular concretions on the cornea or nodules within the iris include tuberculosis, syphilis, sarcoidosis, Vogt-Koyanagi-Harada disease, and sympathetic ophthalmia. The group of nongranulomatous diseases includes ankylosing spondylitis, reactive arthritis, and juvenile idiopathic arthritis. Table 74.2 shows how these parameters contribute to the differential diagnosis.

Additionally, ethnic and geographical considerations factor into the differential diagnosis. For example, sarcoidosis, Behçet syndrome, and Vogt-Koyanagi-Harada disease have strong ethnic predispositions, whereas certain infections, such as cytomegalovirus (CMV) in association with acquired immunodeficiency syndrome

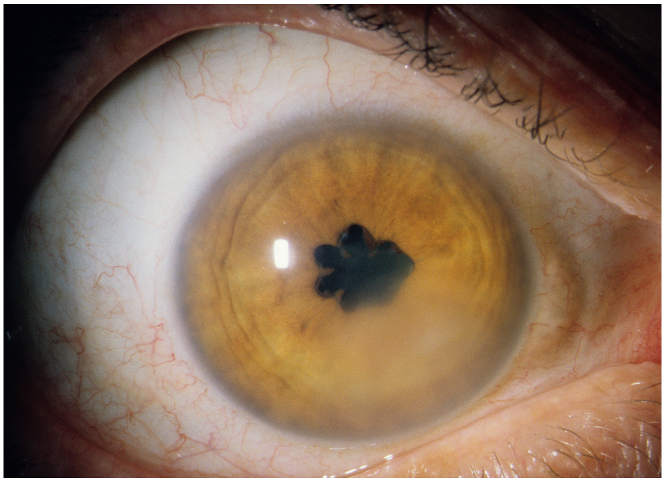

FIG 74.5 **Posterior Synechiae.** The cloverleaf appearance of the pupil is caused by the adherence of the iris to the lens capsule.

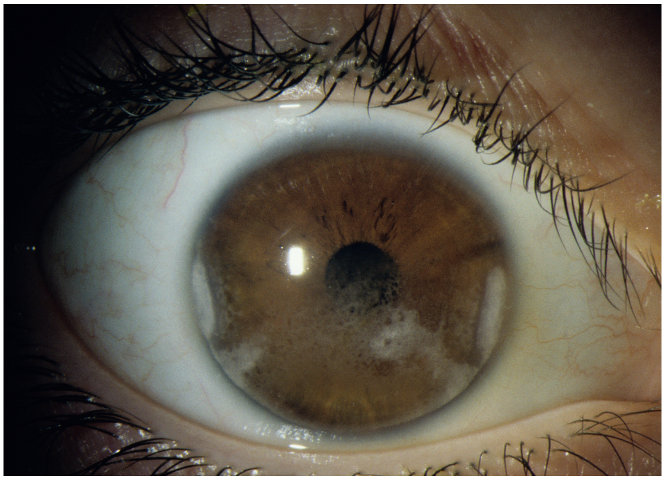

FIG 74.6 **Band Keratopathy.** Calcium deposition in the corneal endothelium complicates the iridocyclitis in a patient with juvenile idiopathic arthritis.

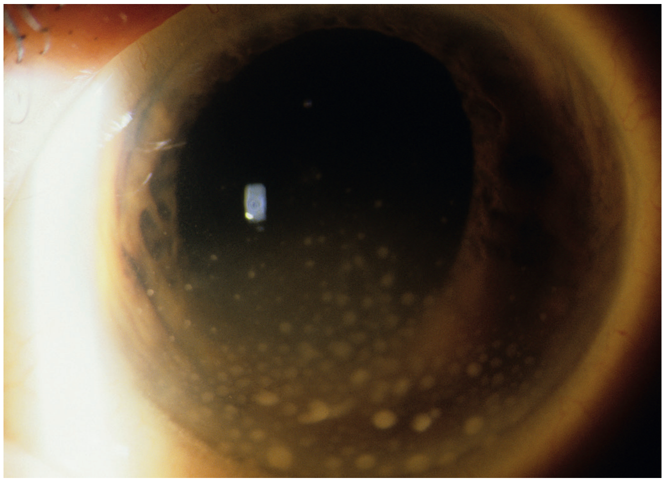

FIG 74.7 **Granulomatous Keratic Precipitates.** Round white dots are scattered in a triangular shape. The dots represent concretions of leukocytes adherent to the corneal endothelium.

TABLE 74.2 Characteristic Features of Common Forms of Uveitis

Parameter	
Location	Anterior: ankylosing spondylitis, reactive arthritis, juvenile idiopathic arthritis Intermediate: Pars planitis Posterior: Vogt-Koyanagi-Harada syndrome (panuveitis most common)
Onset	Sudden: ankylosing spondylitis, reactive arthritis Insidious: pars planitis, juvenile idiopathic arthritis
Symmetry	Unilateral: ankylosing spondylitis, toxoplasmosis, herpetic Bilateral: pars planitis, lymphoma, juvenile idiopathic arthritis
Course	Self-limiting: toxoplasmosis Recurrent: Behçet disease, ankylosing spondylitis Chronic: pars planitis

TABLE 74.3 Likelihood of Developing Uveitis in Association With a Specific Disease

Diagnosis	Likelihood (%)
Ankylosing spondylitis	30
Sarcoidosis	25–50
Behçet disease	80
Inflammatory bowel disease	1–9
Psoriatic arthritis	7
Juvenile idiopathic arthritis	<2–53
Multiple sclerosis	<1–2

(AIDS), leprosy, or onchocerciasis, vary in prevalence depending on geographical area. Together with a medical history, sex, and age, these findings help to narrow the differential diagnosis of uveitis. For example, a 22-year-old man with low back pain and a red painful eye caused by episodic, unilateral, sudden-onset anterior uveitis is highly likely to have a spondyloarthropathy (Chapter 57). A 6-year-old girl with no ocular complaints but bilateral band keratopathy and leukocytes in the anterior chamber is likely to suffer from pauciarticular juvenile idiopathic arthritis (Chapter 53).

The most obvious sign of uveal inflammation is the presence of leukocytes in the anterior chamber or the vitreous humor of the eye. Most patients with anterior uveitis will experience pain, redness, photophobia, miosis, and a variable degree of visual loss. In contrast, many forms of uveitis that affect the posterior segment will cause no redness, pain, or change in pupil size. Instead, ocular disturbances may vary from normal vision to seeing floaters, flashing lights, or photopsia, blurred vision, or blindness.

Epidemiology

The incidence and prevalence of the different types of uveitis varies throughout the world, depending on numerous factors: human leukocyte antigen (HLA) distribution, prevalence of different infectious diseases, and the methodology employed to evaluate and classify uveitis (Table 74.3). Gritz and Wong[14] reported an incidence of 52.4 per 100 000 per year and a prevalence of 115.3/100 000. Anterior uveitis is much more common than intermediate or posterior uveitis.

Prevention and Patient Management

Uveitis can be the first sign of systemic disease (*e.g.*, sarcoidosis, syphilis, or central nervous system [CNS] lymphoma). It is essential to identify the cause of uveitis as accurately as possible. A targeted approach is preferable, with a limited workup guided by the type and severity of uveitis and the presence of systemic findings. The history is of great importance. The minimal workup for uveitis of unknown etiology requires an extensive and careful review of systems, a syphilis serology, and a chest X-ray.[15]

Most practitioners use a stepladder approach to treat uveitis. The first step is corticosteroids for all patients with noninfectious uveitis (topical, especially for anterior uveitis, regional injection, or systemic administration). A surgically implantable intravitreal device to release fluocinolone for approximately 2.5 years is an option that is limited by cost and complications, which can include cataract, glaucoma, and scleral thinning. New delivery approaches include injectable corticosteroids complexed with polymers to prolong the beneficial effects; iontophoresis to deliver medication across the sclera; and small molecules, which seem to have a much broader biodistribution within the eye compared with topical prednisolone. Systemic immunosuppressive therapy should be used in cases of inadequate benefit from corticosteroids or unacceptable steroid side effects. Immunosuppression is usually reserved for bilateral forms of uveitis with a severity sufficient to alter activities of daily living and is frequently chosen for eye involvement with Behçet disease. Immunosuppression may be contraindicated by active infection in the eye or elsewhere.

The role for therapy with biologics to treat uveitis is being assessed in randomized controlled trials. Antibodies to IL-1β or to anti–IL-17A have proven disappointing in the treatment of uveitis.[16-20] However, adalimumab (an anti-TNF-α biologic) was shown to be effective in a randomized clinical trial for active uveitis[17] and as a corticosteroid sparing agent in inactive uveitis.[18] In an open label trial, infliximab has proven effective but had frequent severe toxicities for this indication.[19] The authors frequently prescribe infliximab to treat Behçet disease (see below). Biologic therapy for uveitis might also be guided by the underlying disease, such as Crohn disease, juvenile idiopathic arthritis, or psoriatic arthritis, all of which are particularly responsive to biologics.

Overview of the Most Common Uveitis Diagnoses

Ankylosing Spondylitis–Associated Uveitis

Ankylosing spondylitis (AS) is the most common systemic diagnosis associated with uveitis in Western nations. A genetic predisposition with the HLA-B27 allele is found in 88–96% of patients. About 30–50% of patients with AS develop anterior uveitis transiently during their lifetime. Approximately 50% of patients with sudden-onset anterior uveitis are HLA-B27 positive.[20] In some studies, 80–90% of individuals with HLA-B27–associated iritis have spondyloarthritis. AS should be considered in any patient with sudden-onset, primarily anterior, unilateral uveitis associated with redness and pain. Recurrent disease, fibrin in the anterior chamber, posterior synechiae, relatively brief inflammation that resolves in <2 months, and lowered intraocular pressure are additional hallmarks that help to distinguish HLA-B27–associated iritis from other categories.[21] Inflammation is sometimes so severe that a hypopyon (Fig. 74.8) develops. The posterior segment of the eye is not commonly involved in this disease except for the development of a vision-reducing cystoid macular edema (see Figs. 74.2 and 74.4). HLA-B27–associated anterior uveitis usually responds to topical corticosteroids.

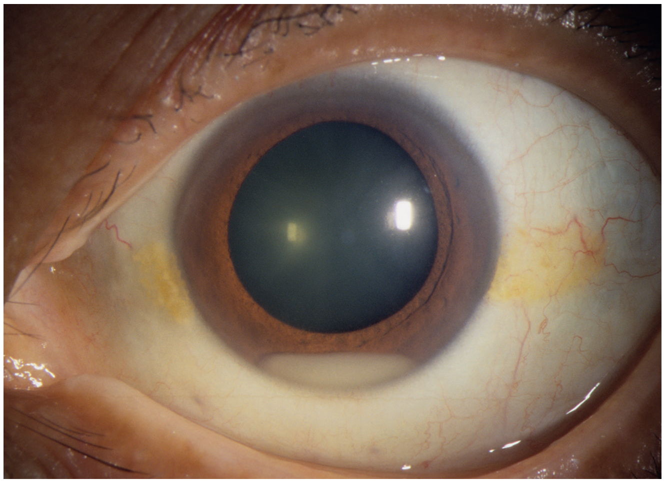

FIG 74.8 Hypopyon. Intense inflammation has resulted in a creamy exudate (pus), seen as whitening over the inferior portion of the anterior chamber. In this example, hypopyon was secondary to rifabutin, not ankylosing spondylitis.

In frequently recurrent cases, therapy with sulfasalazine[22] or TNF inhibitors is effective in reducing the frequency of the attacks.[23]

Several studies have emphasized that spondyloarthritis may be overlooked in patients with acute anterior uveitis (AAU). A study from Ireland evaluated patients with AAU in the emergency room. About 40% had spondyloarthritis that had not been recognized.[24] A study from Spain included 798 patients who had either HLA-B27–associated AAU or recurrent, HLA-B27–associated anterior uveitis. As in the Irish study, all patients with known spondyloarthritis were excluded. The study utilized the Assessment of Ankylosing Spondylitis (ASAS) criteria.[25] Fifty percent of this large group had axial spondyloarthritis and close to an additional 20% had peripheral spondyloarthritis.[26]

Inflammatory Bowel Disease–Associated Uveitis

Ocular manifestations of inflammatory bowel disease (IBD) (Crohn disease and ulcerative colitis; Chapter 75) include anterior uveitis, episcleritis, and scleritis (1–9% of all cases). Less common ocular inflammatory manifestations include peripheral keratitis, intermediate uveitis, optic neuritis, and retinal vasculitis.[27] Twenty percent of patients with IBD may have sacroiliitis; 60% of them are HLA-B27 positive. The anterior uveitis in patients with IBD is often similar to that seen with the HLA-B27 spectrum of joint diseases: sudden in onset, unilateral, and self-limiting. Like sarcoidosis, it may result in intraocular inflammation that is insidious in onset, bilateral, posterior to the lens, chronic, or associated with a retinal vasculitis.[28]

Crohn disease is a complex genetic disease—that is, multiple genes contribute to susceptibility. One of the best characterized of these genes is *NOD2.* This gene functions as an intracellular Toll-like receptor (TLR) that recognizes muramyl dipeptide from bacteria. The *NOD2* gene is also implicated in autoinflammatory diseases. A mutation in the portion of the *NOD2* gene known as the *nucleotide-binding domain* results in a rare autosomal dominant form of uveitis known as *Blau syndrome.*

Psoriatic Arthritis–Associated Uveitis

According to one study in the UK, 1–2% of the population have psoriasis (Chapter 64); roughly 10% of patients with psoriasis have arthritis[29]; and 7% of patients with psoriasis and arthritis have uveitis. The diagnosis of psoriatic arthritis is made clinically with the typical findings of cutaneous changes (erythematous, hyperkeratotic rash) and joint disease. Patients with sacroiliac disease and psoriatic arthritis are especially likely to develop uveitis.

Sarcoidosis-Associated Uveitis

Ocular disease is the initial manifestation of sarcoidosis (Chapter 73) in 20% of patients. The systemic illness begins as ocular inflammation almost as often as it initially presents as pulmonary disease. Of the patients with sarcoidosis, 25–50% exhibit ocular inflammation during the course of the illness. In most series, sarcoidosis accounts for 3–10% of all patients with uveitis, second to spondyloarthropathy as the most common systemic illness associated with uveitis in North America and Europe. The diagnosis of sarcoidosis should always be considered in any patient presenting with a uveitis of unknown etiology. Sarcoidosis occurs in the United States 10 times more frequently among African Americans than among whites. Because it can affect almost every part of the eye, symptoms of ocular sarcoidosis vary widely. Most commonly, patients have a bilateral chronic granulomatous anterior uveitis.[30] The disease often regresses clinically, with two-thirds of patients becoming symptom free after 3 years. Typical findings include "mutton-fat" keratic precipitates of the cornea (see Fig. 74.7), Koeppe and Busacca iris nodules, posterior synechiae (see Fig. 74.5), and white clumps of cells ("snowballs") in the inferior vitreous humor. Fundus findings include multifocal perivenular sheathing, typical punched out chorioretinal lesions, and/or optic nerve head granulomata. Diffuse retinal vasculitis, predominantly of the retinal venules, can also be seen. A chest X-ray (or computed tomography [CT] scan of the chest[31]) should be included in every basic workup of patients with uveitis of unknown cause. The diagnosis is supported by a biopsy that demonstrates the noncaseating granuloma in the absence of an infection or beryllium exposure. Possible biopsy sites include lymph nodes, lung, skin, oral mucosa, and conjunctiva. Serological abnormalities are not sufficiently unique to establish a diagnosis. In general, the combination of uveitis and symmetrical hilar adenopathy is considered presumed sarcoidosis and can be treated like sarcoidosis. Topical, periocular, and systemic corticosteroids are the mainstay of therapy. Steroid-sparing therapy can be required for more severe or chronic cases affecting the posterior segment, with the antimetabolites as first-line steroid-sparing agents, and TNF-α inhibitors as alternative treatment.[32,33]

Behçet Uveitis

Behçet syndrome is a generalized occlusive vasculitis of unknown cause (Chapter 58). It accounts for about 2.5% of patients at a North American referral uveitis clinic and has a strong ethnic relationship. It is most common in Japan (20% of patients with uveitis) and prevalent in Middle Eastern countries along the Silk Road.

The classic complex includes aphthous stomatitis, genital ulceration, and iritis, sometimes with hypopyon (30% of patients) and skin lesions. Ocular manifestations can range from a hypopyon anterior uveitis to intermediate uveitis, retinitis, and occlusive retinal vasculitis (Fig. 74.9). Extraocular manifestations include arthritis, erythema nodosum, diarrhea (mimicking IBD), and sterile meningitis. There is a strong tendency for symptoms to remit and exacerbate spontaneously. HLA-B51 is more commonly found among patients with Behçet syndrome. Behçet syndrome may lead to blindness if ischemic optic neuropathy and retinopathy are not adequately treated. Patients are often inadequately managed by corticosteroids alone: A regimen with immunosuppressive drugs (cyclosporine or azathioprine) has been proved useful. Some investigators advocate the use of IFN-α.[34] Infliximab has demonstrated dramatic benefit in studies reported from Europe and Japan.[35] It is now approved for this indication in Japan.

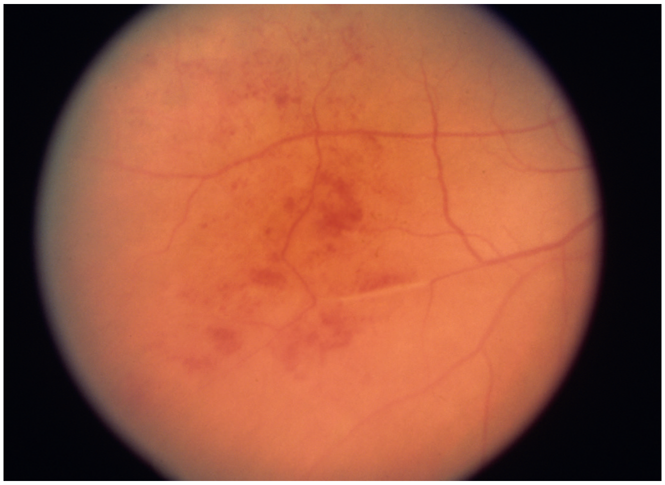

FIG 74.9 Fundus Photograph Showing Retinal Vasculitis. The scattered hemorrhages are secondary to the vasculitis. The patient has Behçet syndrome.

Multiple Sclerosis–Associated Uveitis

Although retrobulbar optic neuritis is the ocular inflammation most associated with multiple sclerosis (MS), intermediate uveitis and bilateral granulomatous anterior uveitis are well described in association with this disease[36] (Chapter 66). Bilateral granulomatous uveitis may indicate a worse prognosis for the neurological disease. The HLA-DR2 antigen, strongly associated with MS, is also associated with uveitis.

Juvenile Idiopathic Arthritis–Associated Uveitis

Patients with juvenile idiopathic arthritis (JIA; Chapter 53) need special consideration as the disease often does not present with a "red eye": The uveitis often occurs as a smoldering, silent inflammation in a quiet, white eye. In 20% of all JIA cases, the joint involvement is pauciarticular (≤5 joints affected). Uveitis occurs far more commonly in this pauciarticular subset, and these patients require routine ophthalmic screening every 3–4 months. Girls are affected four times more often than boys, although boys are more likely to develop complications.[37] Eighty percent of uveitis cases are positive for antinuclear antibodies (ANAs) and negative for rheumatoid factor. The onset of ocular disease is usually within 5 years of arthritis but may precede arthritis as well. Biomicroscopically, bilateral fine keratic precipitates, band keratopathy (see Fig. 74.6), flare and cells in the anterior chamber, posterior synechiae, glaucoma, and cataract formation can be found. Topical and periocular corticosteroid treatment with a slow taper is the mainstay of therapy. Systemic therapy with antimetabolites, such as methotrexate or mycophenolate, can be used to spare corticosteroids and may be indicated to reduce the morbidity of chronic corticosteroid use. A TNF inhibitor, such as adalimumab, is useful in patients with refractory disease.[38] Cataract surgery is a special challenge and may require intense perioperative immunosuppression.

KEY CONCEPT

Unilateral, recurrent, acute anterior uveitis is one of the most common forms of uveitis; it is frequently associated with spondyloarthritis.

CLINICAL PEARL

It is important to rule out infectious causes of uveitis before initiating immunosuppression for uveitis.

Advancements and New Treatments for Uveitis

As molecular diagnostics, such as next-generation deep sequencing techniques and bioinformatics, are becoming refined and more broadly available, additional etiological agents for uveitis may be discovered. Additionally, with an increased understanding of the cellular pathways involved in various uveitic entities, new targets for therapy of uveitis may emerge. For instance, targeting IL-6 with a biologic agent versus targeting lymphocyte trafficking to the eye via an antibody against adhesion molecules may represent emerging therapies. Additional local drug delivery methods may improve ocular efficacy while lowering systemic side effects.

ON THE HORIZON

Newer molecular diagnostic techniques will improve identification of etiological agents in uveitis, and potentially direct novel treatments both locally and systemically for uveitis.

SCLERITIS

Description and Natural History

Scleritis is a relatively uncommon inflammation affecting the *sclera*, the white tunic that encases the eye, and the overlying episcleral tissues. Scleritis is usually presumed to represent a vasculitis of the deep episcleral vessels that overly the sclera. At least one-third of patients with scleritis will have clinical evidence for a systemic vasculitis elsewhere in the body.[39] The most common systemic diseases are granulomatosis with polyangiitis (GPA; Chapter 58), previously known as *Wegener granulomatosis* (often in a limited form), or rheumatoid arthritis (RA; Chapter 52). The subset of patients with RA who develop scleritis are especially likely to develop rheumatoid nodules, high-titer rheumatoid factor, and pleuropericarditis, as well as small vessel vasculitis of the lower extremities. Other systemic diseases commonly associated with scleritis are listed in Table 74.4. The epidemiology of scleritis has not been adequately reported. However, RA accounts for about one-third of all cases of scleritis. Because only 1% of patients with RA develop scleritis, and about 1% of the population has RA, one can estimate that the prevalence of scleritis is 0.01 × 0.01 × 3, or 3/10 000.

Scleritis is frequently divided into five subsets based on the clinical presentation: diffuse anterior (Fig. 74.10); nodular anterior; necrotizing; scleromalacia perforans (Fig. 74.11); and posterior scleritis.[40] Scleromalacia perforans is also known as *necrotizing scleritis without inflammation.* The clinical presentation will vary according to the type, but scleritis is usually a very painful and persistent condition. Even with treatment, median duration reaches 5 years.

TABLE 74.4 Systemic Immune-Mediated Diseases Associated With Scleritis

Relapsing polychondritis

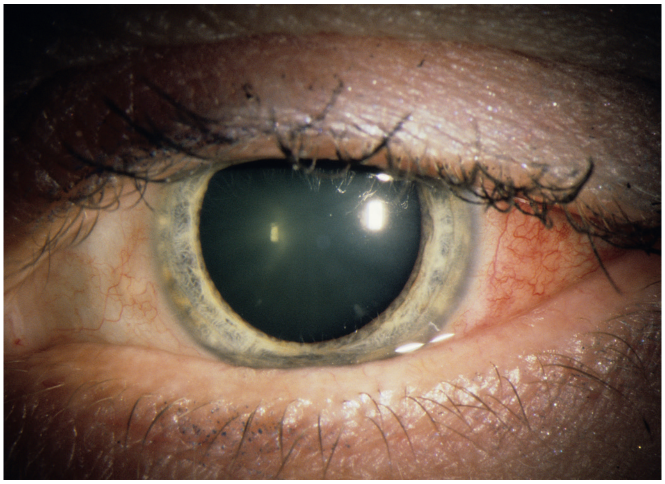

FIG 74.10 Diffuse Anterior Scleritis. The red patch of vessels temporally is secondary to scleritis.

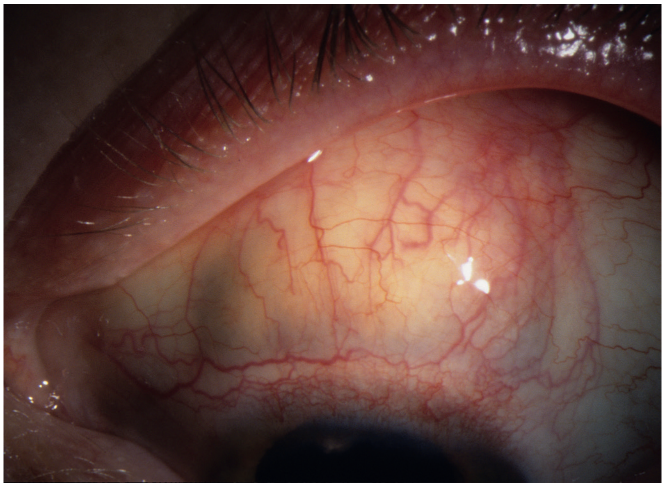

FIG 74.11 Scleromalacia Perforans. Blue sclera is visible secondary to inflammation, resembling a rheumatoid nodule in the eye.

Genetic and Environmental Factors

Genetic factors affecting scleritis have not been adequately studied. Genes that affect the associated systemic diseases, such as RA, GPA, and polyarteritis nodosa (PAN), presumably also influence susceptibility to scleritis. Environmental triggers for scleritis have not been defined, except that some cases of scleritis can be a manifestation of infection, such as herpes zoster ophthalmicus, syphilis, Lyme disease, tuberculosis, or other bacterial and fungal infections.

Immunology and Pathology

Biopsy of the sclera entails some risk. Accordingly, many of the published histological observations are based on end-stage or extremely severe disease. In one pathology study of 55 examples of necrotizing scleritis, the histology was divided into four types: zonal necrotizing granulomatous scleritis; nonzonal diffuse scleritis; necrotizing scleritis with microabscesses; and sarcoidal granulomatous scleritis.[41] Eighty-five percent of patients with zonal necrotizing granulomatous pathology had a systemic disease, usually rheumatoid arthritis. The pathology associated with RA was not distinct from other systemic diseases, such as GPA. None of 19 patients with nonzonal diffuse scleral inflammation had a systemic disease. Just over half the patients with microabscesses had an identifiable infection as the cause of scleritis. Only one patient had "sarcoidal granulomatous inflammation," and that patient had sarcoidosis.

Prevention and Management

Topical medications are only slightly beneficial for most patients with scleritis. Topical nonsteroidal antiinflammatory drugs (NSAIDs), such as ketorolac, have not been proven efficacious. A topical corticosteroid can sometimes help in symptomatic control but also has risk, especially the promotion of cataract formation and elevation of intraocular pressure. The role for topical cyclosporine has not been adequately evaluated, but the authors' clinical experience has not been favorable.

Although most forms of scleritis represent a vasculitis, oral NSAIDs can be immensely beneficial. Although not all patients derive adequate control from oral NSAIDs, a subset will benefit sufficiently such that no other medication is required. We speculate that the subset responsive to an NSAID might have a pathogenesis other than vasculitis, but this hypothesis remains unproven.

Many patients with scleritis will not benefit adequately from an NSAID and will require immunosuppression. In general, for those with an associated systemic disease, pharmacologic control of that disease will control the scleritis. For those without a systemic illness, oral corticosteroids are an accepted initial approach to treatment. For example, therapy might begin with a dose of prednisone of 1 mg/kg bodyweight per day. The use of calcium and vitamin D, as well as other measures to preserve bone mineral density, should be considered for any patient who will be receiving corticosteroid on a chronic basis. If prednisone is not adequate for disease control or if the medication is poorly tolerated and cannot be safely tapered to a modest dose, it is reasonable to add a steroid-sparing medication. There is considerable interest in the use of biologic agents as corticosteroid-sparing agents in scleritis. Multiple recently published case reports and small case series have described the successful use of drugs, including TNF blockers or rituximab, in some patients with resistant disease.[42]

Locally injected corticosteroids may be effective for uveitis, but they are contraindicated for patients with necrotizing scleritis. The corticosteroid might enhance the likelihood that the necrotic sclera will perforate. However, for nonnecrotizing anterior scleral inflammation, there is accumulating evidence that subconjunctivally injected corticosteroid is safe and may be highly effective.[43] Scleral inflammation limited to the posterior sclera can probably be safely treated with a periocular corticosteroid injection.

In choosing to treat with oral corticosteroid or an immunosuppressive, the clinician will, of course, weigh the risk/benefit ratio. The rationale for aggressive therapy is much stronger if the disease is bilateral and is affecting activities of daily living, because of pain or reduction in acuity.

CLINICAL PEARL

Although noninfectious scleritis may be considered a vasculitis of the deep episcleral vessels, oral nonsteroidal antiinflammatory drugs (NSAIDs) are effective in its treatment, and when the disease is refractory, oral corticosteroids, antimetabolites, or biologics can be quite effective.

Evaluation and Differential Diagnosis

Patients with scleritis generally have characteristic findings that allow an accurate diagnosis; scleritis can usually be readily distinguished from other causes of a red, painful eye. The most difficult distinction is between scleritis and episcleritis. The differences between scleritis and episcleritis are highlighted in Table 74.5.

The scleritis associated with a systemic vasculitis is often more severe than scleritis not associated with a systemic illness.[44] The scleritis associated with GPA may be particularly destructive and refractory to therapy. Scleritis in association with RA is often a poor prognostic sign. Before the routine use of disease-modifying antirheumatic drugs, the small subset of patients with scleritis in association with RA had a shortened life expectancy compared with those without evidence for ocular involvement.

Posterior scleritis can be an extremely difficult disease to diagnose. If the anterior sclera is uninvolved, no redness is present. Pain with posterior scleritis is much more variable. The examination may show elevation of the adjacent retina and choroid. The diagnosis can be confirmed with an ultrasound examination or, less commonly, with CT of the orbit demonstrating thickening of the sclera.

Pitfalls and Controversy

Some experts believe that scleritis can sometimes be a *forme fruste* of GPA. In patients with scleritis, a positive antineutrophil cytoplasmic antibody (ANCA) test and no other evidence for GPA has been described.[45]

With the exception of the ANCA test, laboratory studies are generally selected according to the history and general physical examination. For example, although RA is associated with scleritis, the patients almost always have long-standing severe RA. A rheumatoid factor and/or anticyclic citrullinated peptide antibody titer would not be appropriate tests if no joint disease were

TABLE 74.5 **Contrasting Features of Scleritis and Episcleritis**

	Scleritis	Episcleritis
Pain	Prominent	Minimal
Duration	Years	Days to months
Association with systemic disease	Frequent	Uncommon
Vessels blanch with topical vasoconstrictor	No	Yes
Associated ocular complications, including visual loss	Sometimes present	Rarely present
Vessel color	Violaceous	Light pink

present clinically. The findings from one study, however, do support screening patients with scleritis with serological tests to detect RA.[46] Similarly, systemic lupus erythematosus (SLE) can be associated with scleritis, but one would not diagnose SLE on the basis of a positive ANA result, scleritis, and the absence of other findings to suggest SLE. An erythrocyte sedimentation rate (ESR) can sometimes be helpful in ensuring that a systemic process is not present. Other laboratory tests are largely dictated by the medication that is chosen to treat the scleritis.

KERATITIS

The cornea is the anteriorly situated window to the eye. Normally, it should be clear. It can become opacified as a result of trauma, exposure to toxins, infection, dryness, calcium deposition, or genetic diseases, such as corneal dystrophies. The three main immune-mediated diseases that affect the cornea are peripheral ulcerative keratitis (PUK) (Fig. 74.12), Mooren ulcer, and Cogan syndrome.

Most patients with PUK have a systemic disease, most commonly RA, but can have SLE, GPA, or PAN. PUK is usually concomitant with scleritis. Treatment is similar to that for scleritis, with emphasis on controlling the underlying systemic illness and aggressive use of immunosuppression. A complication of uncontrolled PUK is corneal melt, which can lead to corneal perforation. This is usually treated with antimetalloproteinases/collagenases and surgically with tissue adhesives, conjunctival flaps, and possibly corneal transplantation, in addition to aggressive systemic immunosuppression, such as with rituximab. PUK is fortunately a very rare disease. PUK must also be distinguished from other causes of corneal thinning, such as Terrien marginal degeneration or senile marginal furrow, both of which are generally more benign and rarely lead to perforation.

Mooren ulcer is clinically very similar to PUK, except that there is no accompanying scleritis and no evidence for a systemic illness. The superior cornea is especially likely to be involved. Mooren ulcer is too rare for therapeutic options to be studied in randomized clinical trials. It may respond to oral immunosuppression, which is warranted if the severity threatens visual acuity because of impending corneal perforation. Some patients with Mooren ulcer have an autoantibody to calgranulin C. This antigen is expressed in the cornea, in neutrophils, and by filarial nematodes.

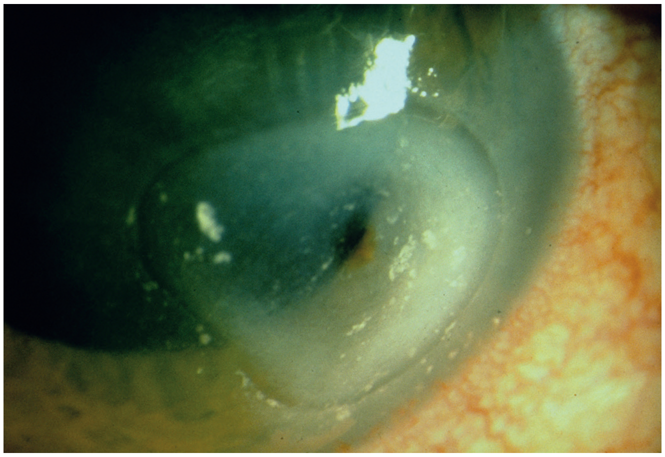

FIG 74.12 Corneal Melt. A pie-shaped wedge of the cornea is thinned. The eye is red secondary to an associated scleritis.

The cornea is divided into five layers: the epithelium facing the atmosphere, Bowman membrane, the stroma, Descemet membrane, and the endothelium abutting the aqueous humor. Opacification of the stroma is known as *interstitial keratitis.* Congenital syphilis and other infections, such as herpes simplex, are important causes of the latter. Cogan syndrome is defined as an autoimmune disease of the eighth nerve combined with interstitial keratitis, presumably on an autoimmune basis.[47] Some ophthalmologists also recognize autoimmune eighth-nerve disease associated with other forms of ocular inflammation, such as uveitis, as examples of Cogan syndrome. The pathogenesis of Cogan syndrome is presumed to be a vasculitis, and many patients will have evidence for vasculitis elsewhere in the body. The treatment usually requires aggressive use of systemic immunosuppressive medications.

CORNEAL TRANSPLANTATION AND TRANSPLANT REJECTION

Corneal transplantation involves the repair of a diseased cornea with healthy cadaver tissue. Since the 1970s, advances in microsurgical techniques and eye banking procedures have led to widespread acceptance of this procedure. Currently, more than 40 000 corneal transplantations are performed annually in the United States alone. The usual indication for a full-thickness corneal graft is poor vision from deep stromal scarring. The most common medical conditions leading to corneal transplantation are *keratoconus,* a condition in which myopic astigmatism develops as the cornea becomes progressively more conical in shape; corneal edema following intraocular surgery; and a failed previous corneal graft.

Although the eye is an immune-privileged site, and corneal transplants enjoy a 91% 1-year survival as shown by Kaplan-Meier survival analyses, only 62% of grafts are functional at 10 years. The most common cause of transplantation failure is immunologic rejection. Corneal allograft rejection rarely occurs within 2 weeks, and may occur as late as 20 years after surgery. Animal studies using monoclonal antibodies (mAbs) directed against different T-cell subsets indicate that CD4 T cells play a critical role in the rejection response. However, the mechanisms responsible for this process are still being studied.

Early recognition of a rejection episode is the most important factor in achieving survival of the corneal transplant. In its most florid form, the anterior eye is obviously inflamed, with intense conjunctival injection, a cellular anterior chamber reaction, and a Khodadoust line. This line, which is visible with the slit-lamp biomicroscope, is a classic sign of corneal graft rejection. It appears as a linear formation of inflammatory precipitates stretching across the corneal endothelium and represents a wave of lymphocytes marching across the cornea and destroying the endothelium in their path. As endothelial pump function is lost, the cornea becomes waterlogged and opaque. At an early stage of rejection, the patient may be asymptomatic, but later, ocular redness, photophobia, halos, and blurred vision are frequent complaints.

An intensive and extended course of topical corticosteroids is the mainstay of treatment for a rejecting corneal graft, and in severe cases intravenous and/or oral corticosteroids may also be administered. Patients considered at high risk of transplant rejection, such as those with corneal neovascularization or a history of other anterior segment inflammation, are often given perioperative systemic immunosuppression. The ideal prophylactic regimen has not been defined, although various combinations of prednisone, cyclosporine, and azathioprine may be used. Despite the critical influence of donor–recipient histocompatibility matching for solid organ transplant survival, the chance of corneal graft survival is not significantly improved by HLA matching.

Corneal transplantation has traditionally been accomplished by penetrating keratoplasty, in which all layers of the cornea are simultaneously replaced. Many centers are increasingly performing lamellar keratoplasty, in which layers of the cornea, such as the endothelium and Descemet membrane, are selectively transplanted.[48] Descemet membrane endothelial keratoplasty (DMEK) is an example of endothelial keratoplasty. Although technically more challenging, lamellar keratoplasty results in faster visual recovery and a reduced likelihood of transplant rejection.

CANCER-ASSOCIATED RETINOPATHY

Cancer-associated retinopathy (CAR) is a rare paraneoplastic syndrome that is most commonly associated with small cell carcinoma of the lung.[49] In addition, the disease has been documented in association with various tumors of the female reproductive tract, carcinoma of the breast, and neuroendocrine bronchial carcinoma. For 50% of patients, CAR is the presenting feature of their malignancy. Interestingly, there are now reports of retinopathy mimicking CAR but occurring in an apparently healthy individual. Melanoma-associated retinopathy is a related syndrome, occurring in patients with metastatic cutaneous melanoma.

Histopathological examinations of postmortem specimens taken from patients with CAR consistently demonstrate loss of inner and outer segments of the retinal photoreceptors. This destruction was initially attributed to the release of a hormone-like substance by malignant cells, but evidence has now accumulated in support of an autoimmune etiology. Affected individuals produce antibodies against one or more retinal photoreceptor antigens.[50] These antibodies induce experimental CAR when injected into laboratory animals. Although more than 15 antigens have been described in relation to CAR, the most common is the so-called CAR antigen.[50] This 23-kilodalton (kDa) protein has been identified as recoverin, a photoreceptor protein that participates in visual adaptation. Experimental work supports the hypothesis that a single mutational event simultaneously activates the recoverin gene and eliminates functional p53, a tumor suppressor protein. Consequently, there is development of a tumor that encodes CAR antigen and stimulates formation of antirecoverin antibody. Antirecoverin antibodies are capable of inducing photoreceptor apoptosis, leading to the characteristic loss of both rods and cones.

CAR generally occurs after the age of 60 years. Patients usually complain of decreased vision, although other symptoms may include transient visual obscurations, night blindness, scotomata, glare, and photosensitivity. Although visual acuity can be dramatically reduced, other clinical signs are often subtle. An afferent pupillary defect can be present if the retinopathy is asymmetrical. There may be mild iridocyclitis and/or anterior vitritis, narrowing of retinal arterioles, mottling of retinal pigment epithelium, and optic disc pallor. Visual field abnormalities occur. Electroretinography shows either reduced or completely flattened amplitudes. The disease must be differentiated from optic neuritis which, unlike CAR, typically occurs in younger persons, some of whom suffer from MS, and is painful. In contrast to CAR, optic neuritis typically has an abrupt onset. In patients with malignancy, ocular metastatic tumor spread and the effects of drugs, including chemotherapy agents, must be excluded before CAR is diagnosed.

The natural history of CAR is one of progressive visual loss, although this occurs over a variable period. Corticosteroid and other immunosuppressive drugs have been successfully used to treat the ocular disease.[51] It is suggested that serum antibody levels can be monitored to guide therapy. In some cases, advanced photoreceptor damage can be irreversible despite therapy.

IMMUNOLOGIC ETIOLOGIC FACTORS IN “NONIMMUNOLOGIC” OCULAR DISEASE

Age-related macular degeneration (ARMD) is the leading cause of irreversible visual loss in older persons in Western nations. A spectrum of pathologies can occur at the macula, ranging from relatively benign lipid deposits, called *drusen,* to the sometimes visually devastating retinal pigment epithelium atrophy or subretinal/choroidalneovascular membranes. The pathogenic stimulus for these age-related changes is unknown. Genetic polymorphisms of the complement regulatory protein, complement factor H, influences the susceptibility to ARMD, suggesting that this disease is related to chronic inflammation.[52] Subretinal scar tissue removed from patients with advanced, neovascular disease may contain immunoglobulins and complement components. The histopathology of ARMD includes inflammatory cells, including lymphocyte subsets, and local cell populations can express class II MHC antigens. Inhibition of complement activation is under study to treat or prevent ARMD.

MULTIPLE-CHOICE QUESTIONS

1. What is anterior chamber–associated immune deviation (ACAID)?
   A. Uveal or lens proteins, when exposed to the immune system, result in a robust reaction against these self antigens
   B. When an autoimmune process only affects the eye, but no other tissue
   C. Describes ocular immune privilege; antigens injected into the anterior chamber induce selective suppression of antigen-specific T-lymphocyte responses
   D. When viral infections affect only the anterior chamber but not the vitreous or retina

2. Acute anterior uveitis is:
   A. Associated with human leukocyte antigen B27 (HLA-B27) positivity 50% of the time
   B. Seldom associated with systemic disease
   C. Associated with spondyloarthritis without prior recognition 40% of the time
   D. None of the above
   E. A and C

3. Juvenile idiopathic arthritis (JIA)–associated uveitis:
   A. Often presents with pain, redness, photophobia
   B. Causes a smoldering asymptomatic bilateral uveitis most commonly
   C. Is typically associated with polyarticular arthritis in antinuclear antibody (ANA)–negative patients
   D. Cannot be treated with anti–tumor necrosis factor (TNF) treatment

Immunological Diseases of the Gastrointestinal Tract

Peter J. Mannon

The gastrointestinal (GI) tract contains the largest mass of immune cells of any organ in the body. To manage the continuous exposure to environmental and dietary antigens as well as pathogens, commensal microbes, and their metabolic products, the gut uses a number of strategies that support mucosal structural integrity and immune regulation to maintain homeostasis. In spite of these defenses, the GI tract is susceptible to chronic immune-mediated inflammation from pathogens, autoimmunity, and immunodeficiency. This chapter discusses some of the most frequent immunological diseases of the GI tract likely to be encountered in the clinic, including autoimmune gastritis, chronic *Helicobacter pylori* gastritis, celiac disease, inflammatory bowel diseases (IBDs; Crohn disease, ulcerative colitis [UC], microscopic colitis, and eosinophilic esophagitis) and GI complications of primary immunodeficiency. The coverage focuses on the clinical presentation, mechanisms of disease, and approaches to diagnosis and treatment of these conditions.

GASTRITIS

Gastritis is a histological term that describes stomach inflammation resulting from toxic exposures, infection, idiopathic inflammation, and autoimmunity. Although symptoms tend to be very nonspecific, the etiology and treatment of gastritis can be extremely specific, particularly for *H. pylori* infection, which has important implications for outcomes and natural history.

Atrophic Gastritis/Pernicious Anemia

The most classic autoimmune disease of the GI tract is atrophic gastritis characterized by antiintrinsic factor and antiparietal cell autoantibodies and an association with autoimmune thyroiditis, vitiligo, and type I diabetes.[1] Loss of acid-producing parietal cells leads to atrophic gastritis or "pernicious anemia (PA)." The age-old stereotype of the patient with atrophic gastritis/PA is an older Caucasian woman with progressive effects of iron and vitamin B_{12} deficiency. However, a female preponderance (approximately 2 : 1) notwithstanding, 25% of cases are diagnosed below age 50 years, and disease does occur in African and Asian ethnicities. The detection of both antiintrinsic factor and antiparietal cell serum antibodies has 73% sensitivity and 100% specificity for PA.[2]

Murine models suggested that induced immunity to H^+-K^+-ATPase (the parietal cell membrane protein that secretes H ions into the gastric lumen) may result in PA. Although potentially pathogenic H^+-K^+-ATPase–responsive CD4 T cells can be isolated from the gastric mucosa of patients with PA, it remains unclear how these cells arise, but observations implicate a role for *H. pylori* infection. Antral inflammation (up to 92%) and mucosal atrophy (up to 30%) together with histological evidence of *H. pylori* infection (up to 30%) occur in PA, with antigastric antibodies present in up to 65% of patients with *H. pylori* infection (and none in noninfected patients with gastritis).[3] In addition, gastric mucosal CD4 T cells can display cross-reactivity to H^+-K^+-ATPase and *H. pylori* antigens.[4] The actual identity of *H. pylori* infection as the major causal link to PA has not been established.

Helicobacter pylori Gastritis

H. pylori infection of the gastric mucosa has been identified as the leading cause of peptic ulcer disease and is a WHO-designated class I carcinogen for gastric carcinoma. Current data consistently show that primary infection is largely acquired in childhood, at which stage in life poor sanitation enhances acquisition via fecal/gastrooral pathways.[5] Although acute infection can cause abdominal pain and dyspepsia, there is typically no clinical recognition of acute infection. Rather, the burden of *H. pylori* results from chronic infection of the stomach; *H. pylori* is uniquely adapted to the acidic environment of the stomach through its ability to metabolize urea to ammonia, which provides a buffered microenvironment that allows prolonged asymptomatic colonization.

The ability of *H. pylori* to confer risk of peptic ulcer disease in 15% of chronically infected persons has been linked to *H. pylori* infection lowering the mucus pH adjacent to the gastric epithelium and increasing the permeability of the mucus to hydrogen ions. In addition to inhibition of bicarbonate secretion by the epithelium, expression of cytotoxins (vacuolating cytotoxin, VacA) and upmodulation of the mucosal inflammatory response by virulence factors, such as CagA, may contribute to pathogenesis. The recognition of *H. pylori* as a causative agent in the vast majority of recurrent peptic ulcers and that its elimination could cure this disease led to the Nobel Prize in Medicine or Physiology to Marshall and Warren in 2005.

The development of peptic ulcer disease and adenocarcinoma caused by chronic *H. pylori* infection correlates with the anatomical distribution of inflammation. When *H. pylori* chronic gastritis affects the antrum predominantly, there is an association with duodenal ulcers, increased serum gastrin levels and excess acid production, and no gastric mucosal atrophy.[6] However, when *H. pylori* affects the body and the antrum in a confluent or patchy manner, intestinal metaplasia develops, oxyntic mucosa atrophies, and acid production decreases. This latter type of *H. pylori* chronic gastritis is associated with gastric ulcerations and increased risk for adenocarcinoma and mucosa-associated lymphoreticular tissue (MALT) B-cell lymphoma. Although eradication of *H. pylori* can reverse the mucosal atrophy and restore acid production in this setting, mucosal restoration occurs only in a minority of patients and does not necessarily reverse the intestinal metaplasia. Histologically, this form of atrophic gastritis is differentiated from primary autoimmune atrophic gastritis by the presence of *H. pylori* organisms in the specimen (and concurrent involvement of the antrum). Specific immunohistochemical methods for detecting *H. pylori* are required when organisms are not seen on hematoxylin and eosin staining, when intestinal metaplasia occurs widely (*H. pylori* does not colonize intestinal metaplasia heavily), or when confirming *H. pylori* eradication after antibiotic treatment.[7] Although there are many pieces of evidence to support immune mechanisms for the persistence of *HP* infection in the stomach,[8] data suggest that pro-regulatory effects of *H. pylori* infection, including local IL-10 production, increases in regulatory T cells (Tregs) in the gastric mucosa and increased antigen-presenting cell (APC) phagocytosis of apoptotic cells all contribute to persistence of chronic *H. pylori* gastritis.[9-11] The indications for diagnosis and treatment of active *H. pylori* infection include active gastroduodenal ulcer disease, gastric MALT lymphoma, and, in highly endemic areas, dyspepsia symptoms (upper abdominal pain, bloating, early satiety, and nausea). Active disease can be diagnosed with endoscopic biopsy, which has high sensitivity and specificity, while simultaneously assessing peptic and malignant complications.[12] Noninvasive testing for *H. pylori* infection includes serum antibody detection (best used in highly endemic areas to predict active infection), urea breath testing (limited by expense and possible false-positive results), and fecal antigen testing (which has potential advantages in the setting of intestinal metaplasia and after antibiotic treatment).

Once *H. pylori* infection is diagnosed, there are many effective eradication therapies that need to be tailored to patients' drug tolerance and allergy history as well as local antibiotic resistance patterns. In general, a 14-day course with a proton pump inhibitor (histamine 2 [H2] blockers may be substituted) and two antibiotics (clarithromycin with amoxicillin or metronidazole) is recommended as first-line treatment.[13] Alternative regimens, including bismuth or sequential therapy, may be needed in cases of antibiotic resistance. Eradication of infection can be confirmed by either invasive or noninvasive (but not serum antibody) methods. In addition to the cure of recurrent gastroduodenal ulcer disease, eradication of *H. pylori* can cause regression of gastric MALT lymphoma in a majority of coinfected patients.[14] Investigation continues into enhancing eradication or preventing chronic infection through targeting molecules critical for *H. pylori* survival in the gastric environment as well as vaccine strategies.

KEY CONCEPTS

Gastritis

- Atrophic gastritis/Pernicious anemia results from loss of the acid-producing cells of the gastric body and is associated with antiparietal cell antibodies, an intact antral gastric mucosa, and no evidence of *Helicobacter pylori* infection.
- However, *H. pylori* infection has been linked to atrophic gastritis/pernicious anemia via increased rates of antigastric antibodies, autoantibodies to H^+-K^+-adenosine triphosphatase (ATPase), and gastric mucosal CD4 T cells with cross-reactivity to H^+-K^+-ATPase and *H. pylori* antigens.
- *H. pylori* infection of the stomach is chronic because of metabolic and immune adaptations by the pathogen that allow persistence in the acidic gastric environment.
- *H. pylori* infection is a leading cause of peptic ulcer disease and a World Health Organization (WHO) class I carcinogen because of its link to gastric adenocarcinoma.

ON THE HORIZON

Gastritis

- Development of an ultimate *Helicobacter pylori* eradication treatment with easy global implementation yet without significant adverse effects or antibiotic resistance issues.

CELIAC DISEASE

Celiac disease (also known as *gluten enteropathy*) is the most prevalent immune-mediated disease of the human GI tract. Gluten peptide–specific T cells drive specific autoantibody formation, small intestinal villus atrophy, and malabsorption caused by subsequent intestinal surface injury. The identification of the specific antigen-presenting human leukocyte antigen (HLA) molecules and the gluten peptide cognate ligands that activate the T cells have advanced the understanding of the pathophysiology and genetics of celiac disease and are driving innovative therapies.

Presentation

The classic clinical presentation of celiac disease—chronic diarrhea, weight loss, and abdominal bloating—results from defective nutrient absorption by the small intestine as a result of inflammatory injury. However, patients with celiac disease are more likely to present with complications of nutrient deficiency (anemia, osteoporosis, failure to thrive in children) without overt GI complaints. Celiac disease can also present with a gluten-reactive skin eruption (dermatitis herpetiformis), cerebellar ataxia, infertility and miscarriage, chronic fatigue, and associated autoimmune disorders, such as diabetes and thyroiditis, Addison disease, Sjögren syndrome, autoimmune hepatitis, and primary biliary cirrhosis.[15] A high frequency of nonspecific GI symptoms, such as abdominal pain and constipation, reported in over one-fifth of newly diagnosed subjects, complicates targeted disease screening. The variations of celiac disease presentation may reflect several features: *(i)* celiac disease severity follows a dose effect of risk alleles; *(ii)* the actual occurrence of celiac disease requires genetic and environmental factors in addition to the well-characterized HLA molecules; *(iii)* celiac disease expression depends on the quantity and quality of gluten exposure; and *(iv)* celiac disease complications reflect the severity of the inflammation and the length of involved bowel.[16] The concept of a vast subclinical celiac disease prevalence has led to an "iceberg model," where the visible tip is the group with symptomatic GI disease and the characteristic gut mucosal lesion, and below the surface are those with silent disease (no overt symptoms but gut mucosal lesions) and latent disease (no symptoms or mucosal lesions but genetic susceptibility possibly with positive serology).

The key to diagnosing celiac disease is simply to consider it in the differential diagnosis of classic gut malabsorption as well as subtle manifestations of malabsorption (*e.g.*, unexplained iron deficiency anemia). Conversely, the differential diagnosis of villus blunting or intraepithelial lymphocytosis includes small-intestinal bacterial overgrowth, tropical sprue, autoimmune enteropathy, common variable immunodeficiency (CVID) enteropathy, and *H. pylori* gastritis, emphasizing that celiac disease is also not solely a histological diagnosis.

Immune Pathophysiology

Celiac disease results from the activation of T cells by gluten peptide–MHC complexes on APCs in the lamina propria of the gut (primarily the small intestine). In the absence of dietary gluten or the specific MHC molecules HLA-DQ2 or -DQ8, celiac disease, theoretically, cannot occur. Dietary gluten, largely from wheat, barley, and rye, exists in polymeric (glutenin) and monomeric (gliadin) form and is incompletely digested to small peptides by gut luminal enzymes because of their high glutamine and proline content.[16] These large gluten peptides cross the epithelial barrier and bind to the specific HLA-DQ2 or -DQ8 molecules. The enzyme tissue transglutaminase can deamidate gluten peptides, and the resulting negatively charged gluten peptides actually have increased affinity for the HLA binding site. Gut microbes also can affect the immunogenicity of gluten peptides via their own proteolytic enzymes.[17] The gluten peptide-activated T cells produce proinflammatory cytokines interferon-γ (IFN-γ), interleukin-18 (IL-18), tumor necrosis factor (TNFGr-), and IL-21. The activated T cells also induce B-cell maturation to plasma cells producing antibodies to gluten peptides as well as the tissue transglutaminase. The reason for tissue transglutaminase being targeted for autoantibody production and its role in disease is unknown.

According to animal models, the activated T cells are not sufficient to induce the epithelial damage and villus blunting. The characteristic villus atrophy is induced by gut APC- and epithelial cell–produced IL-15, which enhances infiltration of CD8 T cells into the epithelium and upregulates NKG2D receptors on intraepithelial T lymphocytes (IELs) conferring cytotoxicity against the epithelium. More recently, it was found that the IEL signaling induced by NKG2D ligands MICA/B upregulated on epithelial cells stimulates a leukotriene pathway (together with IL-15 exposure) that itself produces cysteinyl leukotrienes (CystLT) that appear to drive the IEL-based killing. The impact of this observation is the possible use of montelukast, a CystLT inhibitor and drug widely used in allergic asthma, to treat celiac disease.[18]

Beyond the HLA associations with disease, genome-wide association studies (GWAS) have linked over 30 disease susceptibility loci with non-HLA regions. One such locus is a polymorphism in *lnc13*, a long noncoding RNA, which affects its binding with a heterogeneous nuclear ribonucleoprotein to undo its repression of other genes, including inflammatory mediators.[19]

Diagnosis

The diagnostic workup of celiac disease is initiated by both suggestive symptoms and signs (weight loss, chronic diarrhea) as well as by atypical presentations, such as specific micronutrient deficiencies or unexplained hyperamylasemia or hypertransaminasemia.[20] Initial tests include measuring serum immunoglobulin A (IgA) antibodies against tissue transglutaminase and endomysial proteins, which have an estimated specificity/sensitivity of 95%/95% and 100%/>90%, respectively.[21] It is necessary to measure a total serum IgA level at the same time to be certain that these IgA-based screening tests do not yield false–negative results. However, in the setting of IgA deficiency (where celiac disease has an increased incidence), elevated IgG anti–tissue transglutaminase (TTG) or deamidated gliadin levels and identification of celiac disease susceptibility HLA genes can help determine the risk and presence of disease.

In any case, an important part of celiac diagnosis is biopsy of the upper small intestine mucosa (Fig. 75.1B,C); typically three to four endoscopic biopsy specimens are obtained from both the duodenal bulb and the distal duodenum. Although the absolute requirement for histological diagnosis of celiac disease may be debated (and cannot be used alone because of lack of specificity), it remains important for several reasons: *(i)* Currently, the serologic markers should only be used as a screening test, identifying which patients are at highest risk for the disease and appropriate for biopsy confirmation; *(ii)* even in the presence of celiac-susceptible HLA genes, only a minority of persons will develop celiac disease (latent disease), so evaluating nonspecific symptoms will require histological examination; and *(iii)* because the treatment can be life altering, the most comprehensive information is needed to make a definitive diagnosis.

Beyond celiac disease, a true gluten-induced enteropathy, other gluten-centric entities have been identified, namely, non–celiac disease gluten sensitivity and IgE-mediated gluten allergy. Non–celiac disease gluten sensitivity includes a set of poorly characterized gut and extraintestinal symptoms that lack the defining features of celiac disease yet respond to a gluten-free diet (GFD).[22] Increased levels of serum markers for bacterial translocation (lipopolysaccharide [LPS]-binding protein, soluble CD14) and epithelial damage (circulating fatty acid binding protein 2) that is reversed following a wheat-free diet in a subset of subjects suggests altered gut permeability related to wheat and cereal exposure may be a factor contributing to symptoms.[23]

Treatment

The treatment of celiac disease is avoidance of gluten, specifically foods containing wheat, barley, and rye. The expected response to gluten restriction is the resolution of symptoms and malabsorption. Follow-up endoscopy to assess response to therapy should be done only after 6–12 months of a strict GFD, although full recovery of the villus mucosa may take several years. There are no accurate biomarkers to monitor adherence to a GFD, although one indication may be a fall in the pretreatment level IgA anti-TTG serum antibodies; therefore, follow-up endoscopy with biopsy is needed to document restoration of the villus architecture. Symptom improvement, correction of malabsorption, and regrowth of villi (seen by endoscopy or video capsule) may not reflect complete full histological healing, yet the long-term risk of partial histological recovery is unknown.

About 5% of patients with celiac disease do not respond to a GFD. Ensuring a strict adherence to a GFD is important to identify the reasons for nonresponse, whether through inadvertent gluten exposure or whether the inflammation is truly refractory to a strict GFD. One group of patients with the so-called refractory celiac disease with polyclonal IEL populations may respond to corticosteroids and immunosuppressant treatment; another group with monoclonal IELs do not respond to such treatment and are at increased risk of lymphoma.[24]

The majority of patients with celiac disease respond positively to a GFD with return of normal gut absorption. However, ongoing inflammation is associated with risk of small bowel lymphoma, so ensuring adherence to a GFD and documenting mucosal healing can affect the natural history of this disease. Finally, since first-degree relatives are at increased risk of celiac disease, patients should be advised of serum antibody screening of these family members.

CROHN DISEASE

Crohn disease is a chronic idiopathic inflammation of the gut characterized by transmural involvement of the bowel wall (mucosa, muscle layer, and serosa) (Fig. 75.1D). Although often referred to as "terminal ileitis," the majority of patients with Crohn disease have colonic inflammation in addition or solely.

KEY CONCEPTS

Celiac Disease

- Patients with celiac disease present more often with complications of malabsorption than chronic diarrhea and weight loss.
- Human leukocyte antigen (HLA)-DQ2 or -DQ8 alleles are necessary but not sufficient for celiac disease to develop, as they are present in more persons unaffected by celiac disease.
- Immunoglobulin A (IgA) antibodies to tissue transglutaminase and endomysial proteins should be used for screening only (not diagnosis) and should be measured along with total IgA for validity.
- The goals of gluten-free diet treatment are relief of symptoms, reversal of malabsorption, and restoration of villi.

ON THE HORIZON

Celiac Disease

- Discovery of additional genetic and environmental factors (beyond gluten) that strongly confer risk for celiac disease in the setting of human leukocyte antigen (HLA)-DQ2 and -DQ8 alleles leading to strategies to modify or eliminate that risk
- Novel therapies that modify gluten to nonimmunogenic forms or that induce tolerance to gluten in persons at risk for or suffering from celiac disease or are alternatives to a gluten-free diet
- Identification of specific celiac disease–relevant components of the microbiome that influence the expression of disease

Crohn disease typically runs a chronic, relapsing course often complicated by bowel obstruction as a result of fibrous strictures as well as abscesses and fistulae caused by extension of inflammation beyond the bowel wall. Most of these patients will require surgical treatment at rates up to 80% after 20 years' disease duration. Crohn disease is treated with corticosteroids and immunosuppressants and more recently with antibodies targeting TNF-α and the integrin molecules α_4 and $\alpha_4\beta_7$.

The cause of Crohn disease is unknown, but it is thought to result from a dysregulated immune response to gut microbes. There is clear evidence for heritable disease susceptibility in twin and multiplex family studies, and several genes involved in innate immune function, notably mutations in *NOD2,* have been linked to Crohn disease risk. However, it seems clear that the complex interactions of environmental exposures (including the gut microbiome and its metabolome), innate and adaptive immune dysfunction, and complex genetic and epigenetic features are all complicit in disease causation and expression.[25]

Presentation

Patients with Crohn disease most often come to medical attention because of abdominal pain, altered bowel habits, and rectal bleeding. Abdominal pain may indicate bowel obstruction (especially if the pain is postprandial), an inflamed viscus, or a penetrating complication, such as an abscess or fistula. Diarrhea is related to malabsorption and dysmotility secondary to the effects of inflammatory cytokines on gut function. Diarrhea can also result from noninflammatory mechanisms (bile salt wasting, small intestinal bacterial overgrowth, etc.). Conversely, constipation in Crohn disease can be a sign of stricturing of the bowel. Rectal bleeding results from mucosal friability and ulceration. In addition, fever, unexplained weight loss, fatigue, anemia, and growth retardation (in children) can accompany the GI complaints or even be the primary presentation. Extraintestinal manifestations of Crohn disease include arthritis, uveitis, inflammatory skin lesions (pyoderma gangrenosum and erythema nodosum), and stomatitis. The arthritis can affect the axial (spine and pelvis) and articular skeleton, with the latter more often mirroring the activity of the gut disease. The joint complaints range from usual arthralgias to frank synovitis with swelling and tenderness (without erosive joint destruction). The uveitis most commonly occurs as episcleritis and iritis. Many of these lesions will subside with effective therapy aimed at the gut, but they can also have independent courses that require site-targeted treatment.

The incidence of Crohn disease in North American populations has been estimated to be ≈3.1–14.6 cases/100 000 person-years. Ashkenazi Jewish heritage confers increased risk in Caucasians, whereas African Americans seem to have rates similar to those of non-Jewish Caucasians, and Hispanics and Asians have much lower rates.[26,27] There is a genetic risk with up to 10-fold increased rates of IBD in relatives of patients with Crohn disease and a 30% concordance rate in monozygotic twin pairs.[28] The typical patient is diagnosed in his or her second or third decade, and there is no significant gender preference. The only environmental exposure that has been repeatedly linked to risk of Crohn disease has been tobacco use.

The majority (up to 70%) of Crohn patients experience a remitting and relapsing course, but some have chronically active symptoms refractory to medication. The recognized phenotypes of disease include inflammatory (manifesting primarily as intestinal edema and ulceration), fibrostenotic (luminal narrowing by fibrous strictures dominate with symptoms of painful obstruction), and fistulizing (inflammatory tracts between the bowel and other intestines, the bladder, vagina, skin, and other structures). Although the majority of patients have inflammatory disease at the time of diagnosis, over time this phenotype changes so that after 20 years of disease duration, up to 70% and 18% of patients with Crohn disease report penetrating and fibrostenotic complications, respectively.[29] Accompanying this change in phenotype is the need for surgical treatment in most patients after 20 years of disease duration.

Immune Pathophysiology

The current paradigm of Crohn disease inflammatory origins is a dysregulated immune response to gut commensal microbial components (antigens and pathogen-associated molecular patterns). Initial rodent colitis models showed a predominant T-helper cell-1 (Th1) inflammation, where the colitis could be blocked or reversed by treatment with anti–IL-12 antibodies. Roles for IL-23 and IL-17 in Crohn disease were later supported by the IL-10–deficient mouse model of spontaneous colitis and the cell transfer model of induced colitis, where colitogenic naïve $CD4^+CD45RB^{high}$ T cells from wild-type mice are infused into T cell–deficient mice.[30,31] However, despite the important role of the IL-23/IL-17 axis in the transfer model of colitis, blockade of IFN-γ activity also prevented development of gut inflammation.[32] Although studies of Crohn disease confirm that production of IL-12, IL-23, IFN-γ, and IL-17 are significantly elevated,[33] the hierarchy of cytokine control of inflammation in Crohn disease has been tested by clinical trials using agents that have targeted IFN-γ, IL-12, IL-23, and IL-17. The anti–IFN-γ monoclonal antibody (mAb) fontolizumab showed no clinical efficacy in Crohn disease (but did decrease C-reactive protein [CRP] levels[34]). However, anti–IL-12/-23 p40 subunit mAbs targeting the Th1 and Th17 pathways resulted in clinical improvement that led to the current use of ustekinumab for Crohn disease.[35,36] Unexpectedly, antibodies targeting IL-17A alone (secukinumab) or the IL-17AR receptor subunit (transducing IL-17A, -17E, and -17F intracellular signals) either did not show clinical improvement (and was associated with increased fungal infections[37]) or even induced clinical deterioration (the anti–IL-17AR antibody).

To date, it is estimated from multiple genome polymorphism studies that over 160 IBD susceptibility loci exist, most associated with risk of both Crohn disease and UC, 30 loci associated only with Crohn disease, and 23 loci associated only with UC. However, it was further estimated that all the loci together could account for no more than 13.6% of Crohn disease and 7.5% of UC disease risk.[38] Although most of these loci are in the noncoding regions of genes thought to modulate gene expression, the actual genes implicated have roles in the immune response and epithelial integrity, providing biological plausibility for their involvement in IBD. Several examples stand out: *(i)* the *NOD2* gene, encodes an intracellular protein that binds muramyl dipeptide (MDP), a component of the bacterial cell wall TLR2 ligand peptidoglycan. Disease-associated mutations in the MDP-sensing leucine-rich repeat domain of *NOD2* are associated with defective activation of nuclear factor (NF)-κB. This disrupts the microbe recognition pathway, but because *NOD2* is also expressed by small intestinal epithelial Paneth cells, mucosal production of antimicrobial defensins is decreased as well. *(ii)* The *ATG16L1* autophagy gene is important for the metabolism of autologous cell proteins as well as intracellular microbes. Expression of the Crohn disease–associated Thr300Ala polymorphic *ATG16L1* sequence in a colon cancer cell line showed *in vitro* inhibition of packaging of intracellular *Salmonella* into autophagosomes, supporting the hypothesis that this mutation could lead to impaired clearance of microbes and chronic inflammation.[39] This *ATG16L1* polymorphism provides a caspase cleavage site that enhances degradation of this allele and leads to defective autophagy.[40] *(iii)* A polymorphism in the coding region of the IL-23 receptor gene (Arg381Gln) found in 14% of healthy controls is associated with protection from Crohn disease (less so UC) and is associated with decreased Th17 cascade effector cells.[41]

The emergence of the role of the commensal microbiota in immune homeostasis has produced renewed interest in its role in IBD, where a number of studies show a dysbiosis compared with the healthy gut microbiota. This change in the microbiota in IBD has been characterized as a flipping of the Bacteroidetes-to-Firmicutes phyla ratio with reduction in Firmicutes.[42] In addition, Crohn disease has been associated with a reduction in the butyrate-producing *Faecalibacterium prausnitzii* compared with healthy controls, but it is not known whether this is a cause or effect of the gut inflammation. The roles of antibiotics, probiotics, prebiotics, or actively changing the microbiota through fecal transplant have not been clarified sufficiently to employ these strategies as conventional treatments in Crohn disease.

Diagnosis

The diagnosis of Crohn disease is based on findings from radiographic, endoscopic, and histological examinations. In general, a combination of colonoscopy (with ileal intubation, if possible) and small bowel examination (barium small bowel follow-through, computed tomography [CT] or magnetic resonance enterography, and capsule video endoscopy) is usually sufficient to demonstrate active inflammatory disease of the colon and small bowel. Endoscopically, mucosal ulceration and friability in a patchy distribution separated by unaffected mucosa ("skip areas") are hallmarks of the disease. Radiographically, evidence of patchy bowel wall thickening, mucosal hyperemia, stricturing, and penetrating complications, such as fistulae, abscesses, and extraintestinal inflammatory masses involving the bowel, all suggest Crohn disease. Histologically, although the appearance of noncaseating granulomata is highly supportive of a diagnosis of Crohn disease, in practice, they are not often detected by endoscopic biopsy, particularly in adults. More often evidence of chronic inflammation, such as architectural crypt distortion and basal lymphoplasmacytosis, are sought to differentiate the inflammation from an acute, self-limiting colitis or enteritis. Other findings, such as fecal leukocytes or elevated fecal calprotectin, may indicate an inflammatory colitis but is not specific for diagnosis of a chronic idiopathic IBD, such as Crohn disease or UC. In the setting of supportive findings through imaging or endoscopy, the measurement of certain serum antibodies can further strengthen the diagnosis of Crohn disease and even help differentiate it from UC, but they should not be used by themselves as diagnostic tests.[43] It has been shown that up to 68% of patients with Crohn disease are seropositive for antibodies targeting microbial antigens, such as anti–*Saccharomyces cerevisiae* antibody (up to 16% of patients with UC are seropositive). Additional antimicrobial antibodies, such as anti-OmpC, anti-I2, anti-flagellin 3, X, and CBir, also develop in Crohn disease.

It goes without saying that prior to treatment, Crohn disease may need to be differentiated from other similarly presenting conditions, including UC, chronic ischemic colitis, infectious enteritis/colitis (amebiasis, *Yersinia enterocolitica* infection, *Mycobacterium tuberculosis* infection), intestinal lymphoma, celiac disease, diverticula-associated colitis, and radiation- and nonsteroidal antiinflammatory drug (NSAID)–induced enteropathy.

Treatment

The treatment of Crohn disease includes medical and surgical approaches. Since there is no cure for Crohn disease, the principles of therapy are to first make sure that symptoms are secondary to the underlying idiopathic inflammation and not caused by infectious or noninflammatory factors, such as coexisting irritable bowel syndrome (IBS). The goal is to induce quick remission of symptoms and establish therapy to maintain the remission with aggressive initial therapy commensurate with the extent and activity of the disease. A traditional approach to therapy has been to use short-term corticosteroids and mesalamine preparations to start with in mild disease (these agents are not useful for long-term maintenance of a clinical response), add immunosuppressants (azathioprine, 6-mercaptopurine, or methotrexate) if symptoms persist or are moderate, and finally start anti–TNF-α agents for recalcitrant or initially severe disease.[44] Only corticosteroids and the anti–TNF-α agents are relied on for inducing clinical responses in short periods, within days to weeks. Therefore corticosteroid use may need to be prolonged while immunosuppressants are begun concomitantly, since the latter's clinical effects may not be maximized until months later. For maintenance of remission, only immunosuppressants and anti–TNF-α agents reliably exert long-term control of symptoms. In this way, they may be used for years as long as the disease is responding. Currently, medically refractory inflammatory disease may be treated with natalizumab, an anti-α_4 integrin antibody, although this is being supplanted by vedolizumab, an anti-$\alpha_4\beta_7$ antibody inhibiting the trafficking of lymphocytes from the blood specifically into the gut lamina propria. Because of substantially reduced concerns about a rare infectious side effect with vedolizumab (progressive multifocal leukoencephalopathy has been associated with natalizumab), it is a more attractive antiintegrin therapy for IBD. An established approach to immunosuppressant- and biological-naïve patients is to begin with a combination of azathioprine and infliximab, as this has been shown to be superior to either a single agent alone for inducing remission, especially 1 year later.[45] This "top-down" approach continues to be studied for long-term efficacy as well as for identifying those patients with Crohn disease with a pretreatment risk profile predicting more aggressive disease.

Surgery is required in cases of complications, such as bleeding, pain/obstruction, and fistulae that are refractory to medical therapy. Surgery typically involves resection limited to inflamed segments of small intestine and colon; small strictures can be treated *in situ* by stricturoplasty. In addition, surgery is required for treatment of intestinal adenocarcinoma, which also complicates the chronic inflammation of the bowel.[46] There is a high incidence of endoscopic and symptomatic recurrence of inflammation by 2 years after surgery, but to date, there is no consensus about who should routinely receive preventive therapy.

KEY CONCEPTS

Crohn Disease

- Crohn disease affects the full thickness of the bowel wall resulting in fistulae and abscesses in 70% of patients by 20 years' disease duration.
- Crohn disease is a chronic, relapsing inflammation of the bowel, and up to 80% of patients will require surgical treatment at some point.
- Several gene mutations and many genetic loci are associated with disease risk, including *NOD2* and *ATG16L1*, which are important in innate immune function.
- T-helper 1 (Th1) and Th17 cytokine pathways mediate disease in animal models, but the hierarchy of these cytokine pathways in human disease is still being tested by targeting strategies in clinical trials.

ULCERATIVE COLITIS

UC also involves chronic idiopathic inflammation of the gut, but this is limited to the mucosal layer of the colon (Fig. 75.1E). It can affect the rectum alone (ulcerative proctitis), the distal transverse colon to rectum (left-sided colitis), or the entire colon (pancolitis). Because it lacks the transmural inflammation of Crohn disease, penetrating complications, such as fistulae and abscesses, are generally not features of UC. Oral and topical (per rectum) mesalamine preparations are most often used to treat UC, although patients also may require corticosteroids, immunosuppressants, and anti–TNF-α antibody agents to induce and maintain remission. Unlike Crohn disease, total colectomy eliminates the disease. However, there can be ongoing complications of the surgery, such as pouchitis, when an ileal pouch–anal anastomosis is performed. Over 40% of patients with UC require surgery to treat medically refractory symptoms or development of dysplasia over their lifetime.[47]

Presentation

The presentation of UC reflects the primary involvement of the rectum and extent of proximal colitis. Bloody stool and diarrhea (including nocturnal) are common symptoms, with proctitis-specific complaints of rectal urgency and incomplete evacuation also being prominent. As in Crohn disease, fever, unexplained weight loss, fatigue, and anemia can accompany the GI complaints or be the primary presentation. Extraintestinal manifestations may include arthritis, uveitis, inflammatory skin lesions, and stomatitis. An interesting genetic connection exists between UC and HLA-B27–positive spondyloarthropathy (Chapter 57), with 60% of patients with ankylosing spondylitis showing inflammation on colonoscopy. UC is also closely associated with primary sclerosing cholangitis (PSC; Chapter 76); up to 3% of UC patients develop PSC, and up to 75% of all patients with PSC have UC.[48]

With an incidence up to 20.3 cases per 100 000 person-years, typically the diagnosis of UC is in the second or the third decade, and there is no significant gender preference. Approximately 6–15% of first-degree relatives of patients with UC have a history of UC, but in general, the genetic contribution to risk is lower than in Crohn disease. There is a higher incidence of UC in European and North American populations compared with that in Asian and Latin American countries. The only environmental exposures linked to risk of UC are the protective effect of tobacco use and appendectomy in the first decade of life.

The natural history of UC shows that most patients experience a remitting and relapsing course (60%), although some have prolonged remission after one episode of disease (20%), and others have chronically active symptoms refractory to medical remission (20%). Total colectomy is performed to treat refractory symptoms or development of epithelial dysplasia. Chronic inflammatory UC (and Crohn colitis) is accompanied by an increased incidence of colorectal cancer (18% after 30 years' disease duration), so much so that recurring colonoscopic surveillance for dysplasia with biopsy is recommended starting 8–10 years after diagnosis.

Immune Pathophysiology

UC has been characterized as a Th2-like disease because of the increased IL-5 and IL-13 production in inflamed gut tissue seen in an animal model of UC, oxazolone-induced colitis, as well as from patient specimens.[49] In this model, not only were mucosal natural killer T (NKT) cells the source of excess IL-13, but the colitis was reversed by immunoneutralizing anti–IL-13.[50,51] When translated to humans, patients with UC were found to have high capacity for IL-13 production, also by type II NKT cells. It turns out that IL-13 is a biologically plausible effector cytokine in UC injury because it disrupts the epithelial tight junction by upregulating claudin-2 and has a direct toxic effect on human gut epithelial cells *in vitro.*[52] However, results from a clinical trial using an anti–IL-13 antibody in UC did not show significant treatment efficacy.[53]

Data from genetic susceptibility studies in UC have provided less compelling examples of disease-specific mechanisms compared with those in Crohn disease, but there are associations with HLA class II genes distinct from Crohn disease. Furthermore, other associated loci contain genes involved in epithelial barrier function, such as *GNA12* for tight junction formation, *CDH* for epithelial cadherin-1, and *LAMB1* for the laminin constituent of basement membranes.[28] When specifically assaying epithelial cells (vs whole tissue) for epigenetic markers associated with genomic risk loci, there is an enhanced association supporting the epithelium as a primary target for dysfunction in UC.[54]

Diagnosis

The diagnosis of UC is based on a colitis that typically involves the rectum and adjacent proximal colonic segments in a confluent inflammatory injury. This is best accomplished by colonoscopy (ileal intubation can confirm that the inflammation is limited to the colon). Biopsy specimens should contain histological features of chronic inflammation, including crypt distortion, crypt dropout, and lymphoplasmacytosis. The presence of acute inflammatory features alone (polymorphonuclear cells, crypt abscess, and cryptitis) may also be seen but, when in isolation, these features suggest other etiologies, such as acute infectious, drug-induced, ischemia, and toxic exposures. Although no blood test can be used to diagnose UC, the presence of high-titer perinuclear antineutrophil cytoplasmic antibodies (pANCAs) can be seen in up to 70% of patients with UC; this information can help differentiate chronic indeterminate colitis when coupled with anti-*Saccharomyces cerevisiae mannan* antibodies (ASCAs; see above). At all times, acute infections from enteric pathogens, including *Clostridium difficile,* should also be excluded, as these may also occur during active IBD treatment and mimic exacerbation of disease (evaluation for cytomegalovirus [CMV] infection should be performed in the setting of UC seemingly refractory to immunosuppressants). Once a diagnosis is established, elevations in transaminases or alkaline phosphatase should prompt an evaluation for PSC starting with magnetic resonance cholangiopancreatography.

Treatment

Treatment is tailored to the extent and activity of disease.[55] For instance, mild to moderate proctitis can respond to topical corticosteroids or mesalamine alone (enemas and/or suppositories). Most often with more extensive colonic involvement, oral mesalamine is required, which can be useful for induction and maintenance of remission. In moderate to severe disease, corticosteroids may be required to induce rapid responses, whereas immunosuppressants, such as azathioprine or 6-mercaptopurine, are used for remission. Anti–TNF-α agents are used to induce fairly rapid clinical responses and remission and may also be used as maintenance therapy. Vedolizumab has been a recent addition to conventional therapy as well.

Mesalamine-based drugs are a cornerstone of therapy in UC and are generally included in most ongoing UC medical regimens. Whether use of mesalamine even in quiescent disease confers chemoprotection from developing dysplasia is still being debated, but because of their generally low adverse event rate and high tolerance, long-term use is a reasonable choice.

As discussed, surgery has a definite role in treating medically refractory disease or addressing dysplasia discovered by surveillance colonoscopy (dysplasia surveillance is done every 1–2 years after 8–10 years of disease by taking four-quadrant biopsy specimens every 10 cm). Total colectomy is performed, and options include an ileal pouch–anal anastomosis or a permanent end ileostomy. However, even the pouch can become chronically inflamed; generally antibiotic-responsive, this inflammation can also become refractory and require steroid, immunosuppressant, or biological therapy and even pouch removal.

KEY CONCEPTS

Ulcerative Colitis

- Ulcerative colitis is a chronic, relapsing inflammation of the colon that is limited to the mucosa and is not transmural.
- Animal models and human disease show the dominant cytokines to be interleukin (IL)-5 and IL-13, suggesting a T-helper 2 (Th2)–like (without IL-4) inflammatory response, although IL-17 and interferon (IFN)-γ are also active.
- Although less strongly associated with genetic inheritance compared with Crohn disease, several disease susceptibility loci have been identified and are associated with epithelial barrier function.
- Over the course of the disease up to 40% of patients will undergo total colectomy for refractory symptoms or detection of epithelial dysplasia.

ON THE HORIZON

Inflammatory Bowel Disease (IBD)

- Establishment of new therapies targeting key cytokines and signaling pathways, especially anti-SMAD7 for transforming growth factor (TGF)-β enhancement, JAK/STAT inhibition, and immune cell–based treatments
- Improvement in detection of dysplasia using molecular techniques for better understanding of the incidence, natural history, treatment, and prevention of colonic epithelial dysplasia and neoplasia
- Refining genome-wide association studies (GWAS) using large-scale fine-mapping to identify the actual polymorphisms in coding and noncoding regions and to better test the mechanisms of IBD susceptibility
- Defining whether the dysbiosis in IBD is a cause or effect and how the microbiome is influenced by genetic background and inflammatory status

OTHER IDIOPATHIC INFLAMMATORY BOWEL DISEASES

Microscopic Colitis

Microscopic colitis is an increasingly recognized condition that links chronic watery diarrhea with isolated intraepithelial lymphocytosis (lymphocytic colitis) or with increased subepithelial collagen deposition (collagenous colitis). It differs from Crohn disease and UC because it does not display endoscopic mucosal damage or show evidence of histological chronicity (no architectural crypt distortion, lymphoplasmacytosis, or loss of Goblet cells). However, it causes significant morbidity and may require chronic immunosuppression for treatment. Although its etiology remains elusive, there are associations with autoimmune conditions as well as with certain drug exposures.

The hallmark symptom of microscopic colitis is chronic, watery, nonbloody diarrhea that is frequently accompanied by marked complaints of poor quality of life. Fatigue, arthralgias, and weight loss may also be reported. Microscopic colitis has its typical onset in the sixth and seventh decades, has a female predominance, and is associated with a history of autoimmunity especially thyroid disease, rheumatoid arthritis, and CREST (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) syndrome.[56] A connection between microscopic colitis and celiac disease has also be observed, with lymphocytosis of the colonic epithelium found in one-third of patients with classic malabsorption symptoms and small-bowel lesions of celiac disease. This may be a sequela of gluten antigen reactivity extended to colonic epithelial responses, but it becomes important to address as an independent process related to the microscopic colitis itself if diarrhea and colonic lymphocytosis persist despite a GFD. Conversely, although celiac-like villus blunting may be seen in <10% of patients with microscopic colitis, celiac serologies will not be positive, indicating that classic gluten enteropathy is not playing a role.

There is no current information on the immune mechanism of microscopic colitis. Activated NF-κB is seen in the mucosa of microscopic colitis, consistent with the general inflammatory picture. Increased nitric oxide and prostaglandin production have also been measured, possibly contributing more to the diarrhea rather than the inflammation. Excessive transforming growth factor (TGF)-β has also been measured in collagenous colitis, consistent with its role in collagen production and fibrosis. Interestingly, medications have been associated with microscopic colitis, including H2 blockers, proton pump inhibitors (PPIs), selective serotonin reuptake inhibitors (SSRIs), and ticlopidine, among others.[57] Reports also suggest that long-term use of NSAIDs may induce or sustain microscopic colitis.

The diagnosis of microscopic colitis relies on histology. The *sine qua non* for microscopic colitis is increased numbers of intraepithelial lymphocytes (>20 lymphocytes/100 epithelial cells) on colonic mucosal biopsy. This can be accompanied by a chronic inflammatory infiltrate in the lamina propria and, less often, a limited appearance of neutrophils (especially cryptitis), the latter finding suggesting that the etiology of the microscopic colitis may actually be related to an injurious drug effect, such as NSAID exposure. In collagenous colitis, a prominent subepithelial collagen band ≥10 μm is seen in addition to the intraepithelial lymphocytosis.

As a general treatment approach to the patient with microscopic colitis, the clinician should review and eliminate suspect concomitant medications, such as NSAIDs. Coexisting celiac disease should be considered, where appropriate, and addressed with gluten withdrawal. Overall the choice of treatment begins with low-risk medications in mild or moderate disease in an attempt to settle on a regimen that delivers the most relief of symptoms with the lowest side effects.[58] Therefore treatment can begin with antidiarrheals (loperamide, diphenoxylate/atropine), adding a trial of cholestyramine (bile salt malabsorption has been hypothesized to play a role in microscopic colitis) and even a trial of mesalamine. Bismuth subsalicylate has been reported to benefit a minority of patients with microscopic colitis; three 262 mg tablets PO three times daily may result in long-term remission in some (some have reservations about the long-term toxic effects of bismuth). In patients with initially severe symptoms or who are refractory to these first treatments, corticosteroids have been very effective. In particular, oral budesonide 9 mg taken once per day has reliably improved diarrhea and induced remission, a result supported by placebo-controlled studies.[59] The challenge is balancing relief of symptoms with the long-term side effects of corticosteroid use (including budesonide) in relapsing or steroid-dependent disease. In this case, emerging strategies include use of lower doses of budesonide while monitoring for side effects or using steroid-sparing immunosuppressive medications, such as azathioprine and methotrexate, for long-term maintenance. Reports of anti–TNF-α drugs for refractory microscopic colitis have been published.[60] Occasionally, patients may need colectomy and ileostomy to manage refractory symptoms or drug intolerance.

Eosinophilic Esophagitis

Eosinophilic esophagitis (EoE) is a more recently recognized disease defined by symptomatic idiopathic eosinophilic inflammation in the absence of other known causes, especially chronic gastroesophageal reflux disease (GERD).[61] Although its etiopathology is unclear, there are gene associations (*FLG* for epithelial barrier effects and *eotaxin-3* and *TSLP* for immune response effects), and data from animal models and human disease have implicated central roles for loss of tolerance to food antigens involving Th2 cytokines IL-5 and IL-13. EoE is being recognized with increasing frequency against a background of increased incidence of inflammatory allergic diseases.

EoE is estimated to occur at 4–5 cases/10 000 children, has a male predominance (up to 70%), and peak incidence in neonates to 3-year-olds. Symptoms include failure to thrive and feeding difficulty in infants (*e.g.,* food refusal, limited variety diet, prolonged feeding times) and abdominal pain and vomiting in older children and adolescents. In adults, the primary symptom is typically intermittent dysphagia, with the first presentation possibly being an acute food impaction in the esophagus. Adult patients may report GERD symptoms that do not respond to adequate acid-suppression therapy. Patients report a high rate (>50%) of atopy (rhinoconjunctivitis, wheezing, or family history of atopy) as well as food allergies (including positive skin prick test, allergen-specific IgE test, or anaphylactic response to a dietary allergen).[62] There is also an association of esophageal disease (strictures or EoE) in the parents of up to 10% of patients.

The diagnosis of EoE requires endoscopic biopsy of the esophagus, since increased eosinophils in the esophageal epithelium must be measured. The endoscopic appearance of the esophagus can show multiple thin rings (“feline esophagus”), with linear longitudinal furrows and whitish papules that represent eosinophilic microabscesses at the surface of the squamous epithelium. Biopsy should show an infiltrate of eosinophils in the epithelium of at least 15—20 eosinophils/high-power field (hpf). These often concentrate just under the epithelial surface and also form microabscesses in groups of ≥4 eosinophils. It is important to take at least three biopsy specimens, since involvement may be variable and patchy; in addition, it is advisable to take biopsy specimens from the distal and mid-to-upper esophagus (to help differentiate changes seen in GERD that can be limited to the distal esophagus) and specimens from the gastric and duodenal mucosae (to show that the eosinophilic infiltration is limited to the esophagus and does not represent a diffuse process, such as that found in eosinophilic gastroenteritis or hypereosinophilic syndrome). Systemic eosinophilia can be seen in over 70% of patients with EoE.

In terms of GERD, it is important to make sure that any excessive acid reflux is treated and controlled; persistent symptoms (and persistent biopsy abnormalities) may prompt a 24-hour ambulatory pH study of the distal esophagus to ensure that the acid-suppression treatment results in a normal acid-contact time. In fact, there seems to be a form of EoE that, while seeming to be without excess exposure to gastric acid, does, in fact, respond well to PPI treatment; this may be attributed to the non–acid-suppressive effects of a drug, such as omeprazole, that can suppress eotaxin-3 secretion from squamous mucosae.[63] Multiple types of esophageal dysmotility, often reversible with treatment, have been described in EoE, contributing more to dysphagia than to strictures.[64]

The pathogenesis of EoE seems to be linked to allergen hypersensitivity. Given a familial association of EoE, atopy, and food allergy, a genetic component may be contributing to disease susceptibility. Several candidate disease susceptibility gene/gene loci in EoE include the 3’ untranslated region of eotaxin (*CCL26*), the TGF-β_1 promoter, a filaggrin (*FLG*) exon, and a thymic stromal lymphopoietin (*TSLP*) intron and TSLP receptor (*CRLF2*) exon.[65] These associations are biologically plausible, since eotaxin is excessively expressed in EoE mucosae, filaggrin is a structural skin protein that helps maintain barrier function (and is downregulated by IL-13), and TSLP has been shown to stimulate IL-13 production by innate helper cells in the lamina propria. Moreover, the inflammation in EoE is characterized by increased IL-13 and IL-5 production; animal models of aeroallergen induction of an EoE-like lesion is blocked in both IL-13–deficient and signal transducer and activator of transcription 6 (STAT6)–deficient (an intracellular molecule important for IL-13 receptor α_1 signaling) animals.[66] These data suggest that IL-13 secretion induces production of eotaxin from epithelial cells, which, together with IL-5, drives the local eosinophilic infiltration. Finally, the association with food allergy has led to successful therapy of EoE by using strict elimination diets (sometimes informed by skin testing) or even the use of elemental diet tube feedings.

Given the strong association with food allergies, strict elimination of suspect foods or those identified by *in vitro* or skin prick testing may be restricted first. Lack of improvement in symptoms would lead to a trial of amino acid–based elemental liquid diet necessitating nasogastric (or later percutaneous gastrostomy) placement, but this can be uncomfortable, impractical, and expensive. If this dietary approach is successful, then after several weeks, individual foods may be added back every 5–7 days. For patients not responding to dietary therapy or with no identifiable dietary allergens, corticosteroid treatment has been used successfully. Both systemic oral and swallowed topical corticosteroids (*e.g.,* fluticasone propionate metered dose inhalers) for 4–6 weeks have been shown to relieve symptoms and resolve histological inflammation; one or the other may be more or less effective based on body weight, dose, steroid resistance, or severity of the EoE. However, relapse rates are high over the year following a course of steroids. Lastly, endoscopic therapy to treat strictures using dilation may incur higher risk of mucosal tears so that conservative treatment (smaller dilators, assessment for tears during the procedure before proceeding further) is encouraged.

Eosinophilic gastroenteritis encompasses an additional group of infrequent conditions that link increased intestinal eosinophilia (from mucosal to full-thickness intestinal wall infiltration) and symptoms, such as abdominal pain, diarrhea, and malabsorption.[67] These are assumed to be primary inflammatory responses, although exclusion of parasitic infections, especially with helminths, is a necessary part of the workup.

GASTROINTESTINAL COMPLICATIONS OF PRIMARY IMMUNODEFICIENCIES

Certain primary immunodeficiency diseases increase the risk for GI complications. These complications fall into three main categories: infectious, idiopathic inflammatory/autoimmune, and neoplastic. Common variable immunodeficiency (CVID) and chronic granulomatous disease (CGD) have some of the most frequent and significant gut manifestations, and these are discussed in detail below. However, a variety of inherited conditions of broad lymphocyte or innate immune cell dysfunction can also lead to gut disease. The study of monogenic diseases that are associated with inflammatory diseases of the gut have come to the attention of investigators, as they may be models for the mechanisms that could contribute to the pathophysiology of more genetically complex conditions, such as Crohn disease and UC.[68]

Common Variable Immunodeficiency

CVID is a syndrome of hypogammaglobulinemia (low levels of IgG and IgA and/or IgM) accompanied by recurrent sinopulmonary infections (Chapter 34). Patients have no isohemagglutinins and cannot mount an adequate antibody response to many vaccine antigens. In general, Ig replacement therapy improves the sinopulmonary infection rate but does not affect other complications, such as autoimmune disease and GI symptoms, including intestinal infections. Case series of patients with CVID have shown that up to 60% of patients experience GI symptoms[69] and that endoscopic and histological abnormalities can occur in the majority of patients with CVID. When considering the differential diagnostic possibilities for the GI complications of CVID, it is helpful to separate them into infectious, immune-mediated, and neoplastic processes. Among the infectious agents, *Giardia lamblia,* nontyphoidal *Salmonella,* and *Campylobacter jejuni* are frequently seen, but *Cryptosporidium* may also be found, and *C. difficile* and viral agents (CMV) may be encountered. In addition to the higher rate of gastric *H. pylori* infection, small-intestinal bacterial overgrowth (SIBO) is present in up to 30% of patients with CVID. The immune-mediated GI complications of CVID include idiopathic enteropathy (villous atrophy, increased intraepithelial lymphocytes/microscopic colitis, nodular lymphoid hyperplasia) (Fig. 75.1F) manifesting as severe malabsorption (see below) and, much less frequently, macroscopic ulcerating disease resembling UC or Crohn disease.[69] CVID-associated autoimmune disease involving the GI tract also includes type II gastritis that can lead to achlorhydria and vitamin B_{12} deficiency ("pernicious anemia") and even autoimmune hepatitis and primary biliary cirrhosis. Last, neoplastic complications of intestinal lymphoma and gastric adenocarcinoma (related to achlorhydric autoimmune gastritis) have been reported.

Presentation

The most common symptom of GI complications of CVID is episodic diarrhea that can progress to chronic diarrhea, regardless of the etiology. Weight loss and evidence of vitamin or mineral deficiencies may occur, with underlying maldigestion or malabsorption. In addition, patients may present with abdominal pain related to splenomegaly (with or without portal hypertension) or ascites (portal hypertension secondary to hepatic nodular regenerative hyperplasia [NRH] as a known complication of CVID). Fever, together with intestinal obstruction and GI bleeding, may indicate the development of small-bowel lymphoma. Patients with CVID may report increased frequency of GERD symptoms as well as dyspepsia, but these complaints are nonspecific and have been difficult to link with immune defects or autoimmune complications.

Immune Pathophysiology

It is not clear if lack of Igs alone causes susceptibility to gut infections and inflammation because patients with X-linked agammaglobulinemia infrequently develop overt GI disease (they lack B cells but have functionally intact T-cell populations). Even persons with selective IgA deficiency have little in the way of GI disease, including infections. In fact, the T-cell dysfunction that often accompanies CVID may contribute substantially to susceptibility to GI disease.

In terms of an increased GI infection risk, autoimmune gastritis-induced achlorhydria could increase small-bowel exposure to swallowed commensals and pathogens escaping this innate gastric barrier to infection. In addition, although the loss of secreted IgA alone is not enough to meaningfully increase susceptibility to intestinal infections, perhaps the additional loss of IgG and IgM and presence of T-cell dysfunction is more permissive, but no mechanism for this has been established. Mucosal nodular lymphoid hyperplasia, characterized by disorganized secondary lymphoid nodules with poorly formed germinal centers, is likely related to the inability of B cells to undergo class switching when presented with antigen *in situ.* Last, CVID enteropathy is characterized clinically by severe malabsorption and histologically by blunted villi and increased intraepithelial lymphocytes, and epithelial apoptosis is associated with excess Th1 cytokine secretion (IL-12 and IFN-γ).[70] It remains unknown why this inflammatory lesion occurs in the first place.

Diagnosis

The workup of GI complications of CVID often takes place as symptoms are usually first episodic but may eventually turn into chronic, progressive complaints.[71] The key to successful diagnosis is the initial search for treatable infectious causes. This requires stool assay and culture for bacterial (especially *Campylobacter*) and protozoal pathogens. In addition, hydrogen breath testing can help detect SIBO to provide another antibiotic-responsive etiology of the symptoms.

Negative results for infectious causes require endoscopy for biopsy of the proximal small intestine and colon. Routine histology will detect the features of enteropathy, including blunted villi and increased IELs, which are often interpreted as celiac disease. Unlike celiac disease, there usually is a lack of plasma cell infiltrate and crypt hyperplasia, as well as a preserved brush border and Goblet cells, and there is often an increase in epithelial cell apoptosis, particularly in the colon.[72] In fact, some of the villus changes in CVID enteropathy can be mimicked by SIBO, which should be investigated as described above. If the diagnosis of celiac disease must be considered, then genetic testing for celiac susceptibility HLA alleles should be performed; the absence of combinations of A and B alleles for HLA-DQ2 or -DQ8 that confer risk will rule this out. However, even if celiac disease gene alleles are detected, it still does not indicate that this is a gluten-driven celiac disease lesion but will require a trial of GFD nonetheless. The functional significance of any histological lesion in the small intestine can be evaluated by a measure of steatorrhea (fecal fat excretion) and small-bowel absorption (d-xylose absorption test), values that can be used to track improvement following treatments.

Treatment

None of the GI complications of CVID is treated by intravenous or subcutaneous immunoglobulin (IV/SCIG) (initial treatment might alleviate GI symptoms, it does not treat overt gut inflammation and ulcers),[73] and in fact, these complications typically occur in patients who have adequate trough levels of IgG. Patients with any bacterial or protozoal pathogens should be treated with a recommended course of conventional antibiotics, including those positive for the *C. difficile* toxin. SIBO should be treated, and recurrent SIBO may need cycling antibiotic regimens.

The treatment of the idiopathic enteropathy is very challenging. Although this seems to be a late complication in a subset of patients, it can be fatal. In the early stages, it may be responsive to a short course of oral corticosteroids, either prednisone or budesonide. Case reports attest to the efficacy of infliximab, but this cannot be routinely advised.[74] It is possible that immunosuppressants may be used to control the inflammatory response underlying the small-bowel mucosal damage, but this should only be done in a closely observed clinical setting, with monitoring for infections. At all times the patient's nutritional status should be maintained, initially using the oral route but administering parenteral nutrition to compliment oral nutrition and when oral feedings are not adequately absorbed and exacerbating the diarrhea.

Portal hypertension may complicate CVID, typically from the nodular regenerative hyperplasia of the liver; however, little fibrosis occurs. It needs to be clarified in individual patients with splenomegaly (≈20%) that portal hypertension is not caused by excessive splenic vein flow associated with splenomegaly (induced by antibody-mediated autoimmune cytopenias) that might be ameliorated by splenectomy. In any scenario, the management of such late complications requires an especially experienced team of internists, surgeons, and nutritionists.

KEY CONCEPTS

Common Variable Immunodeficiency (CVID)

- The majority of gastrointestinal (GI) complications of CVID are infectious and generally do not respond to intravenous or subcutaneous immunoglobulin (IV/SCIG) therapy (compared with sinopulmonary suppurative infections).
- CVID enteropathy is a rare immune-mediated complication of CVID that also does not respond to IV/SCIG.
- CVID enteropathy is often confused with celiac disease because of similar villus damage on biopsy, but additional features (lack of plasma cells, increased epithelial apoptosis, absence of celiac gene risk alleles) can help differentiate them.
- CVID enteropathy has no established therapy though judicious use of short courses of oral steroids, or conventional immunosuppression may relieve the malabsorption and diarrhea temporarily.

Chronic Granulomatous Disease

CGD results from defects in the nicotinamide adenine dinucleotide phosphate (NADPH)–oxidase complex that impair the ability of phagocytic cells to produce the reactive oxygen species required to kill bacteria and fungi within intracellular phagolysosomes (Chapter 22). Patients with CGD have recurrent infections of the skin, lungs, liver, and bone, and nearly half develop gut inflammatory complications affecting areas anywhere from the mouth to the anus. Interestingly, the frequency of GI disease in CGD is higher in the X-linked gp91^{phox} defect, but the most recently described p40^{phox} defect occurred in a young male patient who presented with granulomatous colitis alone.[75-77]

Presentation

The most typical GI complaints in patients with CGD are abdominal pain and diarrhea (with or without rectal bleeding). GI symptoms usually begin in the first decade of life, sometimes preceding the diagnosis of CGD. Although infectious diarrhea (especially *Salmonella* spp. and *C. difficile*) occurs in CGD, an idiopathic CGD-associated IBD also develops: In the mouth, granulomatous stomatitis and dental abscesses cause pain and difficulty eating; in the esophagus, dysphagia, chest pain, and vomiting may result from narrowing by strictures or stenosis and dysmotility related to granulomatous inflammation and fibrosis; in the stomach, loss of motility and capacity caused by thickened walls and narrowed lumen leads to vomiting, epigastric pain, and weight loss as a result of feeding difficulty; in the small and large intestines, diarrhea (including protein losing enteropathy), bowel obstruction (large granulomata compromising the size of the lumen), rectal bleeding, and tenesmus may result from active colitis/enteritis with mucosal ulceration, anal fissures, and perianal abscesses. In addition, because of the transmural nature of the granulomatous inflammation, penetrating complications, such as fistulae and abscesses, can occur. Feeding difficulties and the chronic inflammatory state itself predispose to growth delay that often affects pediatric patients with CGD.

Hepatic abscesses represent another frequent complication in CGD,[78] occurring in up to 45% of patients. These patients most often present with fever as well as abdominal pain, fatigue, and, less often, abdominal tenderness and hepatomegaly on examination. The erythrocyte sedimentation rate (ESR) and the alkaline phosphatase level are elevated in half the affected individuals. However, a high level of suspicion, especially in the setting of fever with or without abdominal pain, should instigate a search for hepatic abscesses.

Immune Pathophysiology

Given the defects in ability to kill intracellular bacteria and fungi, pathogens, and possibly commensals alike, it is thought that the exuberant granulomatous response is caused by delayed antigenic clearance or persistent infection. In this way, granulomata continue to multiply and grow while other inflammatory pathways that normally deal with the microbes or are induced by cytokines are activated. The end results of granulomatous inflammation are most evident in tissues rich in macrophages and reticuloendothelial cells, such as the gut lamina propria, liver, lymph nodes, and spleen.

Diagnosis

The symptoms and signs will dictate the initial diagnostic examinations. For diarrheal complaints, stool culture and examination for *C. difficile* toxin are required; in the setting of hypoalbuminemia, fractional fecal excretion of α_1 antitrypsin can detect protein-losing enteropathy (>50 mg/24 hour) as a result of either diffuse mucosal inflammation or lymphangiectasia. For complaints of dysphagia, vomiting, or epigastric pain, upper endoscopy can help document macroscopic and microscopic involvement with granulomatous inflammation. Radiological studies using oral contrast may be helpful in showing a narrowed lumen, stricturing, and motility and mucosal abnormalities of the esophagus and stomach but cannot provide histological confirmation. However, radiological imaging studies may be the primary diagnostic tools to evaluate obstructive symptoms from the small intestine, including barium small-bowel studies and CT or magnetic resonance enterography. Images can show lumen narrowing; bowel wall thickening; mucosal abnormalities, including ulceration; and penetrating complications, such as fistulization. Finally, to evaluate lower abdominal and perianal pain and rectal bleeding, anoscopy, colonoscopy, and pelvic CT or magnetic resonance imaging (MRI) will help diagnose granulomatous inflammation of the colon and its complications, including perirectal and perianal abscesses. In the case of hepatic abscess detection (generally 1–6 cm), CT, MRI, and ultrasonography have similar sensitivity (≈60%). Active abscesses appear to be solid, hypoechoic lesions on ultrasonography or postcontrast ring–enhancing lesions on CT and MRI.

The GI histological diagnosis hinges on the presence of noncaseating granulomata, both gross and microscopic. These granulomata are often seen against a background of acute inflammation (acute focal colitis, crypt abscesses, cryptitis) as well as chronic inflammation (lymphocytic infiltrate, Paneth cell metaplasia in the colon) that can be mild to severe. The histological picture may resemble Crohn disease except that the granulomata of CGD are well defined, often large collections of epithelioid histiocytes that can expand the mucosa (and even deform the overlying epithelium to make it look flattened in the case of the villous mucosa of the small intestine). Like Crohn disease, the inflammation can affect the three layers of the gut wall, but unlike in Crohn disease, CGD biopsy specimens also show prominent lipid-laden macrophages that have periodic acid-Schiff (PAS)–positive cytoplasmic granules.

Treatment

Current clinical practice for CGD includes using prophylactic antimicrobials to prevent infections, typically trimethoprim-sulfamethoxazole for bacterial and itraconazole for fungal infections. Some clinicians also use IFN-γ (subcutaneous, three-times-weekly dosing) to prevent infections, although this is not a universal practice.[79] Obviously, discovery of infectious etiologies of diarrhea should be treated appropriately.

Once infections are ruled out and granulomatous inflammation of the GI tract is established, with or without complications, such as stricturing of the bowel, treatment with corticosteroids is indicated; beginning doses up to 1 mg/kg/day tapering over 12–20 weeks to maintenance doses of 2.5–5 mg every other day has been reported to induce rapid alleviation of symptoms. Use of sulfasalazine for colitis may have limited benefit in some patients. Isolated reports of successful use of cyclosporine and infliximab have indicated that these agents are best reserved for refractory cases because of the potential for infectious side effects. Similarly both granulocyte–colony-stimulating factor (G-CSF) and granulocyte macrophage–colony-stimulating factor (GM-CSF) have been used with therapeutic benefit in GI complications of CGD because of their success in the granulomatous colitis of glycogen-1-β storage disease.[80] Although there are no data to suggest that IFN-γ worsens established disease, it also may not prevent it as >40% of one cohort developed GI manifestations of granulomatous inflammation after starting it; in contrast, isolated reports have attributed alleviation of GI inflammation to IFN-γ.[81] IL-1 receptor blockade, based on preclinical efficacy data in CGD, may offer limited success.[82]

Finally, it cannot be overstated that surgical drainage of complicating abscesses and resection of fibrotic or refractory strictures need to be pursued, when indicated. Although there can be considerable postoperative complications because of ongoing fistula formation and wound breakdown, these problems can be managed by administration of corticosteroids. In addition, judicious use of endoscopic therapy to dilate narrowed esophageal or pyloric regions is an option for symptomatic strictures.

Treatment of hepatic abscesses has been shown to be amenable to nonsurgical management by adding corticosteroids to the antibiotic regimen.[78] Empiric antibiotic coverage (at least to cover the most frequent isolate, *S. aureus*) is generally appropriate although percutaneous aspiration of hepatic abscesses maybe helpful.[83]

KEY CONCEPTS

Chronic Granulomatous Disease (CGD)

- Half of patients with CGD develop gastrointestinal (GI) involvement with granulomatous inflammation.
- Symptoms are caused by both obstructive complications of stricture formation and mucosal inflammation.
- A resemblance to Crohn disease is suggested by granulomatous inflammation, transmural bowel involvement, and underlying innate immune defect, but unlike in Crohn disease, there are also prominent skin and lung infections and periodic acid-Schiff–positive lipid-laden macrophages in the lamina propria.
- Complicated hepatic abscesses require specialized medical intervention.

GI Complications Occurring in Other Primary Immunodeficiency States

Severe combined immunodeficiency (SCID) covers a wide phenotype of low-to-absent T cells, NK cells, and dysfunctional B cells reflecting the mechanisms of the genetic defect (Chapter 35). Recurrent infectious diarrhea and thrush are typical GI conditions before a diagnosis of SCID in newborns and neonates.[84] After allogeneic hematopoietic stem cell transplantation (HSCT), GI graft-versus-host disease (GvHD) is a possibility. For many of the monogenic immunodeficiency diseases that confer susceptibility to GI inflammation, the success of HSCT to correct the secondary effect on the GI tract will depend entirely on whether the gene defect affects the myeloid or lymphoid cells primarily. If the gut stromal or epithelial cells also depend on normal function of the defective gene, then bone marrow transplantation will not likely relieve the GI effects.

The rare X-linked recessive Wiskott-Aldrich syndrome (Chapter 35) results from Wiskott-Aldrich syndrome (*WAS*) gene mutations, a signaling protein largely restricted to hematopoietic cells, and leads to a syndrome of eczema, thrombocytopenia, and infections related to combined immunodeficiency (impaired antibody responses and T-cell function). An interesting aspect of the gut complication in this immunodeficiency is that patients may develop a noninfectious colitis resembling UC (confluent mucosal inflammation with ulceration, crypt abscesses, and no granulomata) with the bleeding exacerbated by the thrombocytopenia.[85] Patients may respond to mesalamine drugs, but use of steroids and immunosuppressive must be done cautiously because of exacerbating infection risk. Successful bone marrow transplantation can treat the colitis as well.

Early-onset IBD is a severe complication of rare mutations that affect IL-10 production or the IL-10 receptor. Patients present with colitis within weeks of birth that has features of Crohn disease. Diagnosis is made by genetic testing as well as by assay of peripheral blood mononuclear cells for absence of IL-10 production or absent IL-10 signaling demonstrated by decreased/absent induction of phospho-STAT3 following the addition of IL-10.[86] The only cure is with HSCT.

The hyper-IgM syndrome (type 1) (Chapter 34) is an X-linked condition resulting from mutations in CD40 ligand leading to defective antibody class switching (hence high [or normal] IgM with low IgA and IgG) and NK- and T-cell cytotoxicity.

Cryptosporidium infectious diarrhea is seen, and sclerosing cholangitis, cirrhosis, and neoplasms of the hepatobiliary system complicate the course in teenagers and young adults.[87] Rarely, noninfectious colitis has been reported. HSCT, preferably done before chronic complications occur, is the only approach with a potential for cure. X-linked lymphoproliferative syndrome 2 (*XIAP* deficiency) can present with very early-onset fistulizing perianal disease in up to 20% of patients.[88]

Last, IPEX (immune dysfunction/polyendocrinopathy/enteropathy/X-linked) syndrome is interesting in that it results from a defect in FOXP3 expression and function, thereby inhibiting the generation of Tregs (Chapter 18). There is a lack of immune regulation, and enhanced responses, including autoimmunity, occur. The gut mucosa is a major site affected by inflammation, and this complication presents with a watery, sometimes bloody, diarrhea and malabsorption. Biopsies show villus blunting and atrophy in the small bowel and increased intraepithelial lymphocytes, lamina propria infiltration with T cells, eosinophils, and neutrophils elsewhere in the gut.[89] Treatment requires HSCT, but the gut disease may be managed temporarily with corticosteroids and immunosuppressants. Of note, one of the side effects of the anti– cytotoxic T lymphocyte antigen-4 (CTLA-4) antibody ipilimumab, given to augment a T-cell response against solid tumors, is a colitis that can have penetrating ulcers; this unexpected side effect points to the importance of regulatory mechanisms for gut immune homeostasis.[90]

ON THE HORIZON

Primary Immunodeficiency Diseases

- Translation of monogenic immunodeficiency disease mechanisms, especially in very-early-onset inflammatory bowel disease (IBD), into knowledge of pathophysiology (genetic and acquired) of Crohn disease and ulcerative colitis for novel drug development

MULTIPLE-CHOICE QUESTIONS

1. A 73-year-old Caucasian female who is undergoing workup for chronic diarrhea and weight loss has been incidentally found to have a gastrin level of 2500 pg/mL and have serum immunoglobulin G (IgG) antibody positive for *Helicobacter pylori*. There is no history of peptic ulcer disease, pyrosis, or kidney stones, and yet she has been referred for evaluation for gastrinoma. The first test you order is:
   A. Esophagogastroduodenoscopy with biopsy
   B. Abdominal computed tomography (CT)
   C. Serologic testing for celiac disease
   D. Secretin stimulation test
   E. Fecal testing for *H. pylori* antigen

2. A 22-year-old Caucasian female is referred for chronic abdominal pain and bloating. She reports that a cousin has celiac disease, and she says that "every time that I eat bread, I feel bad and get diarrhea." She has maintained her weight and has no other specific symptoms. She is on no medications and reports a history of irritable bowel syndrome (IBD). She says that her primary physician performed a "celiac test but it was negative." Your first choice of tests is:
   A. Esophagogastroduodenoscopy with biopsies of the duodenum and duodenal bulb
   B. Genetic human leukocyte antigen (HLA) testing for DQ2 and DQ8 risk alleles
   C. Repeat testing for serum IgA antibodies to tissue transglutaminase, including total serum IgA level
   D. Monitor anti–tissue transglutaminase levels while the patient is on a gluten-free diet

3. Which of the following is characteristic of ulcerative colitis?
   A. Presence of antiflagellin antibodies
   B. Inflammation of the full thickness of the bowel wall
   C. Tobacco use increases the frequency
   D. Surgery can be curative

Inflammatory Hepatobiliary Diseases

Carlo Selmi, Michael P. Manns, M. Eric Gershwin

Inflammatory hepatobiliary disease generically refers to chronic autoimmune diseases associated with predominant hepatic or biliary clinical manifestations, with no evidence of infectious disease. Based on specific cellular targets, we can distinguish autoimmune hepatitis (AIH) targeting hepatocytes from primary biliary cholangitis (PBC) (also known as primary biliary cirrhosis) and primary sclerosing cholangitis (PSC), both of which target the biliary tract. Cirrhosis is the common evolution of inflammatory hepatobiliary diseases, regardless of the target tissue, eventually leading to liver failure. However, pathogenesis and therapeutics may vary in between the spectrum of inflammatory hepatobiliary diseases.[1,2] This chapter describes the main characteristics of AIH, PBC, and PSC, with particular attention to clinical manifestations, pathogenesis, autoantibodies, and therapeutic options.

AUTOIMMUNE HEPATITIS

Epidemiology

Autoimmune hepatitis (AIH) is a severe liver disease affecting almost all age groups worldwide. Although an accurate estimate of its incidence is not available, it is believed be around 1 per 100 000 person-years, supposedly with higher incidence in Scandinavia.[3] AIH preferentially affects females, with a male:female ratio of 1:4 and a two-peak incidence during adolescence as well as in the age range 30–45 years.[2]

Pathogenesis

AIH is a chronic inflammatory disease of unknown etiology resulting from the immune-mediated destruction of hepatocytes secondary to a breakdown of immune tolerance against liver tissues.[4] Both genetics and environmental factors contribute to the development of the disease. Genetics certainly represents a strong risk factor for the development of AIH, as susceptibility to AIH is strongly influenced by the large and highly polymorphic human leukocyte antigen (HLA) region, which contains several genes related to the adaptive immune system[5] (Chapter 5). AIH has been associated with polymorphisms in the genes encoding the HLA class II DRB1 alleles, which have also been confirmed in genome-wide association studies (GWAS). In particular, expression of *HLA-DRB1*03:01* and *HLA-DRB1*04:01* alleles confers susceptibility to AIH-1 in European and North American populations, whereas the *DRB1*04:05* and *DRB1*04:04* alleles are linked to AIH susceptibility in Japan, Argentina, and Mexico.[6] Interestingly, *DRB1*13:02* and *DQB1*03:01* alleles were found to be protective.[2] Moreover, certain HLA alleles have been associated with AIH clinical manifestations, response to treatment, and prognosis.

Environmental factors have also been linked to AIH development. Specifically, infections such as hepatitis C virus (HCV) may trigger a process of molecular mimicry leading to exaggerated immune responses against self-components with structural homology. In support of this hypothesis, it has been demonstrated that HCV shares high amino-acid sequence homology with the autoantigenic target of antiliver/kidney microsomal-1 (LKM-1) autoantibodies, and that 10% of HCV patients are seropositive for anti-LKM-1. Nonviral environmental factors include medications, in particular antibiotics (nitrofurantoin and minocycline), statins, and anti-tumor necrosis factor (TNF)-α agents (adalimumab and infliximab). However, the disease is slightly different from classical AIH and usually does not require long-term immunosuppressive treatment.[2]

From an immunological standpoint, liver damage is likely orchestrated by CD4 lymphocytes, which can differentiate into T-helper cell-1 (Th1), Th2, and Th17 cells (Chapter 16). These effector cells initiate a cascade of immune reactions largely determined by the cytokines they produce: (i) Th1 cells secrete mainly interleukin (IL)-2 and interferon (IFN)-γ; IFN-γ is considered the main orchestrator of tissue damage since it not only stimulates CD8 cells but also enhances the expression of HLA class I, induces the expression of HLA class II molecules on hepatocytes, and activates monocytes/macrophages, which in turn release IL-1 and TNF-α; (ii) Th2 cells produce IL-4, IL-10, and IL-13, cytokines that induce the maturation of B cells into plasma cells, with consequent production of autoantibodies; (iii) Th17 cells, which arise in the presence of transforming growth factor (TGF)-β and IL-6 and produce IL-17, IL-22, TNF-α, and the chemokine CCL- 20.[7] Th17 cells, which are crucial in PBC, are being evaluated also in AIH, as an increased number of Th17 cells has been reported in the peripheral blood and liver of patients with AIH compared with healthy controls.[8]

Clinical Features and Diagnosis

AIH is a complex disease with various manifestations, predominantly in the liver, but it is not limited to this organ. The onset is most frequently insidious, whereas 20–30% of patients present with an acute icteric hepatitis, which is consistently associated with peripheral hypergammaglobulinemia. Two types of AIH are distinguished primarily based on the autoantibody patterns: *i.e.,* AIH type 1, with antinuclear and/or antismooth muscle antibodies; and AIH type 2, with antiliver/kidney/microsomal type 1 antibody and/or antiliver cytosol type 1 antibody. Type 1 AIH (AIH-1) can affect people of any age and sex, and it is associated with expression of *HLA-DRB1*03:01*. AIH-1 patients are more likely to be male, to present with high immunoglobulin G (IgG) levels, and to be positive for antinuclear antibodies/

anti-SMA. Also, AIH-1 may deteriorate despite corticosteroid treatment and is more likely to progress to liver transplantation.[2] Type 2 AIH (AIH-2) affects primarily girls and young women, and it has been linked to alleles encoding the DR3 (*DRB1*0301*) and DR7 (*DRB1*07:01*) molecules, and to positivity for anti-LMK antibodies.[2]

Blood tests usually show marked elevation of aminotransferases, usually with an increase in the cholestatic pattern (increased alkaline phosphatase, bilirubin). Furthermore, serum globulins, particularly of the γ type, are commonly increased in AIH cases, regardless of the histological stage.

Lastly and most importantly, serum autoantibodies are invariably positive (defined as titer >1 : 80) in patients with AIH. Antinuclear antibodies (ANAs) and/or antismooth-muscle (SMAs, directed against actin) autoantibodies are more frequently detected in AIH-1, whereas anti-LKM-1 antibodies (directed at cytochrome P450 2D6 or UDP-glucuronosyltransferases) predominate in AIH-2.

Without treatment, the clinical course of AIH is characterized by high mortality, with 5- and 10-year survival rates estimated as 50% and 10%, respectively. However, the use of corticosteroids has dramatically improved the course of the disease, with a 10-year survival rate exceeding 90%.[2] Complications associated with AIH are similar to those of other progressive liver diseases, as chronic hepatitis can evolve to cirrhosis and ultimately to hepatocellular carcinoma (HCC), despite the use of immunosuppressive therapy. At the time of diagnosis, approximately 30% of adult patients have histological evidence of cirrhosis; when appropriately treated, however, only a small number of patients develop cirrhosis during follow-up if inflammation is resolved. The occurrence of HCC in patients with AIH is a rare event and develops only in long-standing cirrhosis. In the absence of solid data on large numbers of cases, the incidence of primary liver neoplasia should be regarded as similar to other nonviral cases of cirrhosis.

There is no single diagnostic test for AIH; therefore diagnosis is based upon several indicative clinical, serological, biochemical, and histological findings. The presence of other causes of liver disease must also be excluded. A set of diagnostic criteria has been established, and subsequently updated, with high sensitivity and specificity (Table 76.1). Factors taken into account in this system include sex, plasma biochemical variables, serum autoantibodies, liver histology, possible cofactors (drugs, alcohol, viruses), and response to medical treatment.[9]

TABLE 76.1 Diagnostic Criteria for Autoimmune Hepatitis

Criteria	Points
Sex	
Male	+2
Female	0
Ratio of alkaline phosphatase vs. AST/ALT	
>3.0	+3
1.5–2.0	+2
1.0–1.5	+1
<1.0	0
Autoantibodies (ANA, SMA, LKM-1) titer	
>1 : 80	+3
1 : 80	+2
1 : 40	+1
<1 : 40	0
AMA	
Positive	–4
Negative	0
Seropositivity for other autoantibodies	+2
Viral hepatitis markers	
Negative	+3
Positive	–3
History of drug use	
Yes	–4
No	+1
Average alcohol consumption (g/day)	
<25	+2
>60	–2
Presence of genetic factors (HLA, DR3 or DR4)	+1
Presence of other autoimmune disorders	+2
Liver histology	
Interface hepatitis	+3
Predominant lymphocytic infiltrate	+1
Rosetting of liver cells	+1
None of the above	–5
Biliary changes	–3
Other changes	–3
Response to therapy	
Complete	+2
Relapse	+3

A score >15 or >17 indicates a definite diagnosis of autoimmune hepatitis pre- or posttreatment, respectively. On the other hand, scores of 10–15 and 12–17 indicate a probable diagnosis, pre- or posttherapy, respectively. AMA, antimitochondrial autoantibodies; ANA, antinuclear antibodies; HLA, human leukocyte antigen; LKM-1, antiliver–kidney microsomal antibodies; SMA, antismooth-muscle antibodies.

Serum Autoantibodies

Autoantibodies represent a critical feature of the disease and may guide the diagnosis. In 2004 the International Autoimmune Hepatitis Group established procedures and reference guidelines for more reliable serum autoantibody testing to overcome the lack of standardization.[10] Not only serum ANA, SMA, and LKM should be evaluated, but other sets of autoantibodies should also be tested in suspected cases, including those against liver-cytosol type 1 (LC1), perinuclear antineutrophil cytoplasmic antibodies (pANCA), soluble liver antigen/liver-pancreas antigen (SLA/LP), and the asialoglycoprotein receptor.[11] Finally, other less specific autoantibodies are also detected in a subgroup of patients, *i.e.*, anticardiolipin, chromatin, and *Saccharomyces cerevisiae*, but these are of limited clinical significance.

ANAs were the first autoantibodies observed in AIH sera more than 50 years ago and remain the most sensitive marker of AIH, producing most frequently a homogeneous or speckled pattern. However, the test is not specific for AIH, since ANA positivity is not uncommon in sera from patients with viral or other autoimmune liver diseases, as well as in as many as 15% of healthy subjects, especially in older age groups.[12] Similarly to most autoantibodies, ANA positivity, pattern, or titer does not reflect various AIH phenotypes; nor can these factors predict the disease's natural history.

Serum SMAs are autoantibodies reacting with different proteins (actin, tubulin, vimentin, desmin, cytokeratins) of the cytoskeletal components (microfilaments, microtubuli, intermediate filaments). Their presence characterizes both autoimmune (AIH-1, celiac disease) and viral diseases (chronic hepatitis C, infectious mononucleosis). When detected at high titers (>1 : 80), they are considered a sensitive marker for AIH-1, being found in up to 80% of cases. A recent study showed that anti-SMA-T/G (peritubular/glomerular staining) positive subjects with normal liver function are at low risk of progression to AIH, whereas positive SMA and raised ALT (>55 IU/L) indicate higher risk, with a positive predictive value of 22%.[13]

Serum autoantibodies against LKM-1 are the main serological markers of AIH-2 and recognize the proximal renal tubule and hepatocellular cytoplasm. The 50-kDa autoantigen was identified as the cytochrome P450 2D6 (*CYP2D6*). Interestingly, the sequence between amino acids 316 and 327, which is most likely exposed on the surface of the molecule, appears to be a region capable of differentiating LKM-1 activity in AIH and HCV and may represent a key target for autoimmunity. The mechanisms of onset remain enigmatic, and solid evidence of a causative role of hepatitis C virus cross-reactivity is still awaited. Similarly, the pathogenic role of anti-LKM-1 antibodies and their prognostic significance are debated, despite the development of AIH-2 in animal models after immunization with human CYP2D6 or with adenoviruses in mice transgenic for human *CYP2D6.* Finally, two other types of serum anti-LKM have been described in patients with ticrynafen-associated hepatitis (anti-LKM-2, directed against CYP2C9) and in 10% of patients with type 2 AIH (anti-LKM-3, directed against uridine-diphosphate glucuronosyl transferase 1A [UGT1A]), either alone or in combination with LKM-1 antibodies.

Anti-SLA/LP antibodies are detectable by radioimmunoassay and enzyme-linked immunosorbent assay, but not by immunofluorescence, and are directed against various epitopes of a UGA tRNA suppressor. Serum anti-SLA/LP antibodies are occasionally found in patients with AIH who are negative for ANA, SMA, and anti-LKM and are cumulatively detected in 10–30% of cases of AIH-1 and -2. Recent data indicate that anti-SLA/LP antibodies are also detectable in subgroups of pediatric patients with autoimmune cholangitis or in adult patients with HCV infection when tested with sensitive methods.

Anti-LC1 antibodies are detected by indirect immunofluorescence in sera from up to 50% of patients with type 2 AIH and less frequently in type 1 AIH or chronic hepatitis C. Importantly, however, anti-LC1s are the only detectable markers in 10% of AIH cases. The LC1 autoantigen is the liver formiminotransferase cyclodeaminase, an enzyme involved in folate metabolism. Interestingly, serum anti-LC1 antibodies correlate with AIH severity and progression.

Antibodies to the asialoglycoprotein receptor are observed in up to 90% of all patients with AIH and often coexist with other autoantibodies while lacking specificity for the disease. Similar to anti-LC1, however, antiasialoglycoprotein titers are associated with more florid inflammatory disease activity and with less effective treatment responses.

Finally, antibodies to neutrophil cytoplasmic antigens (pANCA) can be detected by indirect immunofluorescence in sera from patients with AIH-1; they also can be detected in a subgroup of patients with PSC or chronic viral hepatitis.

Histology

The role of liver histology in the management of AIH remains critical, and all patients with suspected cases should undergo a liver biopsy. In fact, although no typical feature can prove the diagnosis, histology remains the gold standard for grading and staging, particularly to determine the response to therapy. Common findings include periportal hepatitis with lymphocyte and plasma cell infiltrate and piecemeal necrosis. Fibrosis usually is observed, and bridging necrosis ultimately indicates advanced disease evolving into frank cirrhosis. Importantly, the presence of granulomas, bile duct damage, or iron or copper accumulation should not be overlooked, since these signs point toward other diagnoses. On the other hand, steatosis is a nonspecific finding that does not rule out AIH.[9]

Therapy

In contrast to other autoimmune liver diseases, immunosuppressants are the treatment of choice for AIH, based on the good response in terms of biochemistry, histology, and survival.[14] Corticosteroids, in particular prednisone, represent the first-line of treatment in monotherapy or in combination with azathioprine, inducing remission (*i.e.,* normal transaminases and IgG levels) in over 80% of patients, regardless of the presence of cirrhosis.[9] Once achieved, remission can be maintained with azathioprine alone. Relapses after therapy discontinuation are common since only 20% of patients remain in sustained remission. It should be noted, however, that subgroups of patients manifest disease progression (approximately 10%) or are intolerant to standard therapy (13%). In such patients, other drugs have been anecdotally tried, including methotrexate, cyclophosphamide, tacrolimus, ursodeoxycholic acid, cyclosporine, and mycophenolate mofetil, the latter two being those most frequently reported as alternative medications. Liver transplantation is the ultimate treatment for AIH patients presenting with acute liver failure or end-stage chronic liver disease and for those with hepatocellular carcinoma that meet the transplant criteria. Although liver transplantation for AIH is very successful, it should be noted that AIH may recur after transplant.[9] Patients with AIH undergoing liver transplant have overall 5- and 10-year survival rates of 90% and 75%, respectively, although infectious complications and disease recurrence are common.[15]

KEY CONCEPTS

- Autoimmune hepatitis (AIH) is a severe autoimmune disease associated with high morbidity and mortality, especially due to the development of cirrhosis and possibly hepatocellular carcinoma.
- Autoantibodies represent a distinctive feature of AIH and can also aid in the definition of AIH subsets.
- Liver biopsy is helpful, and histology remains the gold standard for grading and staging, particularly to determine the response to therapy.

CLINICAL PEARLS

- Autoimmune hepatitis (AIH) may cause an increase in aminotransaminases and in cholestatic markers.
- Autoantibody testing is helpful. Antinuclear antibodies (ANAs), SMAs, and antiliver/kidney microsomal (LKM) are the most important, but other sets of autoantibodies also should be tested in suspected cases, in particular anti-LC1, perinuclear antineutrophil cytoplasmic antibodies (pANCA), soluble liver antigen/liver-pancreas antigen (SLA/LP), and the asialoglycoprotein receptor antibody.
- Diagnostic criteria are available and provide good sensitivity and specificity.

THERAPEUTIC PRINCIPLES

- Glucocorticoids represent the cornerstone of autoimmune hepatitis (AIH) therapy as monotherapy or in combination with azathioprine.
- Other immunosuppressants, *i.e.,* methotrexate, tacrolimus, cyclosporine, and mycophenolate mofetil, have been used in patients who are intolerant or refractory to standard therapy.
- Liver transplantation is very successful; however, AIH may recur after transplant.

PRIMARY BILIARY CHOLANGITIS

Nomenclature

Recently the nomenclature for primary biliary cirrhosis has been shifted toward primary biliary cholangitis (PBC) to correct the inaccurate description and remove the cirrhosis stigma as well as all the misunderstandings, disadvantages, and discriminations emanating from this misnomer. This change was necessary after the dramatic improvement in PBC diagnosis, prognosis, and treatment. Currently, an early diagnosis of PBC can be established with the more accurate measurements of markers of cholestasis and with improvement in the detection of the classic serological hallmark, antimitochondrial antibodies (AMAs). In parallel, treatment was improved with the introduction of orthotopic liver transplantation and ursodeoxycholic acid (UDCA, 13–15 mg/kg daily) therapy. At present, two of three patients diagnosed with primary biliary cirrhosis and treated with UDCA have an expected survival equal to that of the general population, and only a minority will ever develop cirrhosis.[16]

Epidemiology

PBC is a chronic autoimmune cholestatic disease characterized by high-titer serum AMA and immune-mediated destruction of the small- and medium-sized intrahepatic bile ducts.[1] It affects women more frequently, with a female:male ratio of 9 : 1; the average age at diagnosis is within the fifth and sixth decades of life. Geographically, it presents with widely variable prevalence; the highest rate has been described in Minnesota, with a point prevalence of 402 per million in the general population.[17,18]

Pathogenesis

As with essentially every autoimmune disease, genetics and environmental factors interact to lead to PBC. Genetic factors play a significant role in PBC susceptibility, as suggested by the fact that it is more frequent in relatives of affected individuals; the term "familial PBC" has been coined to indicate families that have more than one case. In our experience, 6% of cases have a first-degree relative that is also affected,[19] while AMA may be positive in first-degree relatives and offspring of patients with PBC without any sign of disease, thus indirectly suggesting the existence of a strong genetic predisposition.[20] More importantly, the concordance rate observed among monozygotic twins for PBC is 63%, among the highest reported in autoimmunity, reinforcing the idea that genetic risk factors play an important role.[21] As for other autoimmune disorders, genetic factors are not limited to a single gene but to a complex multigene trait. The relevance of the multifactorial genetic basis in PBC has been reinforced by recent observations including the high concordance rate among monozygotic (identical) twins[21] as well as by reports that lymphocytes from women with PBC preferentially use one of their X chromosomes, rather than the usual random X chromosome inactivation observed in healthy women.[22,23] PBC has been associated with the *HLA-DRB1*08* allele but also with two protective alleles, *HLA-DRB1*11* and *-DRB1*13*. Polymorphisms in HLA class II loci were confirmed to play a key role by GWAS. Notably, this study demonstrated that genes coding for interleukin-12 and its receptor also confer risk for PBC.[24]

However, it can be hypothesized that other factors may contribute to genetics as complementary modes of pathogenetic import, including epigenetics, exposure to environmental factors, etc. Infections and xenobiotics play a key role in increasing the susceptibility to PBC. Urinary tract and vaginal infections are more frequent in PBC than in controls, with *E. coli* being the main etiological agent. The mechanisms linking infections and autoimmune biliary tract damage are suspected to involve molecular mimicry. Besides *E. coli*, a number of other bacteria have been examined as cross-reactive agents in PBC, including *Proteus mirabilis, Klebsiella pneumoniae, Staphylococcus aureus, Neisseria meningitidis, Salmonella minnesota, Mycobacterium gordonae, and Trypanosoma brucei. Novosphingobium aromaticivorans,* a ubiquitous xenobiotic-metabolizing gram-negative bacterium, has been proposed to be the ideal candidate for PBC development because it contains proteins with the highest degree of homology with the major epitope of PDC-E2 while having the ability to metabolize organic compounds and estrogens. Moreover, *N. aromaticivorans* can elicit antibody reactivity in PBC patients but not in controls. Regarding viral infections, a novel human beta-retrovirus was found in perihepatic lymph nodes and other biological samples from patients with PBC; however, the data have remained inconclusive.[24] Xenobiotics are foreign compounds that may trigger an autoimmune response to self-proteins, which may modify their molecular structures or complex to self or nonself proteins to generate neoantigens. In this view, it was shown that 2-nonynoic acid, an organic compound found in nail polish, was able to elicit AMA production in patients with PBC once they were attached to the major mitochondrial epitope backbone.[25]

The complex pathogenesis of PBC, however, is not fully explained by genetics and environmental factors; as suggested for most other autoimmune diseases, epigenetic modifications could represent the link between genetic and environmental factors influencing the onset and evolution of PBC. Epigenetic dysregulation results in the overexpression of certain genes in several key immune cells.[26] However, conclusive data implicating epigenetic modifications in the pathogenesis of PBC are not yet available.

Clinical Features and Diagnosis

In the early phase of disease, symptoms of PBC are mainly fatigue and pruritus, while physical findings may include skin hyperpigmentation, hepatosplenomegaly, and (rarely) xanthelasmas. End-stage symptoms are indistinguishable from those of other types of liver cirrhosis and include ascites, jaundice, hepatic encephalopathy, and upper digestive bleeding. Fatigue is a nonspecific symptom present in 70% of PBC patients and is often overlooked, particularly in middle-aged women. The severity of fatigue is independent of the stage of PBC or its other features (pruritus or severe cholestasis), and it appears not to depend on psychiatric factors. Pruritus is similarly frequent, being present in 70% of patients with PBC and jaundice. Pruritus might long precede jaundice onset and typically worsens at night, after contact with wool, or in warm climates. Portal hypertension is frequently found in patients with PBC and, importantly, does not imply the presence of liver cirrhosis. Over half of untreated patients eventually develop portal hypertension over a 4-year period. Prevention and treatment for PBC-associated portal hypertension are the same as for other chronic liver diseases. Metabolic bone disease is present in PBC when comparing sex- and age-matched healthy individuals. Hyperlipidemia is common in up to 85% of patients with PBC; both elevated serum cholesterol and triglyceride levels are encountered. Interestingly, however, such alterations are not accompanied by a proportionally increased incidence of cardiovascular events or atherosclerosis and do not correlate with disease stage. Autoimmune diseases may overlap with PBC,

TABLE 76.2 **Diagnostic Criteria for Primary Biliary Cholangitis**

Parameters
Elevated ALP > 2 × ULN or GGT > 5 × ULN
AMA positivity
Chronic granulomatous cholangitis on liver biopsy

Diagnosis defined in the presence of at least 2 out of 3 criteria.
ALP, alkaline phosphatase; AMA, antimitochondrial antibodies; ULN, upper limit of normal; GGT, γ-glutamyltransferase.

most commonly Sjögren syndrome, Raynaud phenomenon, autoimmune thyroid disease, scleroderma, and systemic lupus erythematosus, whereas the prevalence of rheumatoid arthritis does not differ when PBC cases are compared with healthy controls. Patients affected by both PBC and scleroderma have a less aggressive liver disease, which suggests an active interaction between the two conditions. As with other types of cirrhosis, end-stage PBC can be complicated by the occurrence of HCC, and patients with intense nodular liver structure on ultrasound should be monitored by computed tomography. Importantly, PBC is not associated with cholangiocarcinoma (CCA) or breast cancer.[1]

The diagnosis of PBC is based on the presence of two out of three internationally accepted criteria, *i.e.*, detectable serum AMA (titer >1 : 40), increased enzymes indicating cholestasis (*i.e.*, alkaline phosphatase) for longer than 6 months, and a compatible or diagnostic liver histology (Table 76.2).[27] In a large number of cases (20–60%), the diagnosis of PBC is established in the absence of symptoms indicating a liver condition or cholestasis, and the proportion of asymptomatic cases at diagnosis has been steadily increasing over the past decade. At presentation, PBC is suspected if a biochemical cholestatic pattern (increased plasma alkaline phosphatase or γ-glutamyltransferase) is present with no similar increase in plasma aminotransferase levels. Serum IgMs are typically elevated in PBC cases, with no correlation with AMA titers or levels of other Ig subtypes. Once cirrhosis has developed, biochemical alterations are similar to those with other types of cirrhosis. The progression of PBC varies widely, and the factors influencing the severity and progression of the disease are largely unknown. Having symptoms at presentation is considered the major factor determining survival rates of patients with PBC. In fact, asymptomatic PBC is accompanied by 10-year survival rates similar to those of the general population. On the other hand, 67% of precirrhotic patients will develop liver cirrhosis over a 7-year observation period, while 70% of asymptomatic patients will develop symptoms. Patients with symptomatic PBC show a more rapid progression to late-stage disease and a worse prognosis than their asymptomatic counterparts, with survival times among symptomatic subjects within 6–10 years.[28] Older age at diagnosis and signs of advanced disease (clinical, histological, or biochemical) are associated with a worse prognosis. The establishment of accurate prognostic models to predict survival in patients with PBC is of obvious importance in clinical practice. The model based on the Mayo score is the only one validated and is the most widely utilized[29]; it is calculated based on clinical (age, presence of ascites) and biochemical variables as represented by cholestasis (bilirubin levels) and liver function (prothrombin time, albumin). However, this model has its limitations, as it is a static representation of a dynamic entity and has a lower accuracy for patients with early disease.

Serum Autoantibodies

AMAs are highly specific for PBC and can be detected in nearly 100% of patients when sensitive diagnostic methodologies based on recombinant antigens are used.[24] In most clinical settings, however, indirect immunofluorescence techniques are used for initial screening of cases and might provide falsely positive or negative results. AMAs are directed against components of the 2-oxoacid dehydrogenase (2-OADC) family of enzymes within the mitochondrial respiratory chain, most frequently the E2- and E3-binding protein (E3BP) components of the pyruvate dehydrogenase complex and the E2 components of the 2-oxo glutarate dehydrogenase and branched-chain 2-oxo acid dehydrogenase complexes. For all three antigens, epitopes contain the motif DKA, with lipoic acid covalently bound to the lysine (K) residue. The role of lipoic acid in epitope recognition by AMA is unclear. A direct pathogenic role of AMA is debatable, since no clinical correlation can be found and animal models developing serum AMA do not develop PBC-like liver lesions. Autoantibodies other than AMA can be found in 76% of PBC patients.[30] ANA can be found in 50% of PBC patients, with the most common patterns being "nuclear rim" or "multiple nuclear dots." The pattern is based on the recognition by the autoantibodies of gp210 and nucleoporin 62 (within the nuclear pore complex) and Sp100 and promyelocytic leukemia protein (PML) (possibly also cross-reacting with small ubiquitin-like modifiers, SUMO), respectively.[31] ANA-positive patients are more frequently AMA-negative, possibly because of the lack of a masking effect of these latter antibodies. Similarly, the pathogenic role of ANA in PBC remains enigmatic, although cross-sectional and longitudinal data demonstrate an association between ANA positivity and a worse prognosis.[32] Finally, patients with PBC and limited systemic sclerosis have detectable serum anticentromere antibodies in 10–15% of cases. Monitoring autoantibody titers does not correlate with PBC severity or clinical outcomes, whereas a change in the sp100 autoantibody level may have prognostic utility with respect to the development of fibrosis on liver biopsy.

Histology

PBC histology is classified into four stages (Fig. 76.1). Stage I manifests with portal tract inflammation with predominantly lymphoplasmacytic infiltrates, resulting in vanishing septal and interlobular bile ducts (diameter < 100 μm). At this stage, bile duct obliteration and granulomas (possibly found at all stages) are strongly suggestive of PBC. In stage II a periportal inflammatory infiltrate is observed, and signs of cholangitis, granulomas, and florid proliferation of ductules are typical. Stage III demonstrates septal or bridging fibrosis, with ductopenia (over half of the visible interlobular bile ducts having vanished) and copper deposition in periportal and paraseptal hepatocytes visible. Stage IV corresponds to frank cirrhosis. The observation of eosinophils in the portal tract is considered a specific finding in PBC histology.

Novel noninvasive biomarkers are under evaluation for predicting liver histology, and in this view the aminotransferase to platelet ratio index (APRI) and fibrosis index on the basis of the four factors (FIB-4) scores are statistically different between groups and may be a predictor of advanced disease in PBC.[33]

Therapy

PBC treatment is currently based on UDCA, which is the only approved drug for this rare disease. Its mechanism of action is

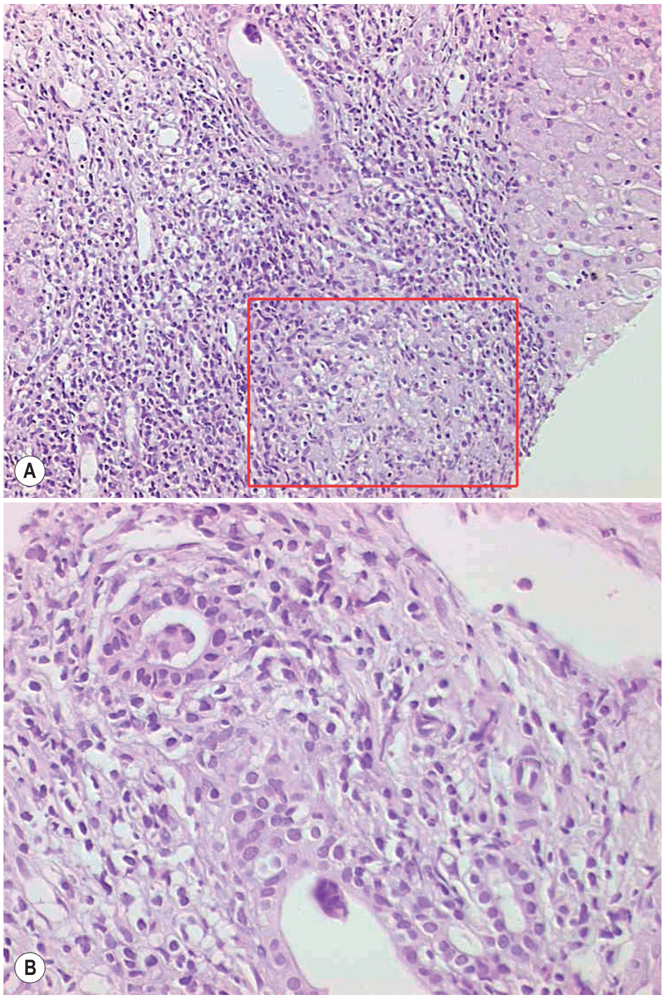

FIG 76.1 Histological Findings in Early Stages of Primary Biliary Cirrhosis, i.e., Nonsuppurative Destructive Cholangitis, Following Hematoxylin and Eosin Staining. (A) Mixed lymphocytic and plasma cell periductular inflammation with bile duct infiltration and granulomatous reaction (square). Magnification × 200. (B) Detail of bile duct disruption with lymphocytic and plasmacellular periductular and intraepithelial infiltration. Magnification × 400.

incompletely understood. Depending on the various phases of the disease, various therapies might be effective.

During the early phase of the disease, glucocorticoids might be effective; however, safety concerns about the long-term use of such medications arise. Budesonide, due to its high first-pass metabolism, has minimal systemic adverse effects; at 6–9 mg daily, it has been demonstrated superior to UDCA both in terms of histology and biochemical markers. Other immunosuppressants, such as methotrexate and azathioprine, have also been suggested, and there is evidence supporting the use of the latter in PBC with autoimmune hepatitis overlap syndrome. In recent years, because of better understanding of PBC pathogenesis, new targeted therapies have been tested. Considering a possible role of the IL-17/23 axis, ustekinumab, a monoclonal antibody against the p40 subunit of IL-23, has been tested. Although associated with a modest decrease in alkaline phosphatase after 28 weeks of therapy, ustekinumab did not otherwise change alkaline phosphatase.[34] Other therapies targeting T-cell costimulation, *e.g.*, cytotoxic T lymphocyte antigen-4 (CTLA-4) Ig (abatacept) or the CD40-antagonist FFP104, are under investigation.[35] When the disease has already progressed and bile is accumulating, obeticholic acid (OCA), an analog of CDCA with a much higher affinity to the farnesoid X receptor, has been shown to decrease bile synthesis, promote secretion, and induce liver regeneration in animal models. In a phase III trial, OCA administered with UDCA or as monotherapy for 12 months resulted in a decrease in alkaline phosphatase and total bilirubin levels that differed significantly from the changes observed with placebo.[35]

Ultimately, UDCA represents the cornerstone therapy of PBC. Doses ranging from 13 to 15 mg/kg are currently used for optimum bile enrichment and in 50% of patients normalize alkaline phosphatase. Other immunosuppressive treatments should be started only in combination with UDCA.

Liver transplantation is the ultimate treatment for end-stage PBC, with survival rates of 92% and 85% at 1 and 5 years after transplant, respectively. Recurrence is common, and its rates seem to be influenced by certain immunosuppressive regimens. The use of UDCA in cases of recurrence is safe and recommended.

KEY CONCEPTS

- Primary biliary cholangitis (PBC) is a chronic autoimmune cholestatic disease affecting preferentially women in the fifth to sixth decades of life.
- Genetics plays a strong role in PBC pathogenesis, as suggested by familial clustering and the high concordance in monozygotic twins.
- Antimitochondrial antibodies (AMAs) are highly specific for PBC and can be detected in nearly 100% of patients.

CLINICAL PEARLS

- Fatigue and pruritus represent the most frequently observed symptoms, which may be disabling for patients.
- Primary biliary cholangitis (PBC) can be frequently associated with other autoimmune diseases, *e.g.*, Sjögren syndrome and systemic sclerosis.
- PBC patients should be observed for metabolic bone disease.

THERAPEUTIC PRINCIPLES

- Ursodeoxycholic acid (UDCA) (13–15 mg/kg) remains the cornerstone therapy for primary biliary cholangitis and is the only approved drug.
- Glucocorticoids may be effective in early phases of the disease.
- Biological therapies are under investigation, *e.g.*, ustekinumab and abatacept.
- Obeticholic acid appears to be effective in reducing cholestatic biomarkers.

PRIMARY SCLEROSING CHOLANGITIS

Primary sclerosing cholangitis (PSC) is a progressive cholestatic liver disease of unknown etiology presenting with autoimmune features and associated with significant morbidity and mortality. Unlike PBC, PSC can affect all tracts of the biliary tree, including the extrahepatic bile ducts.

Epidemiology

The prevalence of PSC is approximately 10 in 100 000 in northern Europe[4,5] and the United States, while it is far less common in southern Europe and Asia. Recent data from Olmsted County, Minnesota, reported a disease prevalence of 20.9 per 100 000 men and 6.3 per 100 000 women.[36] Epidemiological data indicate that annual incidence rates are not increasing over time despite earlier ages at diagnosis, and survival is possibly longer, similar to what was observed in PBC.

In contrast to the vast majority of autoimmune diseases, PSC is more commonly diagnosed in men, with a female:male ratio estimated as 1 : 2, with a preference for 30- to 40-year-olds. PSC has a strong association with inflammatory bowel disease. Approximately 60–80% of patients with PSC present with inflammatory bowel disease, of which 87% have ulcerative colitis and 13% have Crohn disease.[37]

Pathogenesis

The etiopathogenesis of PSC is unknown, but evidence is growing that (auto) immune-mediated mechanisms play a role. The notion of an autoimmune pathogenesis is supported by the frequent association with inflammatory bowel disease (IBD), the presence of serum autoantibodies, and the reported HLA associations. Genetic risk determines PSC susceptibility, including HLA haplotypes on chromosome 6p21, the inhibitory HLA-C2 killer-immunoglobulin receptor (KIR) ligand, and HLA-C1 homozygosity. Also, a positive and negative association with *HLA-HLDRB1*15* and *-DRB1*07,* respectively, has been reported. A recent study on Italian patients with PBC did not find any association with *DRB1*03, *04* or **13:01* alleles typically detected in Northern Europe.[38] Family and twin studies are not available for PSC; however, a GWAS has reported the HLA region as the only major association, albeit in a minority of patients and sometimes overlapping with IBD-associated genes. The innate immune system and microorganisms (possibly derived from an IBD-affected gut) may participate in the onset and/or perpetuation of disease. It has been proposed that cholangiocytes are first activated by bacterial stimuli in the presence of gut-specific chemokines and endothelial cell adhesion molecules in the tissue microenvironment. Also, gut-primed T cells can migrate into the portal tracts and peribiliary spaces to form focal lesions. Finally, chronic inflammation and progressive fibrosis of the biliary epithelium lead to chronic cholestasis secondary to vanishing bile ducts, ultimately causing biliary cirrhosis.

Clinical Features and Diagnosis

PSC symptoms generally are nonspecific and include abdominal pain, jaundice, and fever in the case of bacterial cholangitis; at more advanced stages, symptoms include the characteristics of decompensated cirrhosis or neoplasia. Commonly, PSC is further complicated by episodic bacterial cholangitis, especially in the setting of biliary strictures. Lastly, subgroups of patients manifest the "small duct" variant or overlap syndrome.

The median time span from diagnosis to liver-related death or liver transplantation can be estimated at 18 years,[39] and the prognosis is influenced by the possible onset of CCA, which may be difficult to detect because biliary structures are already altered. It is important to distinguish small-duct PSC, as the natural history is relatively benign and only a minority (12%) of patients develop classical PSC.[40]

Due to the nonspecific symptoms, PSC currently is diagnosed most commonly in the absence of symptoms and during routine blood tests in healthy individuals or patients with IBD. In laboratory testing, PSC is characteristically accompanied by a biochemical cholestatic pattern, as indicated by elevated serum alkaline phosphatase and γ-glutamyltransferase. Liver function tests are normal until late stages. Autoantibodies are of limited use in the diagnosis of PSC due to low sensitivity and specificity. Only a limited percentage of patients (33%) has positive pANCA, which usually is found in IBD patients without PSC.

Imaging represents a useful diagnostic tool, as it may find the unique strictured and dilated tracts within the intrahepatic or extrahepatic bile ducts. Among the imaging techniques, endoscopic retrograde cholangiopancreatography (ERCP) and magnetic resonance cholangiopancreatography (MRCP) are currently considered equal for sensitivity, but their results are influenced by the operator's skill and experience.

Histology

Although not necessary for establishing the diagnosis, liver histology is essential when staging PSC or when the small-duct variant, an overlap syndrome, or CCA is suspected. The histological picture varies widely, from minimal alterations to cirrhosis with portal inflammation, concentric "onion skin" periductal fibrosis, and periportal fibrosis developing into septal and bridging necrosis. Fig. 76.2 illustrates the histological findings in two representative cases of early and advanced PSC.

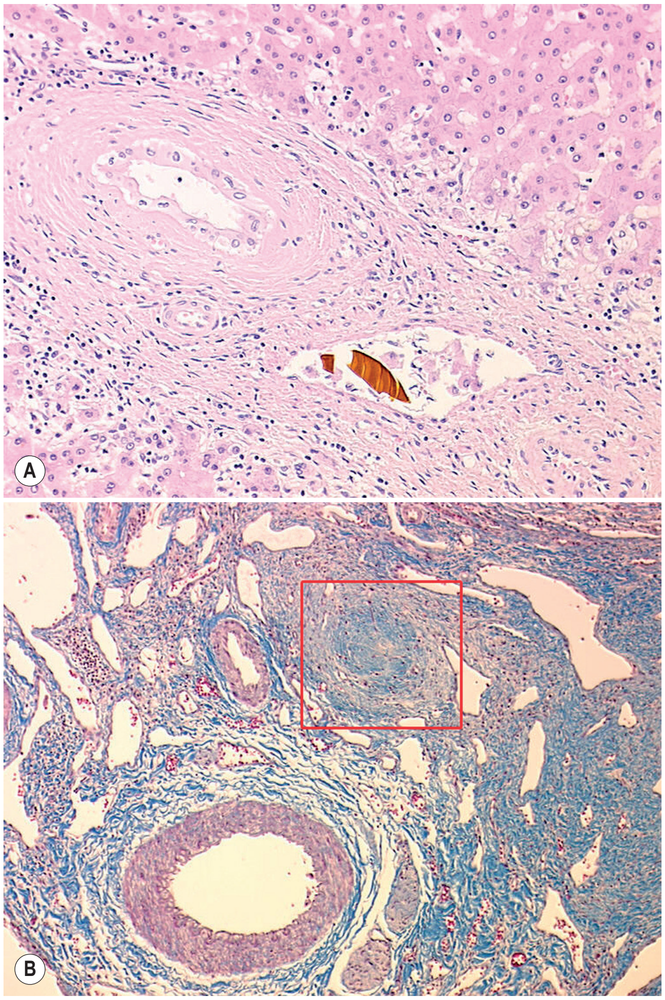

FIG 76.2 Histological Findings in Primary Sclerosing Cholangitis. (A) Early disease and periductular fibrosis. Magnification x 200, hematoxylin and eosin staining. (B) Advanced disease with cirrhosis and bile duct substitution by fibrous scar (square). Magnification × 200, Masson staining.

Therapy

The treatment of PSC includes medical and endoscopic measures as well as liver transplantation. UDCA has been investigated in several clinical trials, with conflicting results. Overall, the available evidence suggests that UDCA fails to induce a substantial change in the course of PSC, despite remaining the most prescribed drug. However, it appears that high-dose UDCA (20 mg/kg/day) might reduce the rate of progression and possibly prevent the development of colon cancer in patients with PSC and Ulcerative colitis (UC). Endoscopic measures are indicated to treat complicated PSC through the opening of short- and long-segment stenosis of the common bile duct and short-segment stenosis of the hepatic ducts near to the bifurcation. The treatment can be repeated over time once restenosis ensues, and resulting survival rates are higher than those of patients not treated endoscopically. Finally, PSC represents an important indication for liver transplantation since patients are commonly younger than those with other autoimmune liver diseases. Recurrence of disease is common and affects 20–40% of transplanted patients during prolonged follow-up. It is still debated whether medical treatment with UDCA in fact produces a longer survival.

KEY CONCEPTS

- Primary sclerosing cholangitis (PSC) is a chronic autoimmune cholestatic disease that can affect all tracts of the biliary tree, including the extrahepatic bile ducts.
- Unlike other patients with autoimmune diseases, the majority are male.
- PSC can be complicated by cholangiocarcinoma.

CLINICAL PEARLS

- Primary sclerosing cholangitis (PSC) is frequently associated with IBD (60–80% of patients).
- PSC is not associated with any specific autoantibodies; however, perinuclear antineutrophil cytoplasmic antibodies (pANCA) may be positive.
- Imaging is helpful in detecting PSC, which manifests with strictured and dilated bile ducts, both intra- and extrahepatic.

THERAPEUTIC PRINCIPLES

- Ursodeoxycholic acid (UDCA) (20 mg/kg) may be effective in slowing primary sclerosing cholangitis (PSC) progression.
- Endoscopic procedures are indicated to treat stenoses.
- Liver transplantation is highly effective, and PSC represents an important indication for such procedure, particularly due to the younger age of affected patients.

AUTOIMMUNE CHOLANGITIS

The term *autoimmune cholangitis* was first introduced to indicate AMA-negative PBC, possibly with serum ANA. However, more recently this category has been expanded to include (i) serum ANA and/or SMA positivity and/or hypergammaglobulinemia; (ii) serum AMA negativity by immunofluorescence; (iii) biochemical and/or histological features of cholestatic and hepatocellular injury; and (iv) exclusion of chronic viral, metabolic, or toxic liver disease. This definition possibly includes PBC with atypical presentation, small-duct PSC, idiopathic adulthood ductopenia, AIH with bile duct damage, concurrent AIH and small-duct PSC, and various transitional stages of the classic diseases. Consensus is awaited on this issue, and standardization of diagnostic criteria for overlap syndromes also has not been achieved.

OVERLAP SYNDROMES

As many as 18% of patients with autoimmune liver disease also present with features of a second autoimmune liver disease. An even higher percentage of patients has an additional autoimmune disease, *e.g.,* rheumatoid arthritis, Sjögren syndrome, or systemic sclerosis. These patients are considered to have overlap syndromes. Patients with hepatobiliary overlap syndromes usually present with both hepatocellular and cholangiocellular injury with biochemical and histological features of AIH and PBC or PSC. When not treated, these patients show a progressive course toward liver cirrhosis and failure. More specifically, AIH–PBC overlap syndrome is found in 10% of adults with AIH or PBC, and AIH–PSC overlap syndromes are found in 6–8% of children, adolescents, and young adults with AIH or PSC. Besides the existence of overlaps, in rare cases transitions are also possible from PBC to AIH, from AIH to PBC, or from AIH to PSC. The pathogenesis of the overlap syndromes is poorly understood, and few data are available regarding the clinical characteristics and outcomes of such patients. Thus the clinical management of overlap syndromes is based on single diseases, and medical treatment remains empiric. Thus UDCA is used for chronic cholestasis, and immunosuppressants (steroids and azathioprine) are used for AIH; for end-stage disease, liver transplantation is indicated.

IgG4-RELATED CHOLANGITIS

There have been numerous reports of a new clinical entity coined *autoimmune pancreatitis/IgG4-associated sclerosing cholangitis* with peculiar clinical and therapeutic characteristics. IgG4-related sclerosing cholangitis is more frequent in men than in women, and usually at an older age. The clinical features of the disease appear similar to those with CCA or PSC. IgG4-related sclerosing cholangitis has been associated with autoimmune pancreatitis, and the coexistence of both manifestations is suggestive of IgG4-related disease. The differential diagnosis with PSC may be difficult; however, elevated IgG4 serum concentration (up to 10% of PSC patients may have elevated levels) and longer stenosis found by imaging may support the diagnosis. Histology is important, as it may discover an IgG4-positive lymphoplasmacytic tissue infiltrate. Overall, the prognosis is considered to be good; however, some cases of portal hypertension and liver cirrhosis have been reported.

Corticosteroids induce a remarkable improvement in clinical and biochemical manifestations, and a dosage of 0.6 mg/kg/day of prednisolone should be started for 2–4 weeks and gradually tapered over 2–3 months. Immunosuppressant agents have been used effectively in anecdotal cases. The optimal treatment is still debated.

ON THE HORIZON

Inflammatory hepatobiliary diseases remain an enigmatic and interesting group of tissue-specific autoimmune diseases, especially due to the frequent overlap among the different entities. However, primary biliary cholangitis (PBC), primary sclerosing cholangitis (PSC), and autoimmune hepatitis (AIH) should be considered single diseases because the pathogenesis, clinical manifestations, prognosis, and therapeutic approaches are different. Autoantibodies may help the clinician in the diagnosis of the various diseases. However, it is important to remember that there are limitations in the use of autoantibodies, especially due to variability in testing procedures, nonstandardized methods, and reporting. Treatment is changing along with new approaches to targeted therapies. However, in most cases corticosteroids and ursodeoxycholic acid (UDCA) remain the cornerstones of therapy.

MULTIPLE CHOICE QUESTIONS

1. Autoimmune liver diseases:
   A. In all cases affects women more than men
   B. Are categorized by the type of cells targeted
   C. Are invariably associated with IBD
   D. Are invariably ANA positive

2. Primary biliary cholangitis:
   A. Is predominant in men
   B. Is predominant in children
   C. Is predominant in women
   D. Affects equally both sexes

3. Primary biliary cholangitis is associated more frequently with:
   A. Rheumatoid arthritis
   B. Fybromialgia
   C. Infertility
   D. Sjogren syndrome

4. Autoimmune hepatitis:
   A. Is associated with serum ANCA
   B. Is associated with serum ANA
   C. Is associated with serum AMA
   D. Is associated with serum hypogammaglobulinemia

5. Primary sclerosing cholangitis:
   A. Is associated with IBD
   B. Is diagnosed most efficiently with liver histology
   C. Is associated with serum ANA
   D. Is associated with serum AMA

Immunotherapy of Cancer

Anu Sharma, Matthew Campbell, Cassian Yee, Sangeeta Goswami,
Padmanee Sharma

The ability of the immune system to recognize and eradicate cancer was first postulated in the 19th century; however, proof of principle remained elusive until later. It was noted that some patients with sarcoma underwent spontaneous regression of their tumors upon incidental development of a skin infection with *Streptococcus pyogenes,* which was conjectured to elicit an immune response against the infection as well as against cancer cells. After this observation, a mixture of heat-killed *S. pyogenes* and *Serratia marcescens* (Coley's toxin) was used to treat patients with sarcoma, which resulted in complete tumor regression in some patients.[1] These early studies with Coley's toxin prompted many clinical trials aimed at stimulating the immune response to eradicate cancer, including the use of Bacille Calmette-Guérin (BCG) as a treatment for superficial bladder cancer.[2] However, incomplete understanding of the mechanistic details of immune responses led to failure of many early clinical trials. With recent advances in our understanding of basic principles that guide immune responses, specifically T-cell responses, immunotherapy is now established as one of the pillars of cancer treatment.

One important principle that has reshaped our thinking of cancer immunology is related to immunosurveillance. Cancer immunosurveillance relies on immune cells, including T cells, which can recognize antigens, including mutated proteins that generate novel antigens. T cells recognize these antigens when they are bound to self-MHC (major histocompatibility complex) molecules.

In the early 2000s, the hypothesis of cancer immunosurveillance was redefined to state that the immune system controls both the tumor quality (immunogenicity) and the quantity (tumor load), thus eliminating tumors and sculpting the immunogenic phenotypes of tumors in immunocompetent hosts. The interaction between the host immune system and the tumor cells has been proposed in three phases, including elimination, equilibrium, and escape (the three E's). In the *elimination phase,* cancer cells are detected and destroyed by the adaptive and innate arms of the immune system before becoming clinically apparent. These data helped to frame the importance of the immune system in cancer development and revived the theory of cancer immunosurveillance.[3]

Cancer cells that evade elimination enter the ***equilibrium phase,*** where T cells keep the remaining cancer cells in check without eliminating them. This phase may extend throughout the host's lifetime.[3] Clinical examples of the equilibrium phase include the duration between successful treatment of the primary tumor and relapse, the existence of disease-free state despite micrometastasis, and the development of donor-derived tumors after organ transplant.[4]

KEY CONCEPTS

Three Phases of Immune Interaction With Tumor Cells

- Elimination: Tumor cells are detected and destroyed by the immune system.
- Equilibrium: Tumor cells are not eliminated by the immune system.
- Escape: Tumor cells escape immune control.

The continuous interaction of cancer cells with the immune system may favor the outgrowth of less immunogenic tumors that can escape immune control, termed the ***escape phase.*** Tumor cell escape can occur through different mechanisms including (i) loss of antigens and/or MHC expression; (ii) increased resistance to the cytotoxic effects of immunity through induction of antiapoptotic mechanisms; (iii) development of defects in antigen processing/presentation; (iv) loss of crucial genes, such as genes related to the interferon (IFN) signaling pathway, which makes tumor cells more resistant to immune-mediated killing by IFN; or (v) recruitment of immunosuppressive cells to the tumor microenvironment, which can inhibit antitumor immune responses and contribute to the escape of edited tumor variants.[5]

KEY CONCEPTS

Mechanisms of Tumor Cell Immune Escape

- Loss of antigen or major histocompatibility complex (MHC) expression
- Resistance to cytotoxicity
- Defects in tumor antigen processing/presentation
- Loss of crucial genes involved in the immune response
- Recruitment of immunosuppressive cells to the tumor microenvironment

Besides increasing our understanding of immunosurveillance, we have gained new insights regarding mechanisms that regulate T-cell responses, which have led to the development of an entirely new field known as immune checkpoint therapy. The current chapter will discuss (i) Activation and regulation of T-cell responses, (ii) Immune checkpoint therapy, (iii) Other inhibitory immune checkpoints, (iv) Immune checkpoint therapy with clinical benefits in solid tumors and hematological malignancies, (v) Early and late-phase trials with immune checkpoint therapy in other tumors, (vi) Immune costimulatory molecules,

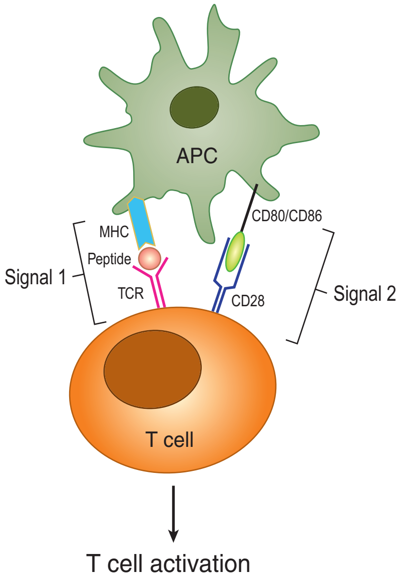
ACTIVATION AND REGULATION OF T-CELL RESPONSES

T-cell activation involves complex interactions involving both T-cell receptor (TCR) signaling and CD28 costimulation (Fig. 77.2) (Chapter 12). T-cell receptor interacts with foreign antigen in the context of self-MHC, which provides "signal 1." However, signal 1 by itself is insufficient to enable T-cell activation. "Signal 2" is provided when CD28 receptor, which is constitutively expressed on T cells, binds to B7-1 (CD80) and B7-2 (CD86) molecules that are expressed on antigen-presenting cells (APCs) but not on tumor cells. Therefore tumor cells alone are unable to start the process of T-cell activation. T cells require fragments of tumor cells to be phagocytosed by APCs such as dendritic cells, with eventual antigen processing and presentation by the APCs. T cells then interact with the APCs to receive both signals 1 and 2 for appropriate T-cell activation, which leads to cytokine production and proliferation as well as active killing of tumor cells.

Early research in the mid-1990s demonstrated that T-cell activation was a complex event, which enabled proliferation and functional differentiation but also induced inhibitory pathways that eventually could attenuate and terminate T-cell responses. The first intrinsic T-cell inhibitory molecule to be described was cytotoxic lymphocyte antigen-4 (CTLA-4), which is expressed on T cells only after T-cell activation. CTLA-4 has high homology to CD28 and binds to B7 (CD80 and CD86) molecules with much higher affinity than CD28. Two research groups independently showed that activation of T cells results in induction of CTLA-4, which accumulates at the T cell–APC interface and eventually outcompetes CD28 for binding to B7,



APC
MHC
Peptide

CD80/CD86
CD28
Signal 1
Signal 2
T cell
T cell activation

FIG 77.2 T cell activation. The "signal 1" for T cell activation, occurs following the recognition of MHC-peptide complex on an antigen-presenting cell (APC) by the T cell receptor (TCR) on a T cell. The "signal 2" for T cell activation is provided by binding of B7 molecules (CD80/86) on the APC to CD28 on the T cells. Following this interaction, T cells are activated and perform various effector functions.

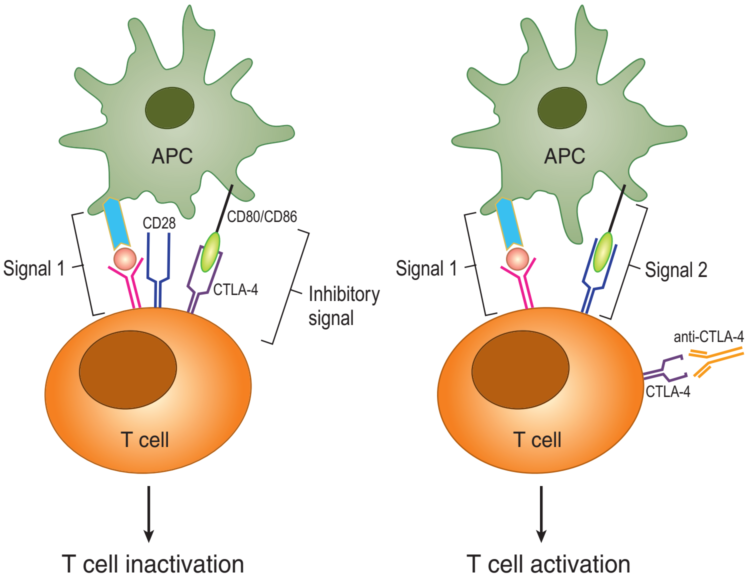

FIG 77.3 Regulation of T cell response. Upon T cell activation, T cells traffic to tumor leading to the cell surface expression of immune checkpoints such as CTLA-4, which bind with a higher affinity to the B7 molecules, thereby downregulating T cell responses. Targeting CTLA-4 with anti-CTLA-4 antibodies blocks this inhibitory interaction and CD28 is again free to interact with the B7 molecules, further amplifying T cell responses against the tumor.

thereby abrogating T-cell responses.[6,7] Based on these data, researchers proposed to enhance antitumor immune responses by blocking the CTLA-4 inhibitory pathway (Fig. 77.3). This approach, termed immune checkpoint therapy, has proven to be a paradigm shift in cancer therapy.

IMMUNE CHECKPOINT THERAPY

Anti-CTLA-4 Therapy

CTLA-4 is an immune checkpoint that is expressed on the surface of activated T cells to restrain T-cell responses. In other words, unrestricted T-cell responses can damage normal tissues and cells; therefore CTLA-4 plays an important role in controlling T-cell responses and in preventing damage to self. This mechanism protects normal cells, but in the setting of cancer, this mechanism also protects cancer cells. Preclinical studies elegantly demonstrated that blocking CTLA-4 enhances antitumor immune responses.[8]

Ipilimumab was the first fully human monoclonal (IgG1) antibody (mAb) against CTLA-4 to enter clinical trials in the late 1990s. Phase I and II trials demonstrated remarkable clinical responses and tumor regression in cancer patients, including patients with melanoma, renal cell carcinoma (RCC), prostate cancer, urothelial carcinoma, and ovarian cancer.[9] In both early and late-phase trials, ipilimumab has shown consistent activity against melanoma. The success of anti-CTLA-4 in eliciting durable clinical responses and in potentially curing some patients with cancer led to the establishment of a new field termed *immune checkpoint therapy,* which has expanded with the identification of additional T-cell inhibitory pathways.[10]

Anti-PD-1/PD-L1 Therapy

Programmed death 1 (PD-1) belongs to the CD28/CTLA-4 family and is expressed on the surface of activated T cells, B cells, monocytes, dendritic cells (DC) and natural killer (NK) cells. Its role in T-cell inhibition was first demonstrated in early 2000. Unlike CTLA-4, PD-1 appears to inhibit T-cell responses by interfering with TCR signaling, which is distinctly different from CTLA-4 and its ability to inhibit T-cell responses by competing with CD28 for binding to B7 molecules. PD-1 interacts with two ligands, PD-L1 and PD-L2, which appear to be equally capable of suppressing T-cell responses.[11]

Antibodies targeting the PD-1/PD-L1 interaction have shown beneficial clinical responses in multiple tumor types. Nivolumab was the first mAb targeting PD-1 to show significant clinical activity in patients with unresectable or metastatic melanoma, non–small-cell lung carcinoma (NSCLC), metastatic RCC, and classical Hodgkin lymphoma.[11]

Given the considerable activity of agents targeting immune checkpoints, numerous early studies have been conducted across several solid tumors. Presented in Table 77.1 is the published literature for agents that have been US Food and Drug Administration (FDA) approved or tested in the phase III setting in melanoma, RCC, and NSCLC.

KEY CONCEPTS

Primary Targets of Immune Checkpoint Therapy

- CTLA-4: interferes with T-cell costimulatory signal
- PD-1: interferes with T-cell receptor signaling

The blockade of CTLA-4 and PD-1/PD-L1 inhibitory interactions has been extensively explored clinically. Nevertheless, these interactions represent only a fraction of the potential targets that can serve to improve antitumor immune responses. Additional inhibitory pathways have been identified and are currently being targeted to improve antitumor immune responses. A few of these are discussed in the sections that follow.

T-Cell Immunoglobulin and Mucin Domain 3

T-cell immunoglobulin and mucin-domain containing-3 (TIM-3) is expressed by dendritic cells, monocytes, and T cells. TIM-3 is postulated to bind to its presumed ligand galectin-9, which is expressed on tumors. Studies in murine models indicate that TIM-3 is coexpressed with PD-1 on T cells. Dual blockade of TIM-3 and PD-1 has been shown to improve antitumor immune responses and reduce tumor growth in preclinical studies.[12] In a phase I/II trial, the safety and efficacy of MBG453, an antibody against TIM-3, is being evaluated as a single agent

TABLE 77.1 FDA Approval of Immune Checkpoint Inhibitors in the Treatment of Cancer

Cancer Type	Drug	Dose, Frequency, Duration	Disease State	Line of Treatment	Approval Year
Melanoma	Ipilimumab	3 mg/kg IV Q3wk × 4 doses until PD/tox	Unresectable/Metastatic	Any	
Melanoma	Pembrolizumab	2 mg/kg IV Q3wk until PD/tox	Unresectable/Metastatic	Refractory	2014
Melanoma	Nivolumab	3 mg/kg IV Q2wk until PD/tox	Unresectable/Metastatic	Post ipilimumab	2014
Melanoma	Pembrolizumab	2 mg/kg IV Q3wk until PD/tox	Unresectable/Metastatic	Initial	2015
Melanoma	Nivolumab	3 mg/kg IV Q2wk until PD/tox	Unresectable/Metastatic	Initial	2015
Melanoma	Ipilimumab plus Nivolumab	Ipi 3 mg/kg IV Q3wk ×4 + Nivo 1 mg/kg IV Q3wk ×4 followed by Nivo Q3wk ×4 until PD/tox	Unresectable/Metastatic BRAF V600 WT	Initial	2015
Melanoma	Ipilimumab	3 mg/kg IV Q3wk × 4 doses 12 until PD/tox	Surgically resected, high risk for recurrence	Adjuvant	2015
Kidney	Nivolumab	3 mg/kg IV Q3wk until PD/tox	Advanced	Post 1 antiangiogenic therapy	2015
NSCLC All PD-L1 +	Pembrolizumab	2 mg/kg IV Q3wk until PD/tox	Advanced	Post platinum	2015
NSCLC All	Nivolumab	3 mg/kg IV Q2wk until PD/tox	Advanced	Post platinum, Post EGFR/ALK for pt with mutation	2015
NSCLC	Atezolizumab	1200 mg/kg IV Q3wk until PD/tox	Advanced	Post platinum, Post EGFR/ALK for pt with mutation	2016
Urothelial	Atezolizumab	1200 mg IV Q3wk until PD/tox	Unresectable/Metastatic	Post platinum	2016
Hodgkin lymphoma	Nivolumab	3 mg/kg IV Q3wk until PD/tox		Post autologous SCT, posttransplant brentuximab vedotin	2016
Head and Neck Squamous	Pembrolizumab	200 mg IV Q3wk until PD/tox	Unresectable/Metastatic	On or post platinum	2016
Head and Neck Squamous	Nivolumab	3 mg/kg IV Q2wk until PD/tox	Unresectable/Metastatic	On or post platinum	2016

ALK, anaplastic lymphoma kinase; EGFR, epidermal growth factor receptor; FDA, US Food and Drug Administration; IV, intravenous; ipi, ipilimumab; nivo, nivolumab; NSCLC, non–small-cell lung carcinoma; PD, disease progression; pt, patients; SCT, stem cell transplant; tox, toxicity; wk, week; WT, wild type.

and in combination with anti-PD-1 in patients with advanced malignancies (ClinicalTrials.gov).

Lymphocyte Activation Gene 3

Lymphocyte activation gene-3 (LAG-3) is expressed on B cells, some T cells, and NK cells. LAG-3 is postulated to bind to MHC class II, which inhibits T-cell responses.[13] Immuntep (IMP321), a recombinant soluble fusion protein of LAG-3, is currently being tested in two or more clinical trials (ClinicalTrials.gov). A phase I study is also testing another anti-LAG-3 (BMS-986016) as monotherapy or in combination with anti-PD-1 (nivolumab) in patients with advanced solid tumors (ClinicalTrials.gov).

V-Domain Ig Suppressor of T-Cell Activation

V-domain Ig suppressor of T-cell activation (VISTA) is a negative immune checkpoint ligand, which shares homology with PD-L1 and is primarily expressed on hematopoietic cells. Preclinical studies with VISTA blockade have shown improved antitumor immune responses, leading to impeded tumor growth and improved survival.[14] Clinical trials with anti-VISTA mAbs are ongoing and include a phase I study with JNJ-61610588, a fully human IgG1 anti-VISTA mAb (ClinicalTrials.gov).

IMMUNE CHECKPOINT THERAPY WITH CLINICAL BENEFIT IN SOLID TUMORS AND HEMATOLOGICAL MALIGNANCIES

Melanoma

In recent years, immunotherapy has dramatically changed the landscape of melanoma treatment: Since 2011, four immunotherapies have been approved by the FDA.

A randomized phase III trial in patients with metastatic melanoma was conducted whereby patients received either anti-CTLA-4 antibody (ipilimumab), with or without a peptide (gp100) vaccine, or vaccine treatment alone. The observed median overall survival (OS) was 10 months for patients who received ipilimumab plus gp100 vaccine, 10.1 months for patients who received ipilimumab alone, and 6.4 months for patients who received only the gp100 vaccine. Importantly, approximately 20% of patients who received ipilimumab had long-term survival of greater than 3 years. These data led to the FDA approval of ipilimumab for metastatic melanoma in 2011.[15]

Another phase III trial in patients with previously untreated metastatic melanoma demonstrated that OS was significantly longer for patients who received ipilimumab plus dacarbazine chemotherapy compared with patients who received dacarbazine alone.[16] Additionally, ipilimumab versus placebo was investigated in patients with high-risk stage III melanoma after complete resection, where ipilimumab was given every 3 weeks for 4 doses, followed by every 3 months for up to 3 years. Median recurrence-free survival was 46.5% in patients treated with ipilimumab versus 34.8% for patients who received placebo, which led to the FDA approval of ipilimumab in the adjuvant setting.[17] Ipilimumab is approved in the metastatic as well as in the adjuvant setting for the treatment of melanoma. Importantly, to provide an accurate estimate of long-term survival following treatment with ipilimumab, a pooled analysis was performed from 10 prospective and two retrospective studies, including the two phase III trials mentioned above. The data demonstrated long-term survival of approximately 20% of patients, with survival of 10 years noted for some patients. The results were independent of ipilimumab dosing or prior therapy.[18]

Antibodies against another immune checkpoint inhibitor, PD-1 (nivolumab), have also been explored for the treatment of patients with metastatic melanoma. A phase III study in patients with advanced melanoma who progressed after ipilimumab therapy demonstrated an objective response rate (ORR) of 31.7% in patients treated with nivolumab compared with an ORR of 10.6% in patients treated with chemotherapy alone.[19]

Another randomized clinical trial in patients with previously untreated metastatic melanoma without BRAF mutation showed an improved OS in patients treated with nivolumab (72.9%) compared with patients treated with dacarbazine chemotherapy (42.1%) at 1 year. Subgroup analysis demonstrated that the nivolumab-treated patients had improved OS regardless of expression of the ligand for PD-1 (PD-L1) on tumor cells.[20] Based on these two phase III trials, nivolumab was FDA approved for the treatment of patients with refractory unresectable or metastatic melanoma and also for the first-line treatment of patients with metastatic melanoma.

Another anti-PD-1 mAs, pembrolizumab, was investigated in a phase II study that randomized patients with metastatic melanoma who were previously treated with ipilimumab and a BRAF inhibitor. Patients received either pembrolizumab 2 mg/kg every 3 weeks, pembrolizumab 10 mg/kg every 3 weeks, or chemotherapy. The 6-month progression-free survival (PFS) was significantly higher in patients treated with pembrolizumab compared with patients treated with chemotherapy (34% in 2 mg/kg cohort, 38% in 10 mg/kg cohort, and 16% in chemotherapy cohort).[21] The FDA approved pembrolizumab at a dose of 2 mg/kg intravenous every 3 weeks for the treatment of refractory melanoma. Pembrolizumab versus ipilimumab was then investigated in another phase III trial, where patients were randomized to two pembrolizumab regimens (10 mg/kg dose every 2 weeks or every 3 weeks) and an ipilimumab regimen (3 mg/kg dose every 3 weeks for 4 cycles), with PFS and OS as the primary endpoints. The 6-month PFS was 47.3% with pembrolizumab treatment every 2 weeks compared with 46.4% with pembrolizumab treatment every 3 weeks, and 26.5% with ipilimumab treatment. One-year estimates of survival were 74.1% for patients receiving pembrolizumab every 2 weeks, 68.4% for those receiving pembrolizumab every 3 weeks, and 58.2% for those receiving ipilimumab, leading to the FDA approval of pembrolizumab as a first-line treatment for patients with metastatic melanoma.[22]

Another phase III trial compared ipilimumab, nivolumab, and the combination in patients with untreated, unresectable, or metastatic melanoma with PFS and OS as coprimary endpoints. Treatment with combination therapy was statistically superior, leading to a median PFS of 11.5 months versus 6.9 months for nivolumab alone versus 2.8 months for ipilimumab alone. However, the data on the OS were not sufficiently mature to present. Based on these findings, the FDA approved combination therapy with ipilimumab plus nivolumab as first-line treatment for patients with previously untreated, unresectable, or metastatic melanoma, regardless of PD-L1 expression on tumor cells.[23]

KEY CONCEPTS

US Food and Drug Administration-Approved Checkpoint Inhibitors in Melanoma

- Ipilimumab: metastatic melanoma, used in the adjuvant setting
- Nivolumab: first-line treatment for metastatic melanoma; treatment of refractory unresectable or metastatic melanoma
- Pembrolizumab: first-line treatment for metastatic melanoma
- Ipilimumab plus nivolumab: first-line treatment for patients with previously untreated, unresectable, or metastatic melanoma

Lung Cancer

Similar to melanoma, NSCLC is also characterized by high mutational load,[24] and immune checkpoint therapy has led to durable antitumor response in NSCLC.

In a phase III study, patients with advanced squamous NSCLC who progressed during or after first-line chemotherapy were randomly assigned to receive nivolumab versus docetaxel chemotherapy. OS and PFS were significantly better with nivolumab compared with docetaxel, regardless of PD-L1 expression on tumor cells. This led to FDA approval of nivolumab for the treatment of patients with squamous NSCLC.[25] This approval was subsequently expanded to all subtypes of NSCLC, based on another phase III study that demonstrated a median OS of 12.2 months for patients with nonsquamous NSCLC who received nivolumab treatment compared with 9.4 months for patients who received docetaxel.[26]

Similarly, another phase III study evaluated pembrolizumab versus docetaxel for the treatment of patients with previously treated advanced NSCLC (both squamous and nonsquamous). Patients enrolled in this trial were selected to have at least 1% of tumor cells positive for the expression of PD-L1. The median OS observed with pembrolizumab was 10.4 months with the 2 mg/kg dose and 12.7 months with the 10 mg/kg dose versus 8.5 months with docetaxel. In patients with at least 50% of tumor cells expressing PD-L1, the OS was 14.9 months with pembrolizumab 2 mg/kg and 17.3 months with pembrolizumab 10 mg/kg versus 8.2 months after treatment with docetaxel. Based on these findings, the FDA approved pembrolizumab as single-agent, second-line therapy for patients with NSCLC whose tumors express PD-L1.[27]

Another phase III trial investigated pembrolizumab versus chemotherapy in previously untreated patients with advanced NSCLC, with PD-L1 expression on at least 50% of tumor cells and without epidermal growth factor receptor (EGFR) or anaplastic lymphoma kinase (ALK) mutations. The study demonstrated statistically significant improvements in OS for patients randomized to pembrolizumab compared with chemotherapy; the study also showed a significant improvement in median PFS of 10.3 months in the pembrolizumab group versus 6.0 months in the chemotherapy group.[28] This study led to the approval of pembrolizumab as first-line therapy for the treatment of patients with metastatic NSCLC whose tumors express PD-L1.

Several other PD-1/PD-L1 checkpoint inhibitors are in late-stage clinical testing for patients with lung cancer.

KEY CONCEPTS

FDA-Approved Checkpoint Inhibitors in Non–Small-Cell Lung Cancer

- Nivolumab: treatment of all subtypes of non–small-cell lung cancer (NSCLC)
- Pembrolizumab: single-agent, second-line therapy for NSCLC expressing PD-L1
- Pembrolizumab first-line therapy for metastatic NSCLC expressing PD-L1

Renal Cell Carcinoma

Antiangiogenic therapies have been the established treatment for patients with metastatic RCC. However, patients eventually develop innate or adaptive resistance to antiangiogenic therapy, which could be attributed partly to changes in the immune microenvironment,[29] proving a strong rationale to investigate the clinical effects of immune checkpoint therapy in RCC patients.

A phase III study in patients with advanced or metastatic RCC, who had received at least one prior treatment, demonstrated improved OS of 25 months after treatment with nivolumab compared with OS of 19.6 months in patients treated with everolimus.[30] Based on this trial, the FDA approved nivolumab as second-line therapy for patients with metastatic RCC. New immune-based treatment strategies for treating RCC patients are in development.

Bladder Cancer

Platinum-based chemotherapy has been the established first-line treatment for patients with metastatic bladder cancer; no new therapies have been established in the past 30 years, including no standardized second-line treatment because of the dismal objective response rates of 10% or less with tested chemotherapies. However, preclinical studies have demonstrated clinical benefits with immune checkpoint therapy in bladder tumors.[31] A single-arm phase II study investigated the role of an anti-PD-L1 antibody (atezolizumab), to block one of the ligands that interacts with PD-1, in patients with locally advanced or metastatic urothelial bladder cancer whose disease had progressed after previous treatment with platinum-based chemotherapy. Compared with the historical control ORR of 10%, treatment with atezolizumab resulted in a significantly improved ORR of 15% for all treated patients, regardless of PD-L1 expression.[32] This study led to FDA approval of atezolizumab in patients with locally advanced or metastatic urothelial bladder cancer whose cancers had progressed during or after treatment with platinum-based chemotherapy.

A phase I/II study investigated nivolumab in patients with locally advanced or metastatic urothelial cancer whose disease had progressed after previous treatment with platinum-based chemotherapy. This study demonstrated that nivolumab monotherapy led to an ORR of 24.4%.[33] Another, larger phase II study assessed the clinical activity and safety of nivolumab in 270 patients with metastatic bladder cancer who had progressive disease despite first-line platinum-based chemotherapy. This study reported an ORR of 19.6% with nivolumab therapy.[34]

Additionally, in another phase I/II study that treated patients with metastatic bladder cancer who progressed after platinum-based chemotherapy, patients who received combination treatment with ipilimumab 3 mg/kg plus nivolumab 1 mg/kg had an ORR of 38.5% versus an ORR of 26% for patients who received ipilimumab at 1 mg/kg plus nivolumab at 3 mg/kg; patients who received nivolumab alone had an ORR of 24.4%.[35] These early findings with higher-dose ipilimumab provide evidence for improved responses with combination immune checkpoint therapy.

Head and Neck Cancer

Head and neck cancer is one of the cancer types for which new immune-based cancer treatments are currently in development.

In 2016, pembrolizumab was FDA approved for the treatment of patients with recurrent or metastatic head and neck squamous-cell carcinoma (HNSCC) that continued to progress despite chemotherapy. The approval was based on data from a nonrandomized trial in patients with HNSCC who failed to respond to platinum-based chemotherapy.[36] Following treatment, pembrolizumab demonstrated an ORR of 16%. The median OS observed with pembrolizumab was 9.6 months, compared with the historical median OS of only 6 months. In this trial, responses were seen in patients with human papillomavirus (HPV)-positive tumors (24%) as well as in patients with HPV-negative tumors (16%), respectively.

Another phase III trial investigated nivolumab versus standard single-agent systemic therapy (methotrexate, docetaxel, or cetuximab) in patients with recurrent or metastatic HNSCC after platinum-based chemotherapy. This study demonstrated that treatment with nivolumab resulted in longer OS of 7.5 months compared with an OS of 5.1 months with standard single-agent therapy.[37] These findings led to the FDA approval of nivolumab in the treatment of platinum-refractory recurrent HNSCC.

Hodgkin Lymphoma

A phase I study of nivolumab in previously treated patients with relapsed or refractory Hodgkin lymphoma demonstrated an objective response of 87%, including 17% of patients with a complete response and 70% of patients with a partial response; the remaining 13% had stable disease. The Reed-Sternberg cells that define Hodgkin lymphoma have frequent amplification of chromosome 9p24.1, which leads to expression of PD-1 ligand in Reed-Sternberg cells and provides strong rationale for immune checkpoint therapy that blocks the PD-1/PD-L1 axis.[38] Findings from this study led to FDA approval of nivolumab for patients with previously treated relapsed or refractory Hodgkin lymphoma.

EARLY AND LATE-PHASE TRIALS WITH CHECKPOINT THERAPY IN OTHER TUMORS

Pancreatic Cancer

Pancreatic cancer has a poor prognosis with limited treatment options. A poor understanding of the immune microenvironment in pancreatic cancer has been a roadblock in developing effective treatment strategies. We have generated preliminary data to indicate that pancreatic tumors have immune infiltrates and differentially express inhibitory immune checkpoints compared with tumors that respond to checkpoint therapy, such as melanoma and bladder cancer.[39] Therefore treatment of pancreatic cancer with combination strategies that include immune checkpoint therapy is being explored.

Early-phase trials with ipilimumab have demonstrated delayed responses in patients with advanced pancreatic cancer.[40] Immune checkpoint therapies that are under development for treating pancreatic cancer include pembrolizumab, nivolumab with or without ipilimumab, and durvalumab with or without tremelimumab (ClinicalTrials.gov).

Prostate Cancer

Despite advances in the treatment of metastatic castration-resistant prostate cancer (mCRPC), novel immune-based strategies that can provide durable and long-term responses in patients are still needed. Sipuleucel-T (autologous cellular immunotherapy) is the only approved immunotherapy for patients with prostate cancer.[41] However, the exact mechanism of action of sipuleucel-T remains to be elucidated, and clinical metrics and/or biomarkers to evaluate responses with sipuleucel-T are currently lacking.

Several early-phase clinical trials have evaluated different doses, schedules, and combinations of immune checkpoint inhibitors in patients with mCRPC. A phase I/II trial (CA184–107) of ipilimumab as a single agent or in combination with radiotherapy in patients with previously treated mCRPC demonstrated a decline in prostate-specific antigen (PSA) in 15% of patients.[42] However, a phase III clinical trial (CA184–043) of bone-directed radiotherapy followed by either ipilimumab or placebo in patients with mCRPC failed to demonstrate an improvement in OS.[43]

Further studies are warranted to investigate the potential effects of combining immune checkpoint therapy with other treatment strategies, including other immunotherapies, chemotherapy, radiotherapy, and hormonal agents, in patients with prostate cancer in different treatment settings (metastatic hormone-naïve or metastatic castration-resistant disease).

IMMUNE COSTIMULATORY MOLECULES

Multiple ligand-receptor interactions play a pivotal role in shaping T-cell responses, including those that positively regulate T-cell function, thus making them potential targets for cancer immunotherapy. Many such costimulatory molecules are being investigated in preclinical or early-phase clinical studies. The two major families of costimulatory receptors expressed by T cells are the immunoglobulin-like (Ig) superfamily (including inducible T-cell costimulator [ICOS]) and the tumor necrosis factor receptor (TNFR) superfamily (including OX40 and 4–1BB).[44] These costimulatory molecules are suitable candidates for the development of targeted therapeutics. A schematic overview of the costimulatory and coinhibitory ligand-receptor interactions is illustrated in Fig. 77.4.

Inducible T-Cell Costimulator

ICOS is another member of the CD28/CTLA-4 immunoglobulin superfamily, whose expression is increased upon T-cell activation. ICOS can be expressed on activated effector T cells as well as on activated T regulatory cells (Tregs). ICOS interacts with its ligand, ICOSL, which is expressed on APCs, and provides a key costimulatory signal for T-cell proliferation and survival. We have shown that ICOS$^+$ effector T cells increase in patients after anti-CTLA-4 (ipilimumab) treatment.[45] An increased frequency of ICOS$^+$ CD4 T cells was also identified as a pharmacodynamic biomarker of anti-CTLA-4 therapy.[46] Another study with a different anti-CTLA-4 antibody (tremelimumab) also reported an increase in ICOS$^+$ CD4 T cells in blood samples obtained from patients with breast cancer.[47] Collectively, these findings indicated a biologically relevant role for ICOS in antitumor immune responses elicited by anti-CTLA-4 therapy.

Furthermore, preclinical studies demonstrated that combination therapy with anti-CTLA-4 plus an agonist to target the ICOS/ICOSL pathway led to a significant improvement in T-cell responses and tumor rejection.[48] These data led multiple pharmaceutical companies to pursue the development of an anti-ICOS antibody, including a recent trial with GSK3359609, an anti-ICOS antibody for treating patients with advanced solid tumors (NCT02723955; ClinicalTrials.gov).

ICOS previously was shown to be expressed on T-follicular helper cells (Tfh cells).[49] A clinical trial is ongoing with administration of an anti-ICOS antibody as treatment for patients with relapsed or refractory peripheral T-cell lymphoma follicular variant or angioimmunoblastic T-cell lymphoma (ClinicalTrials.gov).

4-1BB (CD137)

4-1BB (CD137) is an activation-induced costimulatory molecule that is expressed on activated T cells, NK cells, dendritic cells, eosinophils, mast cells, endothelial cells, and some tumor cells. Anti-4-1BB mAbs have demonstrated improved antitumor T-cell responses, with rejection of established syngeneic tumor cell lines in preclinical models. Several early-phase trials with anti-4-1BB antibodies have been initiated, and they have demonstrated antitumor responses, including partial remission and stabilization of disease in a subset of patients with advanced malignancies; however, immune-related adverse events (irAEs) have led to reevaluation of the dose and schedule of treatment with anti-4-1BB agonists.[50] Two separate phase I clinical studies

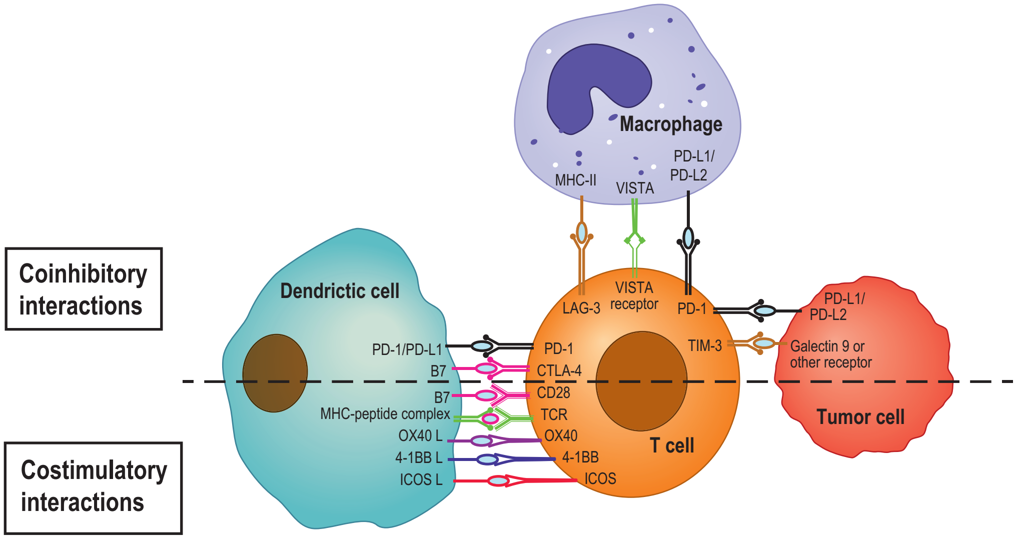

FIG 77.4 **Costimulatory and coinhibitory ligand–receptor interactions:** A schematic overview of the costimulatory and coinhibitory interactions between a T cell and dendritic cell; T cell and a macrophage and a T cell and a tumor cell in the tumor microenvironment.

to assess the safety and immunoregulatory activity of urelumab (BMS-663513) in patients with advanced and/or metastatic tumors and relapsed/refractory B-cell non-Hodgkin lymphoma are under investigation (ClinicalTrials.gov).

OX40 (CD134)

OX40 (CD134) is expressed on activated T cells, including activated effector and Tregs. Engagement of OX40 with its ligand enhances proliferation and survival of T cells. Preclinical studies with OX40 have shown increased antitumor responses and overall survival. A trial with the murine anti-OX40 agonist 9B12 mAb in patients with advanced cancers was well tolerated and demonstrated regression of at least one metastatic lesion in 12 out of 30 patients.[51] Humanized antibodies against OX40 are under clinical development. A phase I first-in-human study to evaluate the anti-OX40 antibody GSK3174998 as monotherapy and in combination with anti-PD-1 therapy (pembrolizumab) in patients with advanced solid tumors is ongoing (ClinicalTrials.gov). In addition, a phase Ib dose escalation study of the anti-OX40 antibody MOXR0916 plus the anti-PD-L1 antibody atezolizumab is ongoing in patients with locally advanced or metastatic solid tumors (ClinicalTrials.gov).

ADOPTIVE CELL TRANSFER

Several clinical studies have demonstrated that the reinfusion of autologous lymphocytes in cancer patients, isolated from their own tumor or peripheral blood, could inhibit tumor growth, and these initial studies formed the basis for adoptive T-cell therapy.[52]

For adoptive immunotherapy, the isolation of antigen-specific T cells from the peripheral blood or tumor is followed by clonal expansion and transfusion back into the tumor-bearing host. Adoptive T-cell transfer has achieved tumor regression and improved survival by increasing the number of reactive T cells, providing long-term immune protection and guaranteeing antigen specificity. The downside to this method is both the expense and the expertise needed to perform this labor-intensive therapy. Assuming that the T cells are already primed to the tumor and are antigen-specific, they can be polyclonally activated *ex vivo* before being reinfused back into the patient. Suppressing the immune system before adoptive transfer is important for improving the antitumor efficacy. Significant progress has been made to establish adoptive T-cell therapy as a standard-of-care method for the treatment of cancer, and multiple studies are ongoing.[53]

Adoptive Transfer of Tumor-Specific Cytotoxic T Cells

Studies in murine tumor models have demonstrated that the lymphocytes in transplantable tumors are capable of recognizing tumor cells *in vitro,* and the adoptive transfer of these syngeneic tumor-infiltrating lymphocytes (TIL) could mediate tumor regression in certain cancers. *In vitro* studies demonstrated that TIL obtained from melanoma patients could specifically recognize autologous tumors. Further studies based on this observation demonstrated that transfer of autologous TIL could mediate objective regression in patients with metastatic melanoma and across other cancers.[53] An alternative source of endogenous tumor-reactive T cells can be found in the peripheral blood of patients. Strategies to isolate and expand these rare circulating T cells are being developed for further investigation in clinical trials to target a broader population of patients.[54]

Adoptive Immunotherapy With Genetically Modified Lymphocytes

In early 2000, studies demonstrated that genetically engineered lymphocytes transduced with a retrovirus encoding a TCR to recognize melanoma-melanocyte antigen (MART-1) could mediate tumor regression.[53]

To improve the T-cell antigen specificity, a new class of "chimeric antigen receptor" (CAR) was developed. This model was capable of overcoming limitations associated with central and peripheral tolerance, generating efficient T cells. The advantage of CAR compared with conventional TCR is that the antigen need not be processed and presented by MHC. Importantly, this approach can be used in all patients who express the same tumor antigen, regardless of HLA type.[53,54]

Clinical Development of Chimeric Antigen Receptor T Cells

Chimeric antigen receptor T cells (CAR T cells) are defined as T cells that are genetically modified to express an artificial construct, consisting of a synthetic TCR targeted at a predetermined antigen expressed on tumor cells.

Coupling the CAR construct, which typically consists of a single-chain variable fragment (scFv; directed against a known tumor antigen), with the aid of a linker and a spacer to the transmembrane domain and a CD3ζ signaling domain, which provides "signal 1" necessary for T-cell activation, paved its way as first-generation CAR T cells. Preclinical studies using first-generation CAR T cells directed against CD19 expressing B-cell malignancies and HER2/Neu showed promising results.[55]

After this success, the second-generation CAR T cells were developed by coupling the intracellular portion of the construct with additional costimulatory signaling domains such as CD28 or 4–1BB, which provided "signal 2" for T-cell activation and further improved the efficacy of CAR T cells.

KEY CONCEPTS

Chimeric Antigen Receptor (CAR) T Cells Synthetic Receptor

- Single-chain variable fragment
- Linker and a spacer to the transmembrane domain
- CD3ζ signaling domain
- Additional costimulatory signaling domains

Further optimization led to the development of the third-generation CAR T cells, which incorporated two-tandem costimulatory domains by coupling ICOS, CD27, CD28, 4–1BB, or OX40 (*e.g.,* CD28/4–1BB/CD3ζ or CD28/OX40/CD3ζ), hence demonstrating varying degrees of *in vitro* and *in vivo* T-cell activation, proliferation, and cytokine (interleukin [IL]-2) production.[55]

The armored CAR T represent the next-generation CAR T cells, which incorporate not only the two-costimulatory domains but also an additional transgene for cytokines (*e.g.,* IL-12) or ligands (*e.g.,* CD40L or 4–1BBL); this helps these CAR T cells to survive and/or disrupt an immunosuppressive tumor microenvironment.[53,55] The key concepts of the four generations of CAR T cells are illustrated in Fig. 77.5.

CTL019 is the first investigational CAR T to receive breakthrough-therapy status by the FDA for the treatment of adult and pediatric relapsed/refractory acute lymphoblastic

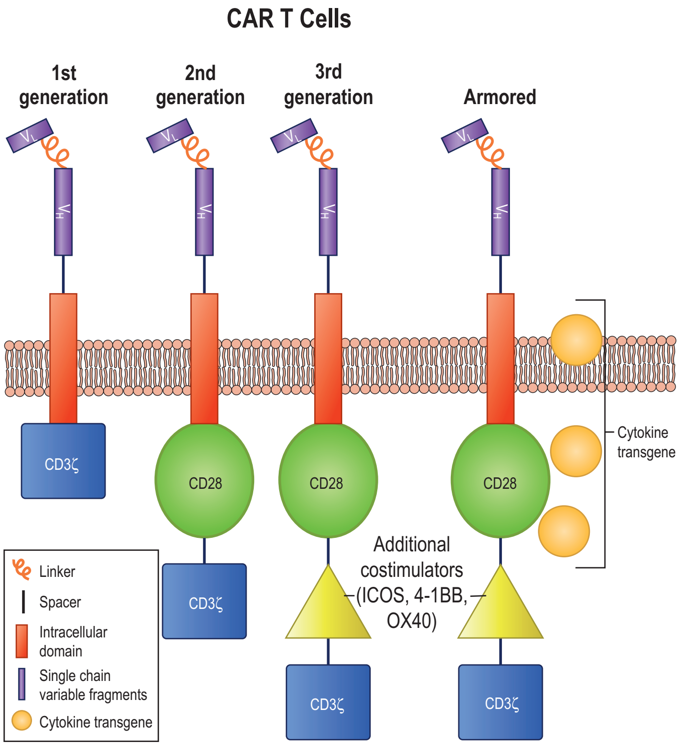

FIG 77.5 Different generations of CAR T cell constructs. The 1st generation CAR T comprising of a T cell signaling domain; the 2nd generation, with one costimulation domain and a T cell signaling domain; the 3rd generation, with two costimulation domains and a T cell signaling domain; and the armored CAR T cell with similar construct to third generation but with an additional pro-inflammatory cytokine transgene.

leukemia (NCT02228096; ClinicalTrials.gov). CTL019 is a second-generation CAR T cell that comprises an anti-CD19 extracellular scFv and CD3-ζ and 4–1BB intracellular signaling domains.

Adoptive transfer of CAR T cells has demonstrated significant promise in targeting hard-to-treat hematologic malignancies and solid tumors. Although the safety concerns related to cytokine release syndrome still need to be fully addressed, multiple CAR T cells are in clinical development.[56]

Adoptive Transfer of Viral-Specific T Cells

The adoptive transfer of T cells isolated or engineered to have specificity and reactivity for viral DNA can efficiently treat Epstein–Barr virus (EBV)-associated posttransplant lymphoproliferative disease.[57] It is known that CD8 and CD4 virus-specific T cells in chronic infections are characterized by the loss of T-cell function due to the upregulation of inhibitory molecules such as PD-1 and TIM-3; therefore the adoptive transfer of autologous T cells with high-affinity TCRs for viral proteins in combination with inhibitors of PD-1 or TIM-3 could be an ideal approach for the targeted therapy of virally induced malignancies.[58]

MONOCLONAL ANTIBODIES

The establishment of *hybridoma technology* in 1975 enabled the efficient development of mAbs. Immortalized B lymphocytes from immunized hosts were fused with nonimmunoglobulin murine myeloma cells, forming hybridomas, which produced large amounts of antibodies with high reactivity.[59] Later the development of *phage/yeasts* or *ribosome display technology* helped generate mAbs from any species and facilitated selection based on specificity, stability, and affinity.

The mounting success of a mAb as a therapeutic agent is based on three characteristics, including (i) an *Fc moiety* that mediates *antibody-dependent cellular cytotoxicity* (ADCC) and *complement-dependent cytotoxicity* (CDC); (ii) an *Fab moiety* that promotes high specificity and affinity for antigen binding; and (iii) a molecular mass of about 150 kDa, which extends the circulatory half-life of the mAb up to 21 days. Importantly, the mechanism of tumor cell killing by mAbs involves (i) binding to specific receptors on tumor cells via the Fab portion of the antibody and triggering cytotoxicity via the Fc portion of the antibody or (ii) binding to specific receptors on tumor cells via the Fab portion of the antibody and blocking important signaling pathways via the Fab portion of the antibody or a combination of both mechanisms.

Over the past 15 years, antibody-based immunotherapy has been established as a successful strategy for treating patients with hematological malignancies and some solid tumors. To enhance the effector functions, mAbs have been conjugated to radioisotopes, chemotherapeutic agents, bacterial toxins, cytokines, and enzymes[60]; therefore mAbs are classified as follows:

Naked mAbs

These mAbs are not attached to any drug or radioactive material and bind to specific molecules or antigens on tumor cells, which can block important signaling pathways, such as EGFR, or enable the immune system to destroy the tumor cells by ADCC or a combination of both.[60] ADCC is an important mechanism for tumor cell killing that is mediated by the interaction between the Fc region of an antibody and FcγRIIIa receptors on the surface of immune cells. mAbs may bind to a cell surface target via its Fab region and engage the effector cell expressing FcγRIIIa with the Fc region of the mAb, leading to subsequent killing of the tumor cell. ADCC is thought to be a key mechanism of activity of the FDA-approved mAbs rituximab and trastuzumab.[60]

Rituximab, a chimeric mAb targeted against the B-cell surface antigen CD20, was the first mAb to be FDA approved for therapeutic use against B-cell non-Hodgkin lymphoma (NHL), CD20-positive NHL, and chronic lymphocytic leukemia (CLL).

Trastuzumab (Herceptin) is another such mAb directed against human EGFR-2, a tyrosine kinase membrane receptor, which is overexpressed on approximately 30% of breast cancer cells in a subset of breast cancer patients. Trastuzumab monotherapy has demonstrated prolonged disease stability in a significant number of advanced-metastatic breast cancer patients.[61]

Other successful mAbs approved by the FDA for patients with solid tumors include bevacizumab targeting vascular endothelial growth factor (VEGF) (as first-line and second-line treatment of metastatic colon cancer in combination with 5-FU chemotherapy; in combination with carboplatin and paclitaxel chemotherapy as first-line treatment of advanced NSCLC patients who have not yet been treated with chemotherapy; as a single agent in patients with glioblastoma whose tumors have progressed after treatment; and for treating mRCC patients in combination with IFN-α); cetuximab targeting EGFR (as a single agent in HNSCC patients with failure to platinum-based therapy; in combination with radiotherapy for regionally advanced HNSCC; and as palliative treatment of pretreated metastatic EGFR-positive colorectal cancer); panitumumab targeting EGFR (as a single agent for treating pretreated EGFR-positive metastatic colorectal cancer); alemtuzumab targeting CD52 (as a single agent for treating CLL);

and ofatumumab targeting CD20 (for the treatment of CLL patients refractory to fludarabine and alemtuzumab).

Conjugated/Tagged/Labeled/Loaded mAbs

These mAbs target a molecule or antigen expressed on tumors and are coupled to a cytotoxic or radioactive agent to enable delivery of a toxic substance directly to the tumor site. Treatment with a radiolabeled mAb is termed *radioimmunotherapy* (RIT). Ibritumomab tiuxetan is a radiolabeled mAb against the CD20 antigen expressed on B lymphocytes and is FDA approved to treat different lymphomas. A randomized phase III trial comparing ibritumomab tiuxetan to rituximab in patients with relapsed or refractory NHL demonstrated a higher overall response rate (80% versus 56%) and complete response (CR) rate (30% versus 16%) for ibritumomab tiuxetan, but similar time to disease progression for both treatment groups.[62]

A different approach that uses mAbs coupled to chemotherapeutic agents is known as *antibody-drug conjugates* (ADC). Brentuximab vedotin (Zevalin) is a mAb conjugated to a chemotoxic drug called monomethyl auristatin E (MMAE), targeting the cell membrane antigen CD30 on lymphocytes. A phase II clinical study (NCT00848926; ClinicalTrials.gov) with brentuximab vedotin in patients with refractory Hodgkin lymphoma demonstrated complete remission in 34% of patients, partial remission in 40% of the patients, and tumor regression in 94% of patients.[63] Brentuximab vedotin is FDA approved to treat Hodgkin and anaplastic large-cell lymphoma. Trastuzumab emtansine (T-DM1) is another example of an antibody-drug conjugate, which is FDA approved for the treatment of HER2-positive breast cancer.[61]

Bispecific Monoclonal Antibodies

These mAbs are formed by coupling two different mAbs together and allowing the construct to bind to two separate proteins simultaneously, thus enabling the mAb to direct the immune system to act against the tumor.

Blinatumomab is one such example where one part of the mAb binds to the CD19 protein expressed on B-lineage acute lymphoblastic leukemia cells, while the second part of the mAb binds to the CD3 protein found on T cells, thereby linking these two cell types to activate the T cell to exert cytotoxicity on the $CD19^+$ tumor cells. Blinatumomab was first approved by the FDA in 2014, based on the observations of a phase II trial in patients with relapsed or refractory acute lymphoblastic leukemia in which 40% of patients achieved a CR or complete response with partial hematologic recovery (CRh).[64]

CYTOKINE THERAPY

Cytokines are low-molecular-weight proteins or glycoproteins that mediate cell-to-cell communication and play a pivotal role in regulating biological activities, including innate immunity, adaptive immunity, inflammation, and hematopoiesis.

IL-2 and IFN-α have been used previously to treat patients with metastatic melanoma and RCC. However, due to the nonspecific activation of the immune response and the toxicities associated with these cytokines, as well as the development of novel immunotherapy agents as discussed above, the use of high-dose IL-2 and IFN-α has diminished in clinical practice. Additional cytokines, including granulocyte macrophage–colony-stimulating factor (GM-CSF), IL-7, IL-12, IL-15, IL-18, and IL-21, have also been investigated in clinical studies for patients with advanced cancers.[65] Currently, the antitumor activity of PEGylated human IL-10 (AM0010) is being investigated in patients with advanced solid tumors.[66]

However, certain properties of cytokines pose significant clinical challenges in achieving antitumor responses. Some cytokines are pleiotropic and act on several immune cells and mediate opposite effects. High-dose IL-2 is known to promote cytotoxic activity of effectors (CD8 T cells and NK cells) and differentiation of CD4 T cells into T helpers. However, IL-2 can also preferentially expand Tregs due to a higher affinity to the IL-2 receptor (CD25) on these cells. Sometimes multiple cytokines have the same functional effect, leading to redundancy of cytokine signaling; therefore the therapeutic manipulation of cytokines can be challenging, as the modification of one cytokine can be compensated by another cytokine.[65]

CANCER VACCINES

Efforts to produce effective anticancer vaccines have been ongoing for decades. The two known categories are preventive cancer vaccines and therapeutic cancer vaccines.

Preventive vaccines consist of those that target infectious organisms that can cause cancer such as strains of HPV, which contribute to the development of some head/neck cancers, anal cancers, and cervical cancers. The three FDA-approved vaccines include Cervarix HPV (against HPV-16,-18, -31,-33,-45), Gardasil (against HPV-6,-11,-16,-18), and Gardasil 9 (against HPV-6,-11,-16,-18,-31,-33,-45,-52,-58).[67]

For the treatment of established cancers, sipuleucel-T was the first vaccine to be FDA approved. It is a cell-based vaccine consisting of autologous peripheral blood mononuclear cells (PBMC), which are collected from each patient and activated *ex vivo* with a recombinant fusion protein PA2024 (consisting of a prostate antigen and prostatic acid phosphatase fused to GM-CSF) before reinfusion into the patient. A phase III clinical trial demonstrated significant improvement in median OS after treatment with sipuleucel-T in asymptomatic men with castrate-resistant prostate cancer. Treatment with sipuleucel-T also resulted in an improvement in the rate of 3-year survival in 31.7% of patients compared with 23.0% for those receiving placebo.[67] The exact mechanism of action for sipuleucel-T remains to be defined.

ONCOLYTIC VIRUS IMMUNOTHERAPY

Oncolytic viruses represent a new class of therapeutic agents that promote antitumor immune responses, which depend on mechanisms that elicit selective tumor cell killing and induction of systemic antitumor immunity. A variety of native and genetically modified viruses are being developed and clinically investigated as oncolytic agents.[68]

IMLYGIC (talimogene laherparepvec, T-VEC) was the first oncolytic viral therapy to receive FDA approval for the treatment of unresectable cutaneous and subcutaneous and nodal lesions recurrent after surgery in melanoma patients. IMLYGIC demonstrated improved median OS in a phase III study in patients with advanced melanoma.[69] IMLYGIC is a genetically modified herpes simplex virus type designed to selectively replicate within the tumor cells and induce lysis.

CLINICAL CHALLENGES IN IMMUNOTHERAPY

Multiple challenges that remain for immunotherapy agents include resistance mechanisms and immune-related adverse events.

Resistance Mechanisms

Durable clinical responses with immune checkpoint therapy have been well documented; some of these responses last for years. However, many patients do not respond to initial therapy or relapse with disease after initially responding to treatment. Resistance mechanisms may involve the following: (i) activation of oncogenic pathways (WNT/B-catenin signaling, loss of PTEN expression), (ii) loss of interferon-gamma (IFNγ) signaling genes, (iii) recruitment of immunosuppressive cells such as Treg, myeloid-derived suppressor cells, M2 macrophages, and expression of other inhibitory immune checkpoints, and (iv) composition of gut microbiome.

KEY CONCEPTS

Mechanisms of Tumor Resistance to Immune-Mediated Therapy

- Activation of oncogenic pathways
- Loss of interferon-γ signaling genes in the tumor cells
- Recruitment of immunosuppressive cells (*e.g.,* Treg cells, myeloid-derived suppressor cells)
- Expression/secretion of inhibitory molecules
- Composition of the gut microbiome

Activation of Oncogenic Pathways

Recent research has identified an intricate interplay between oncogenic pathways and antitumor immunity.

In one such study, the whole exome sequencing and gene expression profiling of melanoma biopsies revealed that tumor-cell intrinsic activation of the WNT/β-catenin pathway correlates with absence of T cells in the tumor microenvironment.[70] Further investigation in a genetically engineered autochthonous mouse melanoma model confirmed that increased oncogenic β-catenin signaling results in a failure to recruit $CD8\alpha^+$ and $CD103^+$ DC populations in the tumor due to repressed expression of the chemokine CCL4. Consequently, mice with tumors expressing active β-catenin responded poorly to anti-CTLA-4 and anti-PD-L1 therapy, compared with mice with tumors lacking β-catenin expression.[70]

Apart from the activation of active β-catenin, the loss of PTEN expression is a frequent event in melanoma, especially in tumors with *BRAF* mutations. PTEN is a negative regulator of the PI3K-AKT pathway, and the complete loss of PTEN is associated with increased signaling through this pathway, correlating with shorter OS in patients with advanced melanoma.[71] A recent study in a melanoma mouse model demonstrated that the loss of PTEN expression can reduce the therapeutic activity of immune checkpoint therapy. The study additionally demonstrated that a selective PI3K-β-isoform inhibitor could induce synergy with immune checkpoint therapy in the preclinical model.[72] Similarly, findings in human melanoma specimens confirmed that the loss of PTEN correlates with exclusion of CD8 T cell in the tumor and increased PI3K activation. Importantly, patients with tumors lacking PTEN expression demonstrated poor clinical responses to anti-PD-1 therapy compared with patients with retained PTEN expression.[72]

Loss of Interferon γ Signaling

It is well established that IFNγ, a critical cytokine produced by T cells and other immune cells, plays a role in promoting innate and adaptive immune responses and in inhibiting tumor cell proliferation. IFNγ functions by binding to the IFNγ receptor, which initiates signaling through the Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathway to regulate gene expression.[73] Data from two independent studies have established that the loss of genes involved in the IFNγ signaling pathway may lead to both primary[74] and adaptive resistance[75] to immune checkpoint therapy.

Previously published data from a study in patients with bladder cancer demonstrated increased frequency of a $CD4^+$ $ICOS^{hi}$ T-cell subset that produced IFNγ following anti-CTLA-4 therapy.[45] We further hypothesized that tumor cells harboring mutations in the IFNγ-signaling pathway are not susceptible to the IFNγ produced by these T cells, which may result in resistance to anti-CTLA-4 therapy.[74] Evaluation of genomic alterations of IFNγ-pathway genes in melanoma patients treated with ipilimumab demonstrated that the tumors of the nonresponders had loss of IFNγ-pathway genes at significantly higher frequencies compared with the responders.

Furthermore, mice bearing melanoma tumors with knockdown of IFNγ-receptor, resulted in impaired tumor rejection when treated with anti-CTLA-4 therapy.

Similarly, another study compared paired tumor biopsies that were collected from four melanoma patients before treatment with anti-PD-1 (pembrolizumab) and at the time of disease relapse.[75] In two out of the four patients whose disease relapsed after initial responses to pembrolizumab therapy, mutations were detected in the genes encoding interferon-receptor–associated Janus kinase 1 (JAK1) or Janus kinase 2 (JAK2), two critical components of the IFNγ signaling pathway.

Taken together, these findings indicate that the loss of IFNγ signaling limits the effectiveness of the immune system to eliminate tumor cells and induces resistance to immune checkpoint therapy.

Immunosuppressive Tumor Microenvironment

In addition to the above-mentioned genomic alterations in tumor cells, other resistance mechanisms within the tumor microenvironment include Treg cells, myeloid-derived suppressor cells (MDSCs), M2 macrophages, expression of other inhibitory immune checkpoints (TIM-3, LAG-3, VISTA), recruitment of inhibitory molecules/ligands (indoleamine dioxygenase [IDO], carcinoembryonic antigen-related cell adhesion molecule 1 [CEACAM1], PD-L1), and the secretion of inhibitory cytokines (IL-10, IL-35, transforming growth factor [TGF]-β); these may have a direct negative effect on effector T-cell function and hence contribute toward immunosuppression and resistance to immunotherapy.[76,77]

Gut Microbiome

Two independent preclinical studies reported that the composition of the gut microbiome can contribute to the difference in responses to immunotherapy in cancer patients.[78,79]

One study compared the tumor growth in mice with distinct gut microbiota and identified that mice that harbored the commensal *Bifidobacterium* species had enhanced spontaneous antitumor immunity compared with mice with a different gut microbiota composition. Importantly, the direct administration of the *Bifidobacterium* species into mice with established melanoma tumors improved tumor-specific immunity and response to anti-PD-L1 therapy.[78]

Similarly, another study in tumor-bearing mice and cancer patients demonstrated that the efficacy of anti-CTLA4 therapy is associated with T-cell responses specific for the microbiota species *Bacteroides fragilis.* The study reported that antibiotic-treated and

germ-free tumor bearing mice did not respond to anti-CTLA-4 therapy compared with mice harboring *Bacteroides fragilis*. Additionally, the study reported that ipilimumab-treated patients with metastatic melanoma tend to have *Bacteroides fragilis* as a significant component of their microbiome.[79]

Collectively, these studies demonstrate the importance of gut microbiota and its role in facilitating the anticancer effects of immune checkpoint therapy.

Immune-Related Adverse Events

The clinical use of immunotherapeutic strategies is expanding rapidly, and the side effect profile of immunotherapeutic agents is distinct from that of conventional anticancer agents.[80] Therefore it is important to recognize and manage the irAEs in the growing patient population treated with immunotherapy. Early recognition and treatment of symptoms, time to discontinuation of therapy in case of an adverse event, and adherence to established treatment algorithms are essential to prevent patient morbidity and mortality.

irAEs With Immune Checkpoint Immunotherapy

Immune checkpoint blockade with antibodies targeting CTLA-4 and PD-1/PD-L1 has been extensively evaluated in the clinical setting. In a subset of patients, nevertheless, treatment with these immune checkpoint antibodies can be associated with distinctive inflammatory tissue damage,[81] which has been termed *immune-related adverse events* (irAEs). Table 77.2 summarizes the adverse events associated with anti-CTLA-4 and anti-PD-1, respectively, in phase III clinical trials. The spectrum of irAEs related to anti-CTLA4 and anti-PD-1/PD-L1 immunotherapy includes common reactions involving the gastrointestinal tract (diarrhea, colitis), skin (rash, dermatitis), liver (transaminitis), or endocrine axis (hypophysitis, thyroiditis).

The combination of nivolumab (anti-PD-1) and ipilimumab (anti-CTLA-4) has a much higher incidence of irAEs compared with monotherapy with either antibody. For instance, a phase III clinical trial in patients with advanced melanoma receiving nivolumab or ipilimumab, or a combination of both antibodies, demonstrated grade 3/4 treatment-related adverse events in 16% of patients treated with nivolumab, in 27% of patients treated with ipilimumab, and in 55% of patients treated with the combination.[82]

The optimal management of irAEs is based on clinical experience, and many of these irAEs are transient and responsive to steroid therapy.[83] Various immunomodulatory or immunosuppressive agents such as azathioprine and mycophenolate mofetil (MMF) have also been effective in the management of steroid-refractory irAEs.[84]

Recent findings from a retrospective study involving two clinical trials with ipilimumab in patients with prostate cancer identified CD8 T-cell clonal expansion within the systemic circulation as a potential correlative biomarker of irAEs.[85] These findings highlight a potential biomarker to predict, and provide early intervention for, toxicities that occur in patients who receive ipilimumab therapy.

irAEs With Adoptive T-Cell Therapy

The adoptive transfer of T cells is generally well tolerated, but it may be associated with the occurrence of life-threatening irAEs. Serious irAEs after adoptive T-cell therapy may occur when T cells targeting differentiation antigens in the tumor also recognize these antigens on normal cells. For example, patients with melanoma who receive adoptive T-cell therapy with T cells that target differentiation antigens such as MART-1 and gp100 may develop vitiligo and uveitis as irAEs, since these antigens are also expressed on normal cells.[86,87] Additionally, patients with metastatic RCC who were treated with carbonic anhydrase-IX (CAIX)-specific CAR T cells developed liver toxicity.[88] In addition, fatal irAEs were reported in cancer patients who received anti-MAGE-A3 TCR-transduced T cells.[89]

Adoptive T-cell therapy with CAR T cells may also be associated with another potentially life-threatening toxicity termed as *cytokine release syndrome* (CRS). The hallmark of CRS is elevated circulating levels of cytokines—including IL-6, TNF-α, and interferon-γ—resulting in fever, rigors, hypotension, and hypoxia.[90,91]

Treatment of irAEs associated with adoptive T-cell therapy, such as uveitis and colitis, can often be managed with topical or systemic corticosteroids; as for CAR T-cell therapy–related CRS, it is generally managed with either high-dose corticosteroids or agents such as tocilizumab (an IL-6 receptor-blocking antibody).[92]

PERSPECTIVES ON FUTURE DEVELOPMENTS

Recent success with immunotherapy in the management of cancer has given credence to the long-held belief that the immune system can be used to treat cancer. However, the current immunotherapeutic strategies form only the tip of the iceberg in terms of potential targets and combinations that can serve to improve clinical responses. A large number of additional agonistic and antagonistic mAbs that target immune checkpoints, as well as costimulatory molecule to potentiate T cell–mediated immune responses, are in various stages of clinical development; these include antibodies against ICOS, OX40, 4–1BB, LAG-3, and VISTA (ClinicalTrials.gov). Furthermore, intense clinical investigation is currently ongoing for the development of effective anticancer vaccines and adoptive cell transfer strategies (ClinicalTrials.gov).

ON THE HORIZON BOX

- Develop optimal patient selection strategy for cancer immunotherapy
- Develop the most appropriate timing for cancer immunotherapy
- Maximize cancer therapy effectiveness through strategies for:
  - Developing combined immunotherapeutic approaches
  - Optimally integrating standard anticancer modalities with immunotherapy

Biomarkers

To identify potential biomarkers that are relevant to antitumor immune responses, clinical trials are being designed to obtain tumor tissues to gain a better understanding of the tumor microenvironment and of immunological changes that occur over time.[10] Several biomarkers have been associated with clinical outcomes to immune checkpoint therapy, including high levels of PD-L1 expression, infiltration of effector T cells, and mutational landscape.[70,93,94] However, it is unlikely that a single biomarker will predict clinical outcome to immunotherapy; therefore, it will be necessary to integrate multiple biomarkers in immune monitoring studies. Additionally, immune monitoring studies should include gene expression studies, epigenetics studies, flow cytometry and CYTOF studies, immunohistochemical studies, mutational load studies, neoantigen studies, and microbiome studies. Sufficient access to longitudinal patient samples will be required to conduct these types of studies.

Combination Therapy

Immune checkpoint therapy has resulted in durable clinical responses, but in only a fraction of patients. On the basis of the encouraging results with monotherapy, combination treatment strategies are being explored extensively.[95]

Because anti-CTLA-4 and anti-PD-1 antibodies have distinct mechanisms of action, preclinical studies evaluated combination treatment with anti-CTLA-4 and anti-PD-1/PD-L1, which demonstrated improved antitumor immune responses.[31,96]

A detailed study in preclinical tumor models demonstrated that treatment with a combination of anti-CTLA-4 and anti-PD-1 antibodies improves antitumor immunity and synergistically eradicates tumors, and this synergy relies on the interdependence between IL-7 and IFNγ signaling in T cells; the lack of either pathway abrogates the therapeutic effects of this combination therapy.[31]

In 2015 the FDA approved the first combination immunotherapy of nivolumab (anti-PD-1) plus ipilimumab (anti-CTLA-4) for patients with previously untreated and unresectable metastatic melanoma.[82,97] Patients receiving this combination had an objective response rate of 50%. Importantly, this combination was effective irrespective of the PD-L1 expression. Several other combination therapies are currently being tested in clinical trials (ClinicalTrials.gov).

Combination treatments with immune checkpoint therapy plus targeted therapy (angiogenesis inhibitors, tyrosine kinase inhibitors, BRAF inhibitors) also hold promise for improved efficacy. A phase I trial (NCT01472081; ClinicalTrials.gov) investigating the combination of nivolumab with sunitinib (a receptor tyrosine-kinase inhibitor) demonstrated tumor regression in patients with metastatic RCC.[98] The safety and efficacy of another tyrosine-kinase inhibitor (lenvatinib) in combination with pembrolizumab (anti-PD-1) are currently being explored in a phase I/II study (ClinicalTrials.gov).

Another interesting combination currently being evaluated is radiotherapy plus immunotherapy. Several studies have demonstrated that radiotherapy supports tumor-specific immunity by enhancing antigen presentation and increasing the vulnerability of tumor cells to T cell–mediated attack.[99,100] Therefore combination therapy with radiation plus immune checkpoint therapy or other immunotherapeutic strategies is warranted.[101] A phase I trial of hypofractionated radiotherapy in combination with MEDI4736 (an anti-PD-L1 antibody) and tremelimumab (anti-CTLA-4) is being tested in patients with metastatic melanoma and lung, breast, and pancreatic cancer (ClinicalTrials.gov).

CONCLUSIONS

Cancer immunotherapy has established itself as a critical pillar in cancer therapy. It has resulted in durable clinical responses in patients whose tumors were refractory to conventional anticancer therapies. Nonetheless, additional research is required to further optimize the existing immunotherapeutic approaches and also to assess new strategies in this emerging field with significant untapped potential. Current challenges include rational development and optimization of combination strategies, identification of biomarkers, and continued support for basic and translational research to provide a greater understanding of mechanisms that drive antitumor immune response. Cancer immunotherapy has made great strides in improving clinical outcomes for some patients, and there is great hope that continued research efforts will enable even more patients to benefit in the future.

MULTIPLE-CHOICE QUESTIONS

1. The immunotherapy regimen associated with the "maximum response" or the most patients with significant reduction in tumor burden based on phase III clinical trials completed to date is ———?
   A. Nivolumab
   B. Ipilimumab
   C. Nivolumab plus ipilimumab
   D. Pembrolizumab

2. A 64-year-old patient was diagnosed with a large 11.5-cm mass in the left kidney. The patient underwent nephrectomy, which revealed a pT3aN0cM0 clear-cell renal cell carcinoma. After 2 years of observation, he was found to have numerous pulmonary metastases. He was treated with sunitinib (Sutent) for 15 months and was later found to have disease progression. His physician is interested in treating him with nivolumab. Which pathway does nivolumab target?
   A. Programmed death 1 (PD-1)/PD-L1
   B. PD-L1/CD80
   C. Inducible T-cell costimulator (ICOS)/ICOS-L
   D. CD68/cytotoxic T lymphocyte antigen-4 (CTLA-4)

3. A 28-year-old female is diagnosed with cutaneous melanoma on her right shoulder. After surgical resection and imaging, she is diagnosed with stage III melanoma. She is interested in receiving adjuvant immune checkpoint therapy to reduce the risk of relapse at 3 years. Which immune checkpoint inhibitor has received US Food and Drug Administration (FDA) approval for this indication?
   A. Nivolumab
   B. Ipilimumab
   C. Atezolizumab
   D. Pembrolizumab

Lymphoid Leukemias

Moshe E. Gatt, Shai Izraeli

Leukemias are a group of hematological malignant clonal diseases arising in bone marrow. This chapter focuses on the two most common lymphoid leukemias: acute lymphoblastic leukemia (ALL) and chronic lymphocytic leukemia (CLL). The immunological aspects of both diseases are extensively discussed, with a special emphasis on the clinical and laboratory features of each disorder.

ACUTE LYMPHOBLASTIC LEUKEMIA

ALL manifests with the clonal proliferation and accumulation of malignant lymphoid progenitors. ALL is a developmental disease. Most childhood ALLs arise as a "developmental accident" during normal fetal lymphopoiesis. Studies of chromosomal translocations in ALL cells have identified key genes involved in normal lymphopoiesis and hematopoiesis. Conversely, basic studies of the development of the immune system and the immune receptors have provided important tools for the diagnosis and management of ALL. These achievements in basic and clinical research have led to the remarkable transformation of ALL from a uniformly fatal disorder to a disease that is curable in more than 80% of children.[1] Adults, however, have not fared as well.

Epidemiology and Etiology

ALL is the most common malignancy of childhood. One of every 2000 children will develop leukemia by 15 years of age. In contrast, ALL accounts for <20% of leukemias in adults. In developed countries, incidence peaks at 2–5 years of age. This low age at peak of incidence is characteristic of affluent societies.[2]

Most ALLs are sporadic. Less than 5% are associated with hereditary or constitutional syndromes. Children with Down syndrome have an approximately 20-fold increased risk of developing ALL. Other diseases associated with increased risk include inherited genomic instability syndromes, such as ataxia–telangiectasia, Bloom syndrome, and Li-Fraumeni syndrome. Conversely, ALL is more common in patients with congenital B-cell immune deficiencies (Chapter 34). These include X-linked agammaglobulinemia (XLA), selective immunoglobulin A (IgA) deficiency, and common variable immunodeficiency (CVID). Interestingly, some cases of CVID associated with leukemia have been recently shown to be caused by germline mutations in *IKZF1,* which encodes the lymphoid transcription factor Ikaros.[3] Germline mutations in additional hematopoietic and B-cell developmental genes, such as *ETV6,*[4], *RUNX1,*[5] and *PAX5,*[6] also predispose to ALL.

Although ALL is not hereditary, there is a markedly increased risk of leukemias in identical twins, and studies in these twins have shed light on the etiology of childhood ALL. This phenomenon has promoted the hypothesis that at least two genetic hits are required for the development of ALL[2] (Fig. 78.1). The first occurs during fetal lymphopoiesis, most likely because of a "developmental accident" of the V(D)J recombination machinery, and results in clonal proliferation of a preleukemic clone. Intrauterine metastasis of this clone from one twin to the other via their shared placental circulation is responsible for the concordant leukemia. Additional genetic hits in the preleukemic cells occur after birth and are required for the development of full-blown leukemia. The initial findings in identical twins with leukemia have been extended to sporadic ALL. In at least 70% of the patients, the preleukemic clone can be detected molecularly in the neonatal blood samples collected after birth (known as *Guthrie cards*). More recently, careful molecular analysis of the cord blood of normal infants has demonstrated that the occurrence of a preleukemic clone carrying a leukemia-defining chromosomal translocation might be common. However, only 1% of children born with such a preleukemic clone will develop leukemia, implying the impracticality of molecular screen for early diagnosis of childhood ALL.

KEY CONCEPTS

Environmental Factors in the Epidemiology of Childhood Acute Lymphoblastic Leukemia (ALL): Roles for Infection and Immunity?

"Common" B-cell precursor ALL at the preschool age is the most common type of ALL in the suburban regions of affluent countries. The causes for this phenomenon are unknown. A popular hypothesis suggests a modified immune response to delayed infections during infancy.

The causes of the relatively rare postnatal leukemogenic genetic hits are unknown. As the risk of B-cell precursor ALL during early childhood is markedly increased by higher socioeconomic status and a suburban style of living in which the exposure of children to infectious pathogens is typically delayed beyond the neonatal period, Greaves hypothesized that many childhood cases are the consequence of an abnormally late immunological response to common infections.[2] One proposed mechanism is that growth inhibitory factors, such as interferon (IFN) or transforming growth factor-β (TGF-β), secreted during this immune response provide a survival advantage to a preleukemic clone setting the stage for additional leukemogenic mutations. Recently a more direct suggestion for the involvement of infection (or the response to infection) in the pathogenesis of ALL has been provided. Pax5 heterozygous mice developed preB-cell ALL only after exposure to common mouse pathogens.[7]

Immunological and Molecular Classification of ALL

Immunological Classification

ALL subtypes are typically identified by their immunophenotype. They are positioned by the lymphoid developmental stage at which the leukemic cell appears to have been arrested (Table 78.1).

B-Cell Precursor Leukemias

B-cell precursor ALLs are the most common childhood leukemias. **ProB-cell ALL** is characterized by expression of CD19 and CD34 without CD10. This is the most common leukemia of infants that contains rearrangements of the *MLL*(*KMT2A*) gene on chromosome 11q23. It is associated with a poor outcome.

Leukemic blast cells of **early preB-cell ALL** resemble normal B-lymphoid cell precursors. They express CD19, CD22, and CD79a. CD10 and terminal deoxynucleotidyl transferase (TdT) are detectable in 90% of cases. CD34 is detected in >75% of cases. Early preB-cell ALL is the most prevalent type of ALL and is thus often called "common ALL" (cALL).

In **preB-cell ALL** lymphoblasts accumulate cytoplasmic immunoglobulin (Ig) heavy chains but have no detectable surface Igs. This subtype also expresses CD19, CD22, and CD79a. It often contains a translocation that fuses the *E2A*(*TCF3*) gene on chromosome 19 with the *PBX1* gene on chromosome 1.

Leukemic cells that express both cytoplasmic and surface Ig heavy chains have been designated **transitional preB-cell ALL**. The surface μ chains on these leukemic cells are noncovalently associated with surrogate light chain (VpreB λ5[λ14.1]), CD79a, and CD79b.

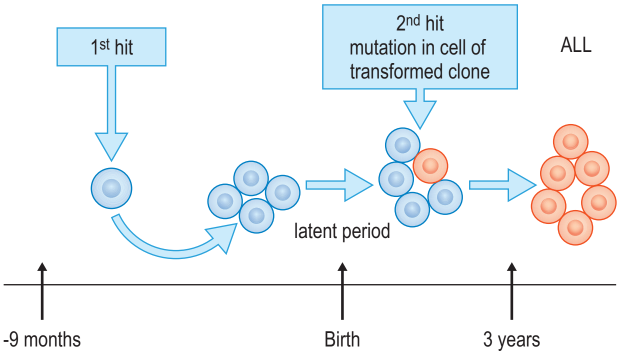

FIG 78.1 A Model for the Development of Childhood Acute Lymphoblastic Leukemia (ALL). The first acquired genomic hit (*e.g.,* chromosomal translocation or change in chromosomal copy number) occurs during fetal hematopoiesis and results in clonal proliferation of a preleukemic clone. This event is common, occurring in up to one in every 20 children. Additional genetic aberrations occurring after birth are required for the development of ALL. These events are rare and estimated to occur in about 1% of children born with a preleukemic clone.[5]

CLINICAL PEARLS

Mature Versus Precursor B-Cell Acute Lymphoblastic Leukemia (ALL)

Since the treatment of mature B-cell leukemia (the leukemic form of Burkitt lymphoma) is vastly different from the treatment of B-cell precursor ALL, it is critical to distinguish between the two. Burkitt leukemia is characterized by mature B-cell phenotype and by the presence of chromosomal translocations involving the *cMyc* gene (Chapter 79).

Mature B-cell ALL is the leukemic form of Burkitt lymphoma (Chapter 79). As treatment is dramatically different from that for B-cell precursor ALL, this subtype must be specifically ruled out as part of the immunophenotypic evaluation of ALL. Mature B-cell ALL cells express surface Ig μ heavy chains in association with either κ or λ light chains. In most cases, cells have L3 morphology and express CD19, CD22, and CD20. CD10 and CD23 are frequently expressed, whereas CD34 is absent.

T-Cell ALL

T-cell ALL is more prevalent in less affluent countries, which is likely a reflection of a lower incidence of the common B-lineage early childhood peak. In affluent countries, T-cell ALL occurs in 10–15% of children with ALL. It is also more common in adults. In many treatment protocols, T-cell ALL is considered to have a less favorable prognosis compared with B-cell precursor ALL.

In T-cell ALL, the cells express surface CD7 and cytoplasmic CD3 (cCD3) antigens. More than 90% of the T lymphoblasts express CD2, CD5, and TdT. Three stages of immunophenotypic differentiation can be determined: early ($CD7^+$, $cCD3^+$, surface $CD3^-$, $CD4^-$, and $CD8^-$), intermediate ($cCD3^+$, surface $CD3^-$, $CD4^+$, $CD8^+$, and $CD1^+$), and late (surface $CD3^+$, $CD1^-$, and either $CD4^+$ or $CD8^+$). However, immunophenotype does not conform to any of these maturation stages in as many as 25% of T-lineage ALL cases. T-cell receptor (TCR) proteins are heterogeneously expressed in T-lineage ALL. In approximately two-thirds of cases, membrane CD3 and TCR proteins are absent.

TABLE 78.1 Immunophenotypic Classification of Acute Lymphoblastic Leukemia (ALL)

	LEUKOCYTE ANTIGEN EXPRESSION (% OF CASES POSITIVE)									FREQUENCY (%)	
Subtype	**CD19**	**cCD22**	**CD79a**	**CD10**	**CD7**	**CD2**	**cCD3**	**cIg μ**	**sIg μ**	**sIg κ/λ**	**Children**	**Adults**
Pre-preB	100	>95[a]	>95	0	0	0	0	0	0	0	5	10
Early preB	100	>95[a]	>95	95	5	<5	0	0	0	0	60–65	50–55
PreB	100	100[a]	100	>95	0	0	0	100	0	0	20–25	10
Transitional preB	100	100[a]	100	50	0	0	0	100	100	0	1–3	?
B	100	100[a]	100	50	0	0	0	>95	>95	>95	2–3	4

T	<5	0	0–20	45	100	95	100[a]	0	0	0	10–15	15–20

c, cytoplasmic; cIg μ, cytoplasmic immunoglobulin μ chain; sIg μ, surface immunoglobulin μ chain; sIg κ/λ, surface immunoglobulin κ or λ chains.

[a] Detectable on the cell-surface membrane in some cases.

TABLE 78.2 Frequencies of Major, Clinically Important Genetic Aberrations in Childhood and Adult Acute Lymphoblastic Leukemia (ALL)

Genetic Aberration	Children	Adults
B-Cell Lineage		
Hyperdiploidy (>50 Chromosomes)	30%	9%
Hypodiploid (<45 chromosomes)	1%	2%
Amplified 21q	2%	2%
TEL-AML1 (t12;21)	25%	3%
MLL rearrangements	9%	13%
BCR-ABL	4%	33%
E2A-PBX1	5%	4%
"Ph like" including CRLF2	8%	25%
MYC rearrangements	2%	5%
T-Cell Lineage		
Notch1 mutations	60%	70%
TAL1 (SCL) cluster	58%	33%
HOX11 (TLX1) cluster	3%	33%
HOX11L2 (TLX3) cluster	20%	5%
LYL1 cluster	12%	37%
MLL-ENL	2%	2%
NUP214-ABL	6% (?)	

In half these cases, however, TCR proteins (TCRβ, TCRαα, or both) are present in the cytoplasm. When membrane CD3 and TCR chains are expressed, the αβ form of the TCR predominates. Only a minority of cases express TCR γδ proteins.

The expression of myeloid-associated antigens, such as CD13, CD15, CD33, or CD65, in leukemic lymphoblasts confounded leukemia classification in early studies. However, the diagnosis of B-lineage ALL should be made when leukemic cells express cytoplasmic Ig, CD79a, or CD19 plus CD22, regardless of myeloid-associated antigen expression. Likewise, the diagnosis of T-lineage ALL should be made when leukemic cells express CD7 plus either surface or cytoplasmic CD3. An immature immunophenotype of T-cell ALL, early T phenotype (ETP) ALL, has been described and is similar to normal ETP precursors.[8] True biphenotypic leukemias usually coexpress B- or T-cell markers with cytoplasmic myeloperoxidase.[9]

Genetic and Molecular Classification

Virtually every leukemic cell contains acquired alterations in multiple genes. These alterations often manifest gross numerical or structural aberrations that frequently define a specific clinical subtype of ALL. Common and/or clinically significant genetic aberrations typically found in ALL are summarized in Table 78.2.

Numerical Chromosomal Aberrations

Deviation from the normal chromosomal modal number is called *aneuploidy* and is the most common chromosomal aberration in cancer. **High hyperdiploid ALL** (Fig. 78.2A), containing 50–60 chromosomes, is the most common type of B-lineage ALL in children and is associated with about 90% cure rate. There is typically an excess of specific chromosomes, most commonly chromosomes 6, 10, 14, 17, 18, 21, and X. **Hypodiploid ALL** (see Fig. 78.2B), containing <45 chromosomes, is much rarer and associated with a very poor prognosis.

Chromosomal Translocations

Chromosomal translocations can be divided into two general subtypes. The first involves translocation of a gene into the proximity of a strong regulatory region. This often results in the marked overexpression of the oncogene. Often these translocations are mediated by the V(D)J recombination machinery (Chapter 4) and can be therefore viewed as an unfortunate developmental "accident" caused by the physiological lymphocyte specific genomic instability. Examples include the activation of the *MYC* oncogene by t(8;14) in Burkitt lymphoma and of the *SCL* (*TAL1*) gene by t(1;14) or by rearrangement with the *STIL* gene on chromosome 1p32 in T-cell ALL. The second involves creation of novel fusion proteins consisting of parts of the genes that participate in the chromosomal translocation. For example t(12;21) fuses the *TEL* (*ETV6*) gene on chromosome 12 with the *AML1* (*RUNX1*) gene on chromosome 21.

Amplifications and Deletions

Amplifications and deletions of small chromosomal regions are another type of structural aberration that is often detected in leukemias. For example, deletions of the INK4A locus or of PAX5 are commonly detected in T- and B-cell precursor ALLs, respectively.

Oncogenic-Activating Mutations

Oncogenic-activating mutations in ALL are reported with an increasing frequency. The Notch pathway, for example, is normally involved in T-cell development. This pathway is activated by acquired mutations in >60% of T-cell ALL.

Genes Involved in Leukemogenesis Often Play Key Roles in Normal Development

Many of the genes modified by chromosomal translocations, amplification, deletions, or point mutations are active during normal lymphoid or hematopoietic development (Table 78.3). The acquired aberrations promote malignant transformation by either overexpression or dysregulated expression (in the wrong cell or in the wrong developmental stage) of the developmental gene.

A recent discovery involving the IL7Rα serves as an example. Loss of function mutations in this receptor causes $T^-B^+NK^+$ severe combined immunodeficiency (Chapter 35). Activating mutations are found in 10% of T-cell ALL.[10] An example involving both misexpression and activation of an immune receptor is the aberrant activation of the receptor to thymic stromal lymphopoietin (TSLP). This receptor, created by heterodimerization of IL7Rα and CRLF2, is normally expressed in dendritic cells (DCs) and some CD4 T cells. It is involved in allergy and inflammation. Activation of this receptor in B-lineage ALL is multistaged. First, chromosomal rearrangements cause the misexpression of CRLF2 in a B-cell precursor. This is followed by activating mutations in the TSLP receptor components—CRLF2, IL7Rα, or the downstream signaling enzymes JAK2 or JAK1.[10] The aberrant expression and activation of the TSLP receptor occurs in 10% of sporadic B-cell ALLs and in 50% of Down syndrome ALLs. It is associated with a poor prognosis. It may also be amenable to targeted therapy. Conversely, the acquired genetic aberration may block the normal developmental function of the involved gene(s). A good example is the genomic deletions or inactivating mutations in B-cell differentiation genes, such as *PAX5*, *EBF*, or *IKZF1*, detected in about 50% of B-lineage ALLs.

TABLE 78.3 Example of Hematopoietic Genes Involved in the Pathogenesis of Leukemia

Gene(s) Names	Normal Hematopoietic Development	Leukemic Involvement
SCL (TAL1)	Hemangioblast specification Erythropoiesis and megakaryopoiesis	T-ALL
LMO1/2	Similar to SCL	T-cell ALL
NOTCH1	T lymphocytes	T-cell ALL
HOX11	Spleen	T-cell ALL
E2A	T and B lymphocytes	BCP-ALL
PAX5	B lymphocytes	BCP-ALL, B-NHL
SLP-65	B lymphocytes	BCP-ALL
TEL	Bone marrow hematopoietic stem cells	BCP-ALL, T-cell ALL rarely myeloid malignancies
RUNX1 (AML1, CBFA2)	Definite hematopoiesis Megakaryopoiesis and T lymphocytes	BCP-ALL, AML (M0-M1) Hereditary FPD/AML
CBFB	Same as RUNX1	AML (M4e)
C/EBP 1-3	Myeloid cells	AML (M1, M2)
PU.1	Myeloid and lymphoid stem cells	AML
GATA1	Erythropoiesis, megakaryopoiesis, and mast cells	AML (M7) associated with trisomy 21
FLT3	Hematopoiesis and lymphopoiesis	AML and ALL
MLL	Hematopoiesis stem cells	AML and ALL
IL7R	T lymphocytes	ALL

Major, Clinically Relevant, Molecular Subtypes of ALL

(See Table 78.2.)

B-Lineage ALL

Hyperdiploid ALL and ALL cells *TEL/AML1* gene translocation comprise the majority of "common ALL" leukemias that occur typically in young children and rarely in adults. Both are associated with an extremely good prognosis. In contrast, the much less common hypodiploidy (<45 chromosomes) and the internal amplification of chromosome 21q (iAMP 21q) are associated with a poor prognosis.

Another aberration with a poor prognosis is the BCRF-ABL fusion protein created by the t(9;22) "Philadelphia chromosome." Its frequency is low in children (3–5%) and much higher in adults (at least 30%). The prognosis dramatically improved by treatment with BCR–ABL1 inhibitors.

The *MLL(KMT2A)* gene located on chromosome 11q23 is involved in fusion translocations with >80 different partner genes. The most common translocation in ALL fuses the *MLL* with the *AF4* gene on chromosome 4. It is characteristic of infant leukemia and is associated with a poor prognosis.

The clinical significance of the E2A (TCF3)-PBX1 fusion protein caused by t(1;19) translocation, occurring in <5% of childhood ALL, has greatly improved by more intensive chemotherapy. The change in the prognostic significance of this particular translocation with improved therapy exemplifies the general principle that the prognostic impact of a clinical or biological parameter is highly dependent on the specific treatment protocol. E2A-PBX1 ALLs also represents a subtype of ALL with activation of signaling downstream to the preB-cell receptor (pre-BCR). Recent therapies with BCR signaling inhibitors effective in CLL or lymphomas may prove useful for pre-BCR ALLs.[11] The *E2A* gene is rarely fused with the *HLF* gene in the t(17;19) translocation. This is an extremely rare translocation that is associated with diffuse intravascular coagulation (DIC), hypercalcemia, and an extremely poor prognosis.[12]

Several genetic lesions have prognostic significance and may be included in risk stratification in future treatment protocols. Examples are deletions of Ikaros (IKZF1) and CRLF2 aberrations. A novel subgroup of ALLs has been termed "Philadelphia-like ALL" because of gene expression that is similar to BCR-ABL. It is generally associated with markedly poor prognosis.[13,14] These leukemias are characterized by activation of either the ABL or the JAK kinase pathway and are caused by many types of fusion genes or aberrant expressed receptors. Their proper diagnosis is important because of the potential therapeutic activity of either ABL or JAK inhibitors.

T-Lineage ALL

Although multiple genetic and molecular subtypes of T-cell ALL have been recently described, their clinical significance is presently unclear, except for the bad prognosis of ETP ALL.[8] Most of the genetic aberrations in T-cell ALL results in the abnormal expression of transcription factors. Examples include SCL (TAL1), which forms a complex with LMO1 or LMO2, HOX11L2 (TLX3) or HOX11 (TLX1), LYL1, and MYB. Other abnormalities include MLL–ENL fusion and amplification of the ABL oncogene. Cooperating mutations are activating mutations in NOTCH1 or interleukin-7R (IL-7R) and inactivating mutations in the E3 ligase FBW7 or the phosphatase PTEN.

Clinical Features

The clinical signs and symptoms relate to the replacement of bone marrow cells by leukemic blasts and to the infiltration of extramedullary sites. Pallor, fatigue, petechiae, bleeding, or fever may be caused by the pancytopenia. Bone pain and arthralgias, the onset of a limp and refusal to walk, and even frank arthritis are not uncommon. The musculoskeletal symptoms may be confused with osteomyelitis or juvenile rheumatoid arthritis, which may delay the diagnosis. Uncommonly, central nervous system (CNS) involvement may present as signs and symptoms of increased intracranial pressure, such as headaches and papilledema; or as cranial nerve palsies, nuchal rigidity, and rarely hyperphagia and obesity caused by infiltration of the hypothalamus. Overt testicular leukemia manifests as painless testicular enlargement. Mediastinal involvement, common in T-cell ALL, may cause dyspnea and superior vena cava syndrome.

Clinical laboratory findings often include anemia and thrombocytopenia. Approximately 20% of children present with leukocyte counts >50 000/µL. Importantly, approximately 40% of children have leukocyte counts of <10 000/µL, and leukemic blasts may or may not be seen on peripheral smears. Therefore the diagnosis of leukemia may occasionally be missed in routine automated blood count. Elevated serum lactate dehydrogenase activity and uric acid and phosphorous concentrations are common in patients with a large leukemic cell burden.

The diagnosis of ALL is established by bone marrow examination. The normal bone marrow contains <5% blasts. A minimum of 25% lymphoblasts on differential examination of the bone marrow aspirate is necessary for the diagnosis of ALL. Most children with ALL have a hypercellular marrow with blasts constituting 60–100% of the nucleated cells.

Traditionally, CNS leukemia has been defined as the presence of at least five leukocytes per microliter of cerebrospinal fluid (CSF) and the detection of leukemic blast cells, by the presence of cranial nerve palsy, or by retinal involvement, as detected by ophthalmoscopy. Although overt CNS leukemia is relatively rare, submicroscopic CNS involvement is present at diagnosis in at least half the patients in the absence of any neurological symptoms. Thus CNS-directed therapy is routinely included in ALL therapy.

The differential diagnosis of ALL includes neoplastic and nonneoplastic diseases. Because children with ALL present with a variety of nonspecific symptoms, several pediatric nonmalignant conditions may be confused with leukemia. Since treatment with steroids may mask the presence of ALL, serious consideration of the diagnosis of ALL must be given before starting treatment with steroids to any pediatric nonmalignant disorder. Bone marrow examination is recommended in case of uncertainty.

Idiopathic thrombocytopenic purpura (ITP) is a common cause of bruising and petechiae in children. ITP is characterized by the absence of any other hematological abnormalities. Bone marrow should be examined if anemia or hepatosplenomegaly are present.

Infectious mononucleosis may present with fever, malaise, adenopathy, splenomegaly, rash, and lymphocytosis. The atypical lymphocytes may morphologically resemble the leukemic lymphoblasts. Rarely, flow cytometry may be necessary to distinguish between the activated atypical lymphocytes and the immature leukemic lymphoblasts.

Leukemoid reactions, observed in sepsis, acute hemolysis, and other disorders, are usually easy to distinguish from ALL by morphological examination of peripheral blood smear. Since occasionally ALL presents with pancytopenia, aplastic anemia is also on the differential diagnosis list.

CLINICAL PEARLS

Acute Lymphoblastic Leukemia (ALL) and Rheumatoid Disorders

- ALL can mimic juvenile idiopathic arthritis (JIA; Chapter 53) and other musculoskeletal disorders.
- Because leukemic blasts may be absent from the peripheral blood, bone marrow examination should be considered in any child with JIA, especially prior to commencing steroid therapy.

As many as 10% of children with ALL are first evaluated at pediatric rheumatology clinics. Fever, arthralgias, arthritis, or a limp accompanied by anemia, mild splenomegaly, and lymphadenopathy frequently can be confused with juvenile idiopathic arthritis (Chapter 53) or osteomyelitis. These patients may be treated with antibiotics and antiinflammatory agents for several weeks to months before the diagnosis of ALL is finally made. Bone marrow examination should be seriously considered in such patients.

As leukemic lymphoblasts are seen as small round blue cells when stained with hematoxylin and eosin, they may be rarely be confused with metastatic small round cell pediatric tumors, including neuroblastoma, rhabdomyosarcoma, and retinoblastoma.

Special Diagnostic Tests

The classification and the risk stratification for treatment protocols of ALL is based on detailed immunophenotyping and genotyping analysis.[15] In most centers, karyotype by classic cytogenetics (see Fig. 78.2) is performed. However, because of the lack of metaphases, the yield of karyotypic analysis of ALL in multicenter protocols is often <70%. Furthermore, normal karyotypes are sometimes derived from the normal cells in bone marrow rather than the leukemia blasts. This drawback can be overcome by interphase fluorescent in-situ hybridization (FISH), a technique that does not require metaphases. All clinically relevant structural and numerical chromosomal aberrations can be detected with the use of commercially available FISH probes (Fig. 78.3). Fusion translocations, such as *BCR–ABL*, *TEL–AML1*, and *MLL–AF4*, can all be detected by using reverse transcription–polymerase chain reaction (RT-PCR).

The elucidation of the human genome and the invention of the genomic technologies are in the process of revolutionizing the diagnostics of leukemias. New methodologies of next-generation genome sequencing (NGS) are likely to transform both our understanding of leukemia biology and the diagnostic approach. Routine use of NGS mutation panels and copy number genomic arrays are likely to replace routine cytogenetic analysis in the near future.

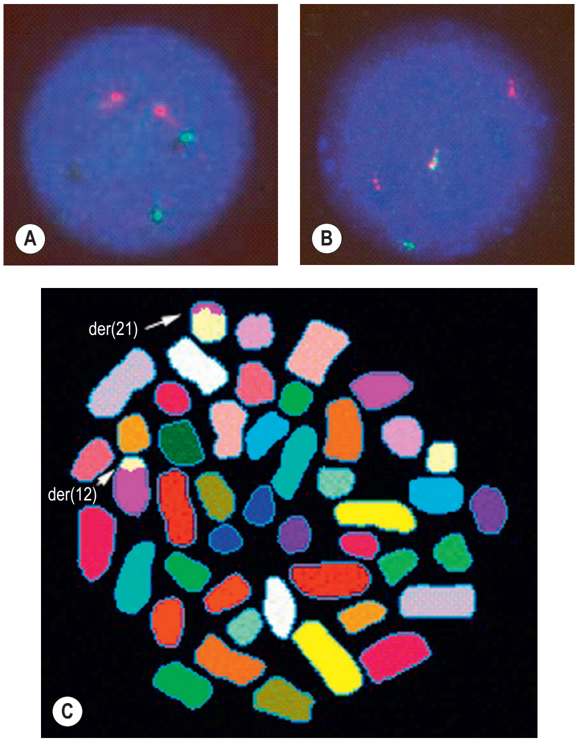

FIG 78.3 Molecular Cytogenetic Techniques for the Diagnosis of Chromosomal Translocations in Acute Lymphoblastic Leukemia (ALL). (A) and (B) display interphase fluorescent in-situ hybridization (FISH) with probes to the *AML1* (*RUNX1*) gene on chromosome 21 (red) and to the *TEL* (*ETV6*) gene on chromosome 12 *(green)*. (A) displays a normal cell, (B) displays a leukemic cell that has undergone a fusion TEL-AML1 translocation *(arrow)*, and (C) displays the same translocation as depicted in B, but on metaphase chromosomes. It uses a molecular cytogenetic technique called spectral karyotyping *(arrows)*. Classic cytogenetic analysis often misses this translocation. (Courtesy of Dr. L. Trakhtenbrot.)

Principles of Therapy[1]

Supportive therapy is given before the initiation of leukemia specific therapy. This includes hydration, treatment, and preventive therapy of hyperuricemia; blood and platelet transfusion; and treatment of emergencies, such as respiratory insufficiency associated with mediastinal leukemia. It is highly recommended that children and adults with ALL be treated in specialized centers as a part of clinical prospective studies. Such clinical trials have led to the dramatic improvement in the outcome of patients with ALL achieved over the last several decades.

Typical remission induction regimens include a glucocorticoid (prednisone, prednisolone, or dexamethasone), vincristine, l-asparaginase, and, in many protocols, anthracycline. The rate of complete remission now ranges from 97% to 99% in children and from 75% to 90% in adults. Intensification therapy uses either high doses of multiple agents not used during the induction phase or repeats the induction regimen. Regimens used for children include high-dose methotrexate with or without 6-mercaptopurine; high-dose l-asparaginase given for an extended period; an epipodophyllotoxin plus cytarabine; or a combination of dexamethasone, vincristine, l-asparaginase, doxorubicin, and thioguanine, with or without cyclophosphamide. Another integral component of many protocols is reinduction therapy. This treatment employs drugs similar to those used during the initial phase of induction therapy and has improved the outcomes of both children and adults with ALL. Maintenance therapy consist a combination of methotrexate administered weekly and mercaptopurine administered daily. Some protocols add intermittent pulses of vincristine and dexamethasone.

CNS prophylactic therapy consisting of cranial irradiation plus intrathecal chemotherapy, introduced after the induction of complete remission, became one of the cornerstones of ALL therapy in the 1970s. More recently, because of concerns about neurotoxicity and the occurrence of brain tumors, intensive intrathecal and systemic chemotherapy are used instead for most patients.

Allogeneic stem cell transplantation (SCT) is reserved for relapsed or refractory leukemia and for patients with a very-high-risk leukemia that is likely to demonstrate a slow response to therapy. With modern therapy, including targeted therapy with imatinib for BCR–ABL, there is almost no indication for SCT in first remission. With improvements in the prevention of transplant-related toxicities, suitable marrow donors are not only human leukocyte antigen (HLA)–identical siblings or single-antigen mismatched family members but also matched unrelated donors and, in some situations, two- and three-antigen mismatched family members.

Prognostic Factors

Modern therapy for ALL is based on adjustment of the intensity of therapy to the risk assessment of the relapse hazard (Table 78.4). The two major clinical parameters of prognostic significance are age at diagnosis and leukocyte count. A presenting age between 1 and 9 years and a leukocyte count $<50 \times 10^9$/L are favorable prognostic factors. In adults, the outcome of therapy worsens with increasing age and leukocyte count. Patients >60 years of age and/or a leukocyte counts $>100 \times 10^9$/L have a particularly poor response to treatment. Females fare somewhat better compared with males. The prognostic significance of the major genetic aberrations has been described above.

TABLE 78.4 Major Prognostic Factors in Acute Lymphoblastic Leukemia (ALL)[a]

Prognostic Factor	Good Prognosis	Worse Prognosis
Age at diagnosis	Age 1 year to <10 years (children)	<1 year; >10 year (children) >60 years (adult)
Peripheral blood WBC	<50 000 cells/μL	>100 000 cells/μL
Response to therapy	Early response to therapy Negative MRD at the end of induction	Slow response to therapy. High MRD
Genetic abnormalities	Hyperdiploidy (>50 chr.); *TEL/AML1 (ETV6/RUNX1)*	*BCR/ABL MLL/AF4* Hypodiploidy <45 chr.

[a] The most important prognostic factor is the *treatment protocol*. Thus the prognostic significance of various clinical and laboratory variables may differ between protocols. Here, the significant parameters common to most studies are listed.
WBC, white blood cells; MRD, minimal residual disease; chr., chromosomes.

The most significant prognostic factor is the initial response to therapy. A rapid clearance of leukemic cells from blood or bone marrow confers a favorable prognosis. More recently, the level of minimal residual disease after the induction of clinical remission has emerged as a powerful tool for gauging treatment response and predicting outcome.

Where Immunology Meets Oncology—Minimal Residual Disease

Modern treatment protocols have led to morphological complete remission in the majority of patients, which is defined as <5% blasts in bone marrow examination. If treatment is discontinued at that stage, in most patients the disease will eventually relapse. Indeed, all prospective clinical studies have shown that ALL should be treated for at least 2 years. These facts indicate that at the completion of remission induction not all clonogenic malignant lymphoblasts have been destroyed, even though most of the patients are in clinical and morphological remission. Indeed, by this criterion, patients may have as many as 10^{10} undetectable neoplastic cells when in remission. Since, by definition, leukemic cells must constitute at least 1–5% of the nucleated cells in bone marrow to be detected by microscopic examination, morphological examination is clearly inadequate for evaluation of the quality of remission in patients with ALL. Therefore more sensitive techniques for the detection of rare leukemic cells are required. This is the rationale behind the recent incorporation of modern techniques of detection of minimal residual disease (MRD) into treatment protocols of childhood ALL.

During the last 2 decades, two general methodologies have been developed for the sensitive detection of submicroscopic residual leukemic cells. These methodologies could not have been developed without elucidation of the scientific basis of the developmental phenotype of immune cells (Chapters 7 and 8) and of the elaborate process of Ig gene rearrangements (Chapter 4).

The most widely studied DNA-based MRD methodology is based on the identification of clonospecific rearrangements of Ig genes or TCRs (Ig/TCR-PCR).[16] This approach exploits the physiological process of somatic rearrangement of Ig and TCR gene loci that occur during the early differentiation of B cells and T cells. Thus any single T or B lymphocyte carries a unique rearrangement that is not shared by any other lymphoid cell.

Since leukemia is clonal (*i.e.*, it originates from one lymphoid cell), all of the leukemic cells of a particular person carry the same Ig and/or TCR rearrangements. Because leukemic cells are genetically unstable, they often (>90% of the cases) carry multiple rearrangements, a fact that facilitates the usefulness of using these rearrangements as a clonal marker for MRD detection. The major advantages of this technique are the exquisite sensitivity (at least 10^{-5}), reliability, reproducibility, and its applicability to >90% of children with ALL. The application of NGS techniques is likely to lower the costs and complexity of this approach.

Current strategies for flow cytometric detection of MRD rely on combinations of leukocyte markers that do not normally occur in cells of the peripheral blood and bone marrow. Such leukemia-associated phenotypes can be identified by multiple color staining techniques (Fig. 78.4). Flow cytometric analysis of these immunophenotypes allows the detection of one leukemic cell among 10^{-4} or more normal cells. The advantages of flow cytometry for MRD detection are adequate sensitivity, and the presence of immunophenotyping facilities in most major centers that facilitate timely performance of the analysis on fresh cells at a reasonable cost. There are, however, a few disadvantages. It requires a flow cytometry operator with a high level of expertise, and it is more difficult to standardize compared with PCR. It may be difficult to distinguish between regenerating B-cell progenitors and leukemic blasts. Thus flow MRD is most reliable and sensitive at very early stages (up to 4 weeks) of therapy.

Many clinical studies of patients enrolled on ALL treatment protocols have revealed strikingly similar results. Fast clearance of leukemic blasts to below 10^{-4} cells within the first 2–4 weeks of therapy is detected in ≈40% of children with ALL and is associated with an extremely good prognosis. Conversely, the presence of >0.1% blasts after 2 or 3 months of therapy defines a very-high-risk group. These initial findings have led the BFM-AEIOP study group to initiate a prospective study on children with ALL that utilize the MRD level determined by Ig/TCR-PCR for risk classification. This study, which involved 3184 patients, confirmed the strength of PCR MRD over genetic classification as a prognostic marker.[17] At present, MRD studies have been incorporated into most treatment protocols. Patients with high MRD are stratified into a high-risk arm and receive more intensive chemotherapy.

Course and Prognosis

With current protocols, the cure rate of children with ALL is ≈80%. More than 90% of the children with low-risk leukemia and ≈70% of those with high-risk leukemia are cured. The cure rate for adults is significantly lower.

Most relapses occur during treatment or within the first 2 years after completion of therapy. However, late relapses (even 10 years after diagnosis) are increasingly seen. The clinical relapse can occur in an extramedullary site, most often the CNS and the testes. Leukemic relapse occasionally occurs at other sites, including the eye, ear, ovary, uterus, bone, muscle, tonsil, kidney, mediastinum, pleura, and paranasal sinuses. The prognosis of relapse depends on the time from diagnosis (earlier is worse), leukocyte count, immunophenotype, and genotype (similar to

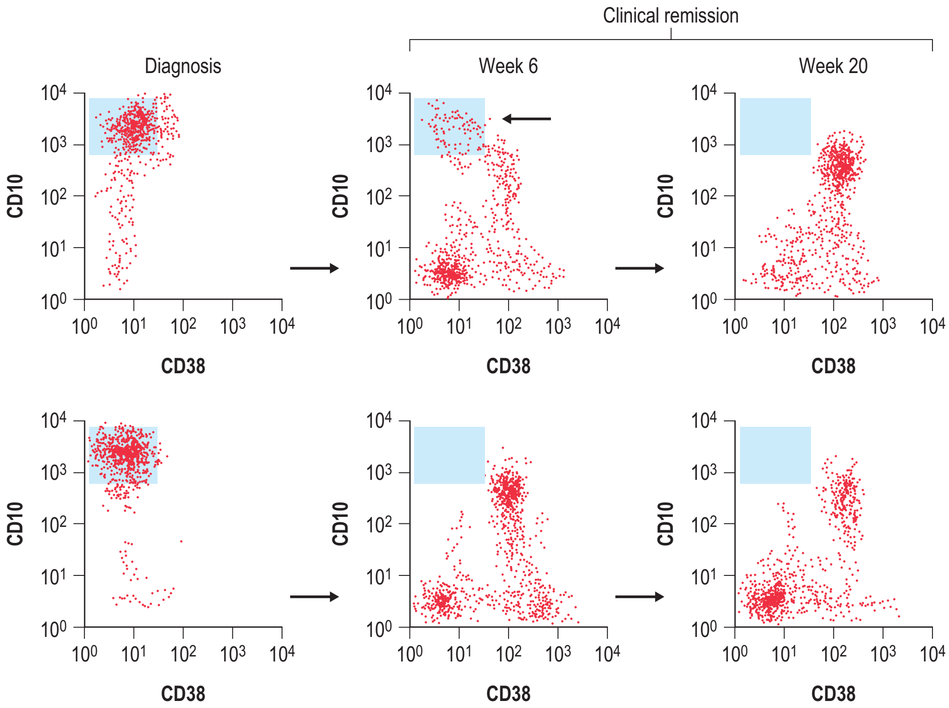

FIG 78.4 Different Kinetics of Leukemia Cytoreduction Revealed by Minimal Residual Disease (MRD) Studies With Flow Cytometry. The left panels illustrate the leukemia-specific immunophenotype ($CD10^+$, $CD38^-$) determined at diagnosis in two children with ALL. This phenotype is not found in normal bone marrow. Bone marrow samples were collected during clinical remission from both patients. In one patient *(top panels),* 0.04% of mononuclear cells expressed the leukemia-specific phenotype at week 6. MRD was undetectable by week 20. In the other patient *(bottom panels),* a profound remission (MRD <0.01%) was achieved by week 6 and maintained at week 20.

the prognostic factors at diagnosis). Isolated extramedullary relapse carries a better prognosis. Although some relapses can be treated with chemotherapy only, most are being treated with SCT. The most important prognostic factor that has emerged is the MRD level before transplantation. More than half the late relapses in patients with "good prognosis" ALL are curable. The prognosis of early relapses and relapsed T-cell ALL is grim.

Treatment Sequelae

In the 1990s, improvements in supportive care reduced the rate of early death to <2%. However, the death rate among older patients during remission induction therapy remains as high as 30% because of hematological, hepatic, and cardiac toxicities.

Long-term toxicity is of major concern for children cured from ALL. Aseptic necrosis of various bones has emerged as a common late toxicity of glucocorticoids, especially in adolescent girls treated with dexamethasone. The rate of long-term neurotoxicity has been reduced as a result of replacement of cranial irradiation with high-dose and intrathecal methotrexate. However intensive methotrexate therapy can also have late neurodegeneration effects. The dose of anthracyclines used in most ALL protocols is unlikely to produce severe cardiomyopathy.

Secondary cancers are a major concern. The development of therapy-related acute myeloid leukemia (AML) has been linked to the use of topoisomerase II inhibitors (teniposide and etoposide), and the risk is apparently dependent on the treatment schedule and the concomitant use of other agents. Children who received cranial irradiation at 6 years of age or younger are most susceptible to the development of brain tumors.

Long-term follow-up studies reported from Scandinavia of children cured of ALL confirm excellent long-term outcomes, as judged by their socioeducational achievements and by reproductive success resulting in healthy offspring.[18]

Current Controversies and Future Perspectives

The high cure rates in patients with ALL (nearly 90% of children and 50% of adults) attest to the steady progress that has been made in treating this disease. A further increase in cure rates will require efforts to maximize the efficacy and minimize the toxicity of current therapy. Currently MRD measurement can reliably identify the extremely good-risk and extremely poor-risk patients. However, about half the patients belong to an "intermediate risk" group in which most of the relapses occur. Optimization of diagnosis and treatment of this group of patients is one of the current major challenges.

Advanced genomic technologies carry the promise of discovering the full spectrum of leukemogenic pathways and the identification of targets for new therapies. Genomic analysis has also discovered marked subclonal heterogeneity.[19] Most of the relapses apparently arise from a minor subclone present at diagnosis. The identification and specific targeting of these resistant cells is a major future challenge.

An exciting development is the advent of immunotherapy. Blinatumomab, a novel bispecific antibody engaging autologous T cells against CD19 positive leukemic cells, has been recently approved for therapy.[20] New cell therapy based on autologous T cells engineered to express anti-CD19 receptor coupled to intracytoplasmic stimulatory molecules (CAR-T cells) have also shown a tremendous efficacy against highly resistant B-cell precursor ALL.[21] This is therefore an exciting period in novel treatments of ALL beyond chemotherapy.

ON THE HORIZON

Translational Research of Acute Lymphoblastic Leukemia (ALL)

- Whole genomic analyses will discover all leukemia genetic abnormalities, enabling further personalization of treatment.
- Novel therapies targeting specific leukemia-associated abnormalities will be implemented.
- Immunotherapy utilizing antibodies directed against lymphoid antigens and conjugated either to toxins or to T-cell engaging molecules or modified T cells will be routinely implemented in treatment of high-risk ALL.

CHRONIC LYMPHOCYTIC LEUKEMIA

Chronic lymphocytic leukemia (CLL) is an often indolent lymphoproliferative neoplasm of mature peripheral circulating B cells. It is the most common leukemia in adults living in countries in the Western hemisphere. CLL originates from a clonal lymphoid evolved mature stem cell that can be identified by its distinct B-cell Ig gene rearrangement. Both clinically and at the molecular level, it is a heterogeneous disease. Some patients have an indolent course, whereas other have a more rapid and aggressive disease. During its progression, CLL may be associated with significant immune deficiencies and autoimmune phenomena that can complicate its course and treatment. These abnormalities may be profound and thus alter the nature of the disease. They are attributed to the clonal nature of its B-cell origin. Less than 5% of patients have T-cell CLL. Understanding the molecular pathways involving BCR moieties enables focusing of novel and targeted chemoimmunotherapy.

Epidemiology

The extensive use of automated peripheral blood lymphocyte counts has increased the rate of diagnosis of asymptomatic patients with CLL. The incidence rate of CLL increases logarithmically from age 35 years, with a median age at the time of diagnosis of 65 years. There is a male predilection, and the disease appears to have geographical and ethnic variations in incidence. In the United States, CLL is uncommon in people of Asian descent. Because many of these patients may never require tissue diagnosis or inpatient treatment, cases among them are not likely to be recorded in a tumor registry, thus making the true annual incidence of the disease higher than previously thought (6.8 per 100 000 population).[22] With sensitive techniques, a monoclonal population of B lymphocytes that is indistinguishable in immunophenotype from CLL cells may be found in the blood of 3.5% of persons >40 years of age.[23]

The presence of B lymphocytes <5000/µL showing clonality is defined as monoclonal B-lymphocytosis (MBL). MBL is an indolent disorder that may progress to frank CLL at a rate of 1–2% per year, and almost all patients with CLL begin with MBL. This state is divided into low or high MBL (below or above 500/µL clonal lymphocytes in the peripheral blood). Low MBL is more abundant and rarely progresses to frank CLL, whereas high MBL may progress at the above-mentioned rate.[24] Some patients with MBL will experience autoimmune phenomenon, as later described for CLL. However, the importance of the MBL clone is not fully understood and does not necessarily imply a future progression to CLL.[24]

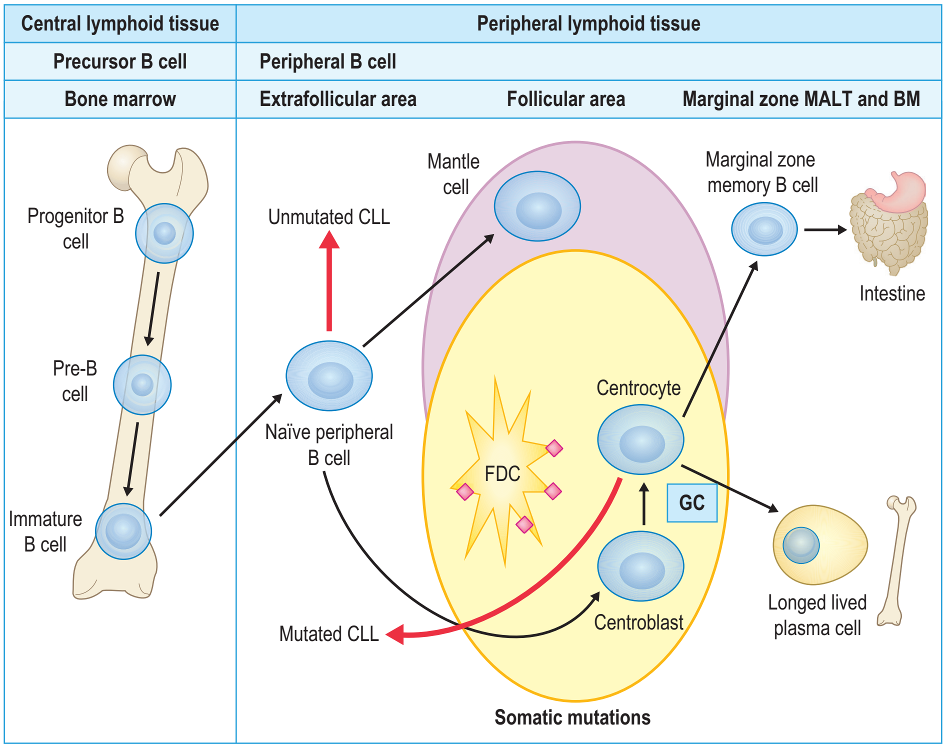

FIG 78.5 **B-Cell Development and Neoplasia.** B-cell lymphoproliferative disorders are related to different stage of normal B-cell development. Maturation starts at bone marrow. The more mature cells exit to the peripheral blood but do not experience the somatic hypermutation in the germinal center (GC), hence giving rise to the unmutated chronic lymphocytic leukemia (CLL) form. When the B cells mature and differentiate within the GC into the hypermutated centrocytes, they will pathologically become the mutated form of CLL. Other forms of B-cell neoplasms may arise at other stages. ProB and preB cells give rise to acute lymphoblastic leukemia; intermediate stages give rise to mantle zone lymphoma; and late and more mature stages give rise to marginal zone lymphomas and plasma cell–derived multiple myelomas.

The etiology of CLL is still unknown. However, as with other forms of malignancy, there is increasing evidence for the role of inherited factors in its development. Family surveys show a genetic predisposition in first-degree relatives, who also demonstrate increased susceptibility to other lymphoproliferative disorders, including other lymphomas.[25] Anticipation, the phenomenon of earlier onset, and a more severe phenotype in successive generations have been reported in families of patients with CLL.

Pathogenesis and the Biology of Leukemic Lymphocytes

CLL is now viewed as two related entities, both of which originate from B lymphocytes but differ in their activation state and in the maturation state of the cellular subgroup.[23.]

Normal B lymphocytes mature in bone marrow (Chapter 7). In the process, they undergo rearrangement of Ig V(D)J gene segments to create the code for an Ig molecule that serves as the BCR for antigen (Chapter 4). When an antigen of adequate affinity engages the receptor, the cell enters a germinal center located in a lymphoid follicle. There, as a centroblast, it rapidly divides and the V domains of its Ig undergo somatic hypermutation. Cells with receptors that have enhanced antigen-binding affinity proliferate in the presence of the antigen, whereas centrocytes with receptors that no longer bind the antigen (or bind autoantigens) are normally eliminated. Once the centrocytes are selected, they become plasma or memory B cells (Fig. 78.5).

The sequence and structure of Igs expressed by CLL cells from various patients have been found to be similar, suggesting a common pathogenetic antigen, such as an autoantigen-provoking clonal expansion. These findings suggest that antigenic stimulus plays a role in the promotion of CLL proliferation.

CLL may originate from a clone with few or no V domain mutations or from a more mature clone where these domains are hypermutated. These differences in the extent of V domain mutation suggest differing entities with two different developmental histories. Both originate from antigen-stimulated mature B lymphocytes. However, in the CLL with mutated Ig V domains, the proliferating B cell may have traversed the germinal centers, whereas in CLL with unmutated Ig V domains, the malignant B cell may derive from a naïve, pre–germinal center B cell.

The mutational status of the V domains strongly correlates with prognosis in that patients with an unmutated clone have a much worse prognosis compared with patients with mutated clones. These patients may differ also in their association with specific genetic aberrations. 11q22-23 (the ataxia–telangiectasia mutated gene) or 17p13 (the *p53* gene) deletions are associated with poor outcome and with an unmutated V domain profile. These genes regulate apoptosis and resistance to chemotherapy.

13q14 deletion or a normal karyotype is associated with a mutated profile and better prognosis. These chromosomal aberrations have independent prognostic significance (unrelated to the mutational status).

Surface membrane antigens typically found on B-cell CLL cells include CD19, CD21, and CD23. Expression of membrane IgM, IgD, and CD79b is reduced and is thus consistent with a phenotype matching that of mature, activated B lymphocytes. The pathological features of biopsy specimens of lymph nodes are those of a small lymphocytic lymphoma.[23] The coexpression of CD5, a T cell–associated antigen, is a phenotypic characteristic and part of the disease defining criteria. CD5$^+$ B cells can be found in the peripheral blood of normal adults, suggesting that specific subsets of CD5$^+$ B cells from the mantle zone may be the normal counterparts of B-cell CLL. The low expression of the BCR is the hallmark of CLL cells and contributes to impairments in the activation of the cell following BCR stimulation.

BCR signaling in CLL has been extensively studied and has shed considerable light on the pathogenesis of the disease, thus aiding in the design of targeted therapies. The BCR is a multimeric complex containing the antigen-specific surface Ig and the two membrane-bound signal transduction elements CD79A and CD79B. Binding of antigen to the BCR induces activation of upstream kinases, which, in turn, activate other kinases by means of their cytoplasmic moieties, including SYK and the Src kinase. These kinases further activate the Bruton tyrosine kinase (BTK), PI3K, and other downstream pathways, including phospholipase C gamma 2 (PLC-γ2), calcium signaling, protein kinase C (PKC), nuclear factor (NF)-κB signaling, mitogen-activated protein kinases (MAPKs), and nuclear transcription.[26] The upstream kinases BTK and PI3K are currently targeted by specific agents, and other kinases and pathways are being explored for novel therapies.

The CD38 surface molecule supports B-cell interactions and differentiation. Under certain circumstances, CD38 also augments signaling of BCR, delivering signals that regulate the apoptosis of B cells. Expression of CD38 correlates with expression of unmutated V domains and suggests a bad prognosis. Another molecule that influences the BCR is the ζ-associated protein 70 (ZAP70). High levels of this receptor associated protein tyrosine kinase (usually found in T and natural killer [NK] cells, but not in normal B cells) are detected in the majority of unmutated CLLs and correlate with a poor prognosis.

The microenvironment may play a role in the pathogenesis of CLL. Interactions with stromal cells rescue CLL cells from apoptosis *in vitro.* Activated T cells support the growth of CLL cells; cytokines, such as IL-4 and vascular endothelial growth factor (VEGF), and chemokines, such as CXCL12, support the expansion of CLL clones. When compared with blood-derived cells, expression profiling of CLL cells in the patient's lymph nodes showed BCR and NF-κB activation promoting cell proliferation, thus indicating the strong effects of the tumor microenvironment.[27] Mesenchymal stromal cells are also commonly found in secondary lymphatic tissues of patients with CLL. There they provide survival and migration signals to CLL cells, as well as protection from apoptosis and modulation of antigen presentation.[26] Endothelial cell and follicular dendritic cells (FDCs) may also play a role.

Interaction with and evasion from the normal immune system has been shown to be of significance.[26] The number of circulating T cells, oligoclonal in both the CD4 and the CD8 compartments, is increased. The function of these T cells is impaired, and they express exhaustion markers, including programmed death protein 1 (PD-1), at higher levels. Accordingly, CLL cells express high levels of PD-1 ligand (PD-L1). In addition, NK cells have reduced effector activities[26] that are associated with low expression levels of the activating receptors NK-cell p30-related protein (NKp30) and NK group 2 member D (NKG2D). Together, these findings provide an explanation for ability of CLL cells to evade immune-mediated destruction.

CLL has been classically characterized by the accumulation of mature B cells that evade apoptosis, with high levels of the BCL2 antiapoptotic protein. Contradicting this dogma is the measurement of CLL kinetics that has shown CLL cells to proliferate at a high dynamic rate of up to 1% of the clone per day.[28] In addition, proliferation-related genes (*e.g., c-MYC* and *E2F1*) have been found to be upregulated, especially in the unmutated CLLs.[27] This finding suggests that CLL is not solely an accumulative disease but also has a proliferative element.

Clinical Features of CLL

CLINICAL PEARLS

Chronic Lymphocytic Leukemia (CLL): Clinical Manifestations

- Absolute blood lymphocytosis >5000 /mm^3 sustained over a period of 4 weeks (to exclude transient lymphocytosis related conditions as viral infections)
- At least 30% lymphocytes in a normo- or hypercellular marrow
- Phenotypically monoclonal lymphocytes
- They express mature B-cell markers (*e.g.,* CD19) and CD5
- Morphologically mature-appearing lymphocytes
- Most patients having some degree of lymphadenopathy on physical examination
- Progression and the need for treatment depend on lymphocyte doubling time, bulky symptomatic disease, anemia, thrombocytopenia, autoimmune phenomenon

The clinical diagnosis of CLL requires an absolute lymphocytosis with a threshold of $>5000 \times 10^9$/L mature-appearing lymphocytes in the blood smear, persistence of the lymphocytosis for >4 weeks, and a distinct immunophenotype (as described above). Approximately a quarter of patients with CLL are asymptomatic at diagnosis. The clinical characteristics at presentation include lymphadenopathy (87%), splenomegaly (54%), hepatomegaly (14%), high white blood cell (WBC) count, anemia, and thrombocytopenia (20%). Very high WBC counts are rare but may develop along the course of the disease. Hyperleukocytosis, which causes leukostasis and necessitates emergency treatment, is extremely rare. Other organs that are involved include other lymphoid tissues and rarely solid organs or skin.

A prognostic evaluation of the patient with CLL begins with study of the patient's blood and bone marrow. Lymph node biopsy is not necessary but, if performed, may reveal the diagnosis of small lymphocytic lymphoma (SLL), which is considered a different manifestation of the same disease. The differential diagnosis includes other low-grade lymphoproliferative disorders, such as a leukemic phase of lymphoma and mantle cell lymphoma (usually negative for CD23); hairy cell leukemia (CD5 and CD21 negative and CD103 and CD25 positive); T-cell leukemia (other T-cell markers, such as CD3, CD4, and CD7); and prolymphocytic leukemia (PLL), which is distinguished by morphologically immature-appearing cells and the presence of FMC7 and CD79b on the cell surface. T-cell CLL is rare (<5%).

TABLE 78.5 **Major Factors Associated With Prognosis of Chronic Lymphocytic Leukemia (CLL)**[30,4,5,6,7,9,31,33,34]

	Definition	Median Survival (Years)	Used in Clinical Practice
Rai stage 0	Leukocytosis	12.5	Yes
1	Leukocytosis and lymphadenopathy	8.4	
2	Lymphocytosis plus hepatosplenomegaly	6.9	
3	Lymphocytosis plus anemia (<11 gr/dL)	1.5	
4	Lymphocytosis plus thrombocytopenia (<100 000 × 10^9/L)	1.5	
Binet	Leukocytosis and lymphadenopathy	Age-matched	Yes
Stage A	Lymphadenopathy of more than two involved areas	7	
Stage B	Anemia or thrombocytopenia	2	
Stage C			
β_2 microglobulin	Normal	9.7	Yes
	Elevated	4.5	
CD 38	>30%	2.9 to <10 years	Yes
Early-stage CLL	<30%	9 to >26 years	
Chromosomal aberrations	17p-	2.7	Sometimes
(FISH analysis)	11q-	6.5	
	Trisomy 12	9.5	
	Normal karyotype	9.3	
	13q-	11.1	
Zeta-associated protein 70 (ZAP-70)	>20%	7.5	If available
Early-stage CLL	<20%	Not reached	
Mutational status	Unmutated	5.7 to <9.9 years	If available
	Mutated	10.2 to >24 years	

The oldest staging systems of CLL risk stratification rely on measurement of disease bulk as reported by Rai[29] and Binet[30] (Table 78.5). These staging systems are very useful for identifying patients who will need treatment at the time of diagnosis, but not for predicting who will subsequently need treatment. About 33% of patients never require treatment and have a long survival. In another third, an initial indolent phase is followed by disease progression. The remaining third of patients exhibit an aggressive disease at the onset and need immediate treatment.

The most powerful predictors for rapid and aggressive progression are the mutational status of the V domains and chromosomal abnormalities, as described above (Fig. 78.6; see Table 78.5). In contrast to genomic aberrations and serum markers, such as CD38, the mutational profile has the advantage of remaining constant during disease evolution. NGS has identified new genetic markers that have altered prognosis for patients with CLL.[31] *TP53, ATM, NOTCH1,* and *SF3B1* mutations indicate a worse prognosis.

Treatment

As CLL remains an incurable tumor, treatment may be delayed and the patient monitored until becoming symptomatic (see Table 78.4). Indications for therapeutic intervention include the development of symptoms, a worsening anemia and/or thrombocytopenia, autoimmune cytopenias, progressive splenomegaly, progressive lymphadenopathy, or a lymphocyte doubling time of ≤6 months. No prospective data yet exist to support the early treatment of asymptomatic patients with adverse prognostic features. However, this group warrants close monitoring.

Chlorambucil, alone or combined with corticosteroids, has been the most commonly used drug. It is advantageous in relieving symptoms, even in advanced disease. However, several randomized controlled trials have failed to demonstrate improved survival, and hardly any patient achieves complete remission (CR). Purine analogues (most commonly fludarabine) with or without cyclophosphamide have been shown to induce higher response rates, with some patients achieving complete remission. Bendamustine is a novel agent that contains both alkylating properties and a purine-like benzimidazole ring. It has been shown to be effective in CLL and less toxic than the fludarabine and cyclophosphamide combination.[32]

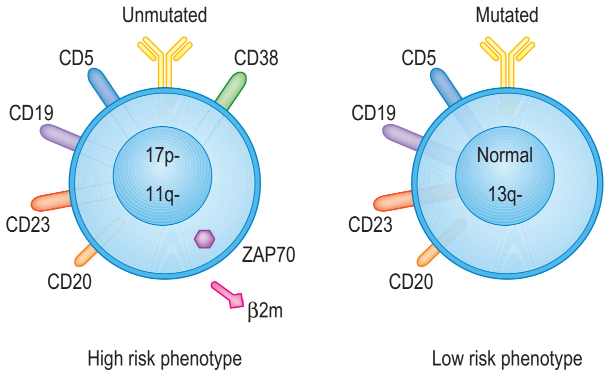

FIG 78.6 Risk Markers and Stratification in Chronic Lymphocytic Leukemia (CLL). CLL is one disease with two different entities. It commonly expresses normal levels of the B-cell surface antigens CD19 and CD23, low levels of CD20, and coexpression of the pan T-cell antigen CD5. The unmutated genotype correlates with a worse prognosis, featuring positive CD38 surface antigen, intracellular ZAP70, chromosomal aberrations as 17p- and 11q-, and high levels of soluble β_2 microglobulin. Conversely, the mutated form of CLL has a better prognosis, lacks these phenotypic features, and has fewer chromosomal aberrations, including 13q-.

THERAPEUTIC PRINCIPLES

Chronic Lymphocytic Leukemia (CLL) Is Incurable, but It Is Possible to Ameliorate Symptoms

- High rates of complete remissions and encouraging survival curves for high-risk patients
- Watch and wait approach in the case of asymptomatic patients with early-stage CLL
- Supportive care (immunoglobulins, blood supplements and erythropoietin, treatment of infections)
- Steroids with or without chemotherapy, especially for autoimmune phenomenon
- Conventional chemotherapy (alkylating agents, such as chlorambucil and cyclophosphamide; purine analogues, such as fludarabine and cladribine; other lymphoma regimens; bendamustine)
- Targeted therapy with or without chemotherapy (*i.e.*, rituximab, ofatumumab, obinutuzumab (all anti-CD20 antibodies) and alemtuzumab (anti-CD52 antibody)
- B-cell receptor pathway inhibitors—BTK (ibrutinib), PI3K-d (idelalisib), and BCL2 antagonists (venetoclax)
- Allogeneic (mostly with reduced intensity) stem cell transplantation

The CD52 antigen is present on lymphocytes (B, T, and NK cells), monocytes, and some granulocytes. The humanized anti-CD52 monoclonal antibody (mAb; CAMPATH-1, alemtuzumab) has demonstrated high activity in previously treated patients and those with refractory CLL.[33] Nevertheless, because of significant B- and T-cell depletion, patients are exposed to severe infectious complications, particularly reactivation CMV infection.

The anti-CD20 mAb rituximab (Mabthera) as a single agent has shown limited efficacy in CLL, possibly because of the weak receptor expression on CLL cells. However, in combination with chemotherapy, particularly with fludarabine and cyclophosphamide or bendamustine,[32] it appears to act synergistically and to achieve high rates of response, including molecular complete remission and prolongation of disease-free and overall survival. A newer fully human mAb targeting CD20 (ofatumumab) has a very potent effect as a single agent in both rituximab-naïve and rituximab-treated patients.[34] It targets a different epitope on the CD20 antigen. A second-generation anti-CD20 antibody, obinutuzumab, was added to chlorambucil in the treatment of the older adult population. When compared with chlorambucil, alone or in combination with rituximab and chlorambucil, obinutuzumab was shown to be superior and relatively safer.[32] Other investigational agents showing efficacy include lenalidomide (an immune modulator related to thalidomide), albeit with an interestingly initial flair-up phenomenon of disease-enlarged lymph nodes.

A major breakthrough in treatment was achieved through drugs targeting the BCR pathway. A BTK inhibitor, ibrutinib, has shown an impressive progression-free survival in relapsing patients and as first-line treatment[35,36] for patients with resistant or high-risk 17p-deleted CLL. In combination with rituximab, another pathway inhibitor, the PI3Kδ inhibitor idelalisib had an efficacy superior to rituximab alone in frail, older patients who were relapsing.[37] Furthermore, clinical trials with small molecules targeting BCL2, venetoclax, have shown promising results, even in patients with relapsing and highly resistant CLL.[38] Under investigation are various novel agents targeting other surface molecules (CD23, CD79b, and other CD20 inhibitors), pathway inhibitors (SYK, PI3K, second-generation BTK, and others), and immune checkpoint inhibitors. Some immunological novel approaches include expanded autoreactive activated T cells (chimeric antigen receptor–modified T cells [CAR-T]), which is showing promise.[39]

Allogeneic hematopoietic stem cell transplantation (allo-HSCT) is the only curative treatment for CLL. Allogeneic HSCT relies on myeloablative doses of chemoradiotherapy, which makes the treatment unacceptably risky for the majority of patients with CLL. In nonmyeloablative, or reduced-intensity, approaches, rates of engraftment are similar to fully ablative conditioning regimens, but with lower rates of early toxicity. Early evidence suggests that the graft-versus-leukemia (GVL) effect is present. Patients with deletion 17p (p53 involvement) with an extremely poor prognosis are physically fit candidates for allo-HSCT,[32] even as newer agents (*i.e.*, ibrutinib, idelalisib, and venetoclax) are showing high efficacy in this high-risk population. Studies involving autologous transplantation and high-dose chemotherapy for CLL have a limited survival advantage.

With treatment advances, the overall survival of patients with CLL has improved across the globe as a result of targeted therapy, even in high-risk and in patients with relapsed and refractory CLL. Thus classic prognostication (as presented in Table 78.5) is becoming less accurate as treatment improves.

Immunological Aspects of CLL

CLINICAL PEARLS

Chronic Lymphocytic Leukemia (CLL): Immunologic Manifestations

- Panhypogammaglobulinemia
- A monoclonal immunoglobulin peak, usually of the immunoglobulin M type
- Downregulation of T-cell function and aberrant cytokine production
- Defects in the complement system
- High risk of recurrent infections—encapsulated bacteria and opportunistic infections
- Autoimmune-associated phenomena:
  - Autoimmune hemolytic anemia
  - Autoimmune thrombocytopenia
  - Pure red cell aplasia and autoimmune neutropenia
  - Other autoimmune disorders (myositis, vasculitis, pemphigus vulgaris, acquired angioedema, glomerulonephritis)

CLL is characterized by multiple immune deficiencies and autoimmune phenomena. It is reasonable to hypothesize that immune incompetence and autoimmunity are two sides of the same coin.

The Pathophysiological Rationale

CLL cells secrete TGF-β, which is a potent inhibitor of B-cell proliferation. They also release high levels of circulating IL-2 receptor, which downregulates the T-helper (Th) cell function. Unlike normal cells, activated B cells, both B-cell CLL cells and anergic normal B cells, fail to present soluble antigen and alloantigens. Moreover, the T cells in patients with CLL often demonstrate profound abnormalities of their antigen receptor (TCR) repertoire and appear dysfunctional in terms of cytokine secretion.[40] This cytokine imbalance may be the cause of upregulation of the BCL-2 antiapoptotic activity. T-cell dysfunction could also explain the higher incidence of autoimmune complications, such as autoimmune hemolytic anemia, among patients receiving purine analogues therapy, which induce T-cell depletion. Certain

T-cell subsets appear to prevent the development of autoreactive B cells. When these are absent (*e.g.,* after treatment with purine analogues), autoreactive B-cell clones may easily emerge and expand.

Immunological Deficiencies

Patients with CLL are extremely sensitive to a number of infectious agents. A monoclonal Ig peak, usually of the IgM type, is found in 5% of patients with CLL, and a small amount of a monoclonal component can be identified in the serum or urine of 60% of patients. Hypogammaglobulinemia occurs in at least 60% of B-cell CLL cases and may include all three classes (IgG, IgA, and IgM). The pathogenesis of hypogammaglobulinemia in B-cell CLL is poorly understood, as this phenomenon is rare in other B-cell malignancies except multiple myeloma. Low Ig levels correlate with recurrent infections of encapsulated organisms. In patients who receive intravenous immune globulin (IVIG), there is a decrease in the incidence of major bacterial infections.

Infections are a major cause of morbidity and mortality in patients with CLL. Impaired humoral and cellular immunities, defects in the complement systems, and variable neutropenia, depending on marrow infiltrates, all contribute to the high rate of infections. Opportunistic infections are initially uncommon as the result of the relative preservation of cellular immunity early in the disease. Infection risk increases following purine analogue therapy because of the side effects of myelosuppression and marked lymphopenia with T-cell depletion. The addition of rituximab, the anti–B cell marker CD20 antibody, to nucleoside analogue-based therapy does not appear to increase the risk of early or late infections but may increase the rate of neutropenia. Active immunization with vaccines is hampered by the patient's inability to generate or retain a long and significant immune response.

Autoimmune Phenomena

Autoimmune-associated features are common in CLL. These manifestations primarily affect hematopoietic cells. For example, the most common known cause of autoimmune hemolytic anemia (AIHA) is CLL.[41] Positive result of direct antiglobulin test (direct Coomb test) has been reported to be as high as in 7–35% of patients with CLL, and AIHA itself occurs in 10–25% of patients during the course of their disease, twice as often in patients with unmutated genes as in those with mutated ones. Autoantibodies against red blood cells (RBCs) are warm-reactive polyclonal IgG. They are not secreted by the malignant clone, but rather by normal B cells.[41] Cold agglutinins are rare. AIHA is thought to arise from the imbalance among lymphocyte subsets, contributed to by therapy, resulting in the emergence of the autoimmune clone. It is usually observed in advanced stages of the disease, correlates with a poor prognosis, and has a close relationship with the activity of the CLL. After therapy, the autoimmune antibodies may remit in 70% of the treated patients.

Idiopathic thrombocytopenic purpura (ITP) is observed in about 2–3% of cases and presents as increased megakaryocytes in bone marrow. It should be distinguished from immune thrombocytopenia induced by marrow infiltration, which is very common in up to 50% of patients at presentation.[41] Two-thirds of patients with CLL-associated ITP also have AIHA (Evan syndrome). Pure red cell aplasia (PRCA) and autoantibodies against neutrophils are only rarely observed but are part of the CLL-related autoimmunity repertoire. Interestingly, the addition of cyclophosphamide represses the emergence of fludarabine-induced AIHA, but the latter may also be seen with other chemotherapies (*i.e.,* bendamustine).[42] Autoimmune phenomena in patients treated with purine analogues (mostly fludarabine-related) are of a more severe nature.

Other rare entities are reported as paraneoplastic autoimmune disorders with connective tissue disease manifestations, such as polymyositis, dermatopolymyositis, and focal myositis or as vasculitis, pemphigus vulgaris, and acquired angioedema. These autoimmune disorders are related to T-cell dysfunction and may be associated with purine analogue treatment. Paraneoplastic pemphigus also occurs in patients with CLL and may be triggered by chemotherapy and radiotherapy. Glomerulonephritis and nephrotic syndrome are seldom reported but, when present, are related to different mechanisms, such as cryoglobulins and antineutrophil cytoplasmic antibodies (ANCAs).

Therapy of autoimmune phenomena includes high-dose steroids and disease control.[41] In patients refractory to or relapsing after steroid therapy, more aggressive treatment is warranted. High-dose Igs offers transient amelioration in some patients. Splenectomy or splenic irradiation, cytotoxic agents, or cyclosporine may represent valid rescue approaches. In cases where AIHA has been triggered by fludarabine, further exposure is hazardous. Rituximab may be an alternative agent for the treatment CLL-associated autoimmune diseases, including rare autoimmune phenomena, such as pemphigus and PRCA.

Other Malignancies

Second malignancies (hematological and solid tumors) are not uncommon in CLL. The most common hematological malignancy is the Richter transformation to diffuse large B-cell lymphoma, which occurs in ≈5% of patients, as well as other high-grade lymphoproliferative diseases. Dermatological tumors, such as basal cell carcinoma, are the most frequent of the solid tumors encountered in patients with CLL, and these malignancies are more likely to be locally aggressive and metastatic.[32] The pathogenesis of these second cancers is not fully understood, and although disease-related genetic factors (*i.e.,* 17p deletion, notch mutation) are a major determinant, it is probably multifactorial and includes Epstein-Barr virus (EBV) infection and BCR configuration to respond to multiple autoantigens and immune/inflammatory stimuli present in the microenvironment.[32,43]

CONCLUSIONS

CLL is a common indolent lymphoid neoplasm with a wide clinical heterogeneity. It is suspected and diagnosed more commonly because of routine blood tests. Diagnosis is made with simple immunophenotyping. Cytogenetics and molecular diagnostic techniques are needed to determine the prognosis. The complications of CLL appear to be unique to this neoplasm and are part of a failing immune system with T-cell and B-cell dysregulation causing both deficiencies predisposing patients to recurrent infections and autoimmune diseases. New molecular and protein markers are key to finding novel effective targeted therapies.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following cell surface antigens is not consistent with the diagnosis of acute lymphoblastic leukemia (ALL)?
   A. CD3
   B. CD19
   C. Surface Immunoglobulin M (IgM)
   D. CD22
   E. Intracytoplasmic IgM

2. The detection of minimal residual disease of ALL is based on:
   A. Bone marrow magnetic resonance imaging
   B. Positron emission tomography with computed tomography
   C. Determination of secreted immunoglobulins
   D. Determination of clonal V(D)J rearrangements
   E. Serial bone marrow biopsies

3. CRLF2:
   A. Is a signaling cytoplasmic molecule
   B. Is part of the receptor to thymic stromal lymphopoietin
   C. Is a major driver of T-acute lymphoblastic leukemia
   D. Modulate the antileukemic effects of mast cells
   E. Inhibits the growth of leukemic cells

Lymphomas

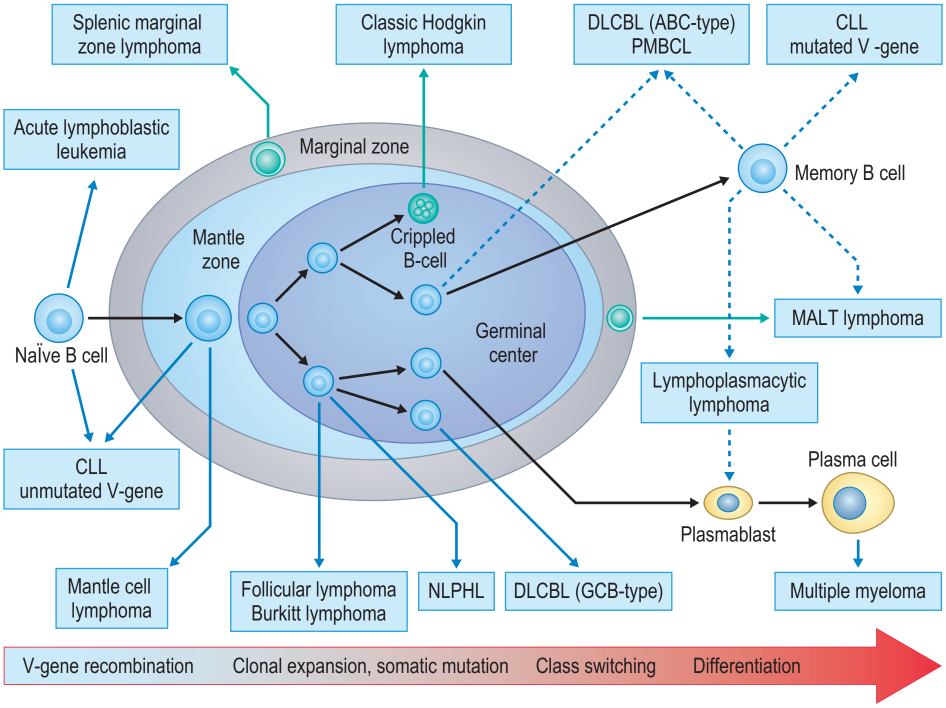
Stefania Pittaluga, Tapan Bhavsar, Elaine S. Jaffe

The classification of malignant lymphomas continues to undergo revision based on insights gained through the application of immunological and molecular techniques and the application of these discoveries to individualized therapeutic approaches. Early classifications were based on morphological characteristics of the neoplastic elements; however, with increasing knowledge of the complexity of the immune system, a more functional approach was sought. Differentiation schemes provided a useful starting point for understanding lymphomas (Fig. 79.1). High-throughput genomic studies of both tumor RNA and tumor DNA have been applied to lymphomas to define their molecular signatures with the aim of improving the understanding of oncogenic pathways and their clinical implications. These studies have led to new prognostic and diagnostic tools, and as a result, more targeted therapies have emerged.[1]

KEY CONCEPTS

Lymphoma

- Classification consists of a list of individual disease entities defined by morphological, immunophenotypic, genetic, and clinical features.
- Neoplastic cells are related to the postulated normal counterpart, when possible.
- Histological grade should be applied within individual diseases.
- Clinical factors for individual patients, as measured by the International Prognostic Index (IPI) and gene expression profiling, are useful in predicting clinical outcome.



Splenic marginal zone lymphoma
Classic Hodgkin lymphoma
DLCBL (ABC-type) PMBCL
CLL mutated V -gene
Acute lymphoblastic leukemia
Marginal zone
Memory B cell
Mantle zone
Crippled B-cell
MALT lymphoma
Naïve B cell
Germinal center
Lymphoplasmacytic lymphoma
CLL unmutated V-gene
Plasma cell
Plasmablast
Mantle cell lymphoma
Follicular lymphoma Burkitt lymphoma
NLPHL
DLCBL (GCB-type)
Multiple myeloma
V-gene recombination
Clonal expansion, somatic mutation
Class switching
Differentiation

FIG 79.1 **Normal B-Cell Differentiation in Relation to a Secondary B Follicle, Mutational Stages of the Immunoglobulin Genes, and Cellular Counterparts for B-Cell Lymphomas.** Simplified version of B-cell development indicates points at which V-gene recombination, clonal expansion, and somatic mutations occur in relation to a secondary B follicle. B-cell lymphomas are related to different stages of B-cell differentiation and function. ABC-type, activated B-cell-like type; CLL, chronic lymphocytic leukemia/lymphoma; DLBCL, diffuse large B-cell lymphoma; GCB-type, germinal-center B-cell-like type; MALT lymphoma, marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT) type; NLPHL, nodular lymphocyte-predominant Hodgkin lymphoma; PMBCL, primary mediastinal B-cell lymphoma.

The guiding principles of the World Health Organization (WHO) classification of neoplasms of the hematopoietic and lymphoid tissues, published in 2001 and updated in 2008 and 2016,[2] were based on the Revised European American Classification of Lymphoid Neoplasms (REAL), which was published by the International Lymphoma Study group in 1994. The focus was on the identification of individual diseases based on an integration of morphological, immunophenotypic, genetic, and clinical features. The recent application of gene expression profiling (GEP) in lymphomas has generated distinct molecular "signatures" for a variety of disease entities, in some cases corresponding more closely to different stages of lymphoid differentiation and in other instances offering insights into mechanisms of neoplastic transformation with delineation of alterations in specific pathways. The advent of whole-genome sequencing contributes additional new insights into pathogenetic mechanisms. Recently, a revision of the nearly 8-year-old WHO classification of lymphoid neoplasms (Table 79.1) was published clarifying

TABLE 79.1 WHO Classification of Tumors of Hematopoietic and Lymphoid Tissues (2016)

B-Cell Neoplasm

- Precursor B-cell lymphoblastic leukemia/lymphoma
    - B-lymphoblastic leukemia/lymphoma, not otherwise specified
    - B-lymphoblastic leukemia/lymphoma with recurrent genetic abnormalities

Mature B-Cell Neoplasm

- Chronic lymphocytic leukemia/small lymphocytic lymphoma
- Monoclonal B-cell lymphocytosis*
- B-cell prolymphocytic leukemia
- Splenic B-cell marginal zone lymphoma
- Hairy cell leukemia
- _Splenic B-cell lymphoma/leukemia, unclassifiable_
    - _Splenic diffuse red pulp small B-cell lymphoma_
    - _Hairy cell leukemia-variant_
- Lymphoplasmacytic lymphoma
- Waldenstrom macroglobulinemia
- Monoclonal gammopathy of undetermined significance (MGUS), IgM*
- μ heavy-chain disease
- γ heavy-chain disease
- α heavy-chain disease
- Monoclonal gammopathy of undetermined significance (MGUS), IgG/A*
- Plasma cell myeloma
- Solitary plasmacytoma of bone
- Extraosseous plasmacytoma
- Monoclonal immunoglobulin deposition diseases*
- Extranodal marginal zone lymphoma of mucosa-associated lymphoreticular tissue (MALT) lymphoma
- Nodal marginal zone lymphoma
    - Pediatric nodal marginal zone lymphoma
- Follicular lymphoma
    - _In situ_ follicular neoplasia*
    - Duodenal-type follicular lymphoma*
    - Pediatric-type follicular lymphoma*
    - _Large B-cell lymphoma with IRF4 rearrangements_*
    - Primary cutaneous follicle-center lymphoma
- Mantle cell lymphoma
- _In situ mantle cell neoplasia_ *
- Diffuse large B-cell lymphoma (DLBCL), NOS
    - Germinal-center B-cell type*
    - Activated B-cell type*
- T-cell/histiocyte rich large B-cell lymphoma
- Primary DLBCL of the central nervous system
- Primary cutaneous DLBCL, leg type
- EBV$^+$ DLBCL, NOS*
- _EBV$^+$ mucocutaneous ulcer_*
- DLBCL associated with chronic inflammation
- Lymphomatoid granulomatosis
- Primary mediastinal (thymic) large B-cell lymphoma
- Intravascular large B-cell lymphoma
- ALK positive large B-cell lymphoma
- Plasmablastic lymphoma
- Large B-cell lymphoma arising in HHV8-associated multicentric Castleman disease
- Primary effusion lymphoma
- _HHV8 positive DLBCL, NOS_*
- Burkitt lymphoma
- _Burkitt-like lymphoma with 11q aberration_*
- High grade B-cell lymphoma, with MYC and BCL2 and/or BCL6 rearrangements*
- High grade B-cell lymphoma, NOS*
- B-cell lymphoma unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classic Hodgkin lymphoma

T-Cell Neoplasm

- Precursor T-cell lymphoblastic leukemia/lymphoma

Mature T-Cell and NK-Cell Neoplasms

- T-cell prolymphocytic leukemia
- T-cell large granular lymphocytic leukemia
- _Chronic lymphoproliferative disorder of NK-cells_
- Aggressive NK leukemia
- Systemic EBV$^+$ T-cell lymphoma of childhood*
- Hydroa vacciniforme-like lymphoproliferative disorder*
- Adult T-cell leukemia/lymphoma
- Extranodal NK-/T-cell lymphoma, nasal type
- Enteropathy-associated T-cell lymphoma
- Monomorphic epitheliotropic intestinal T-cell lymphoma*
- _Indolent T-cell lymphoproliferative disorder of the GI tract_*
- Hepatosplenic T-cell lymphoma
- Subcutaneous panniculitis-like T-cell lymphoma
- Mycosis fungoides
- Sézary syndrome
- Primary cutaneous CD30$^+$ positive T-cell lymphoproliferative disorders
    - Primary cutaneous anaplastic large-cell lymphoma
    - Lymphomatoid papulosis
- Primary cutaneous γ/δ T-cell lymphoma
- _Primary cutaneous CD8 positive aggressive epidermotropic cytotoxic T-cell lymphoma_
- _Primary cutaneous acral CD8$^+$ T-cell lymphoma_*
- _Primary cutaneous CD4 positive small/medium T-cell lymphoproliferative disorder_*
- Peripheral T-cell lymphoma, NOS
- Angioimmunoblastic T-cell lymphoma
- _Follicular T-cell lymphoma_*
- _Nodal peripheral T-cell lymphoma with TFH phenotype_*
- Anaplastic large-cell lymphoma, ALK positive
- Anaplastic large-cell lymphoma, ALK negative*
- _Breast implant-associated anaplastic large-cell lymphoma_*

Hodgkin Lymphoma

- Nodular lymphocyte predominant Hodgkin lymphoma
- Classic Hodgkin lymphoma
- Nodular sclerosis Hodgkin lymphoma
- Lymphocyte-rich classic Hodgkin lymphoma
- Mixed cellularity classic Hodgkin lymphoma
- Lymphocyte-depleted classic Hodgkin lymphoma

*Refers to changes from the 2008 classification.

Note: More common entities are underlined. Provisional entities in italics.

From Swerdlow SH, Campo E, Pileri SA, et al. The 2016 revision of the World Health Organization (WHO) classification of lymphoid neoplasm. Blood 2016;127:2375–90.

the diagnosis and management of lesions at the very early stages of lymphomagenesis, refining diagnostic criteria for some entities, and detailing the expanding genetic/molecular landscape of numerous lymphoid neoplasms and their clinical correlates.[3]

This chapter focuses on the classification of neoplasms derived from mature B cells, T cells, and natural killer (NK) cells, with emphasis on malignant lymphomas. Other chapters in this volume cover lymphoid leukemias (Chapter 78) and immunosecretory disorders, including plasma cell neoplasms (Chapter 80). Special attention is devoted to the impact of clinical features (*e.g.*, age and anatomical site) on disease definition and a greater appreciation of early events in neoplastic transformation. These early lesions can sometimes be detected in otherwise healthy individuals, and these lesions may or may not progress to overt lymphoma or leukemia. These entities appear to carry fewer genetic aberrations compared with the conventional forms of the disease, which perhaps explains their indolent clinical behavior.[4]

CLINICAL PEARLS

Indolent Lymphomas

- Natural history: survival measured in years
- Least sensitive to therapy
- Good response to low-dose oral alkylating agents, radiotherapy, and steroids, but no curability
- Higher response rate and complete remission with combination of standard chemotherapy and anti-CD20 monoclonal antibody
- Gene expression profiling can help identify patients who might benefit from high-dose chemotherapy and autologous stem-cell transplantation, which is a potentially curative modality

MATURE B-CELL NEOPLASMS

KEY CONCEPTS

Somatic Mutation in Relation to Normal B-Cell Development

- *Premutational stage:* circulating naïve B cells (immunoglobulin (Ig)M$^+$/D$^+$) before antigen exposure
- *Stage of somatic mutation, clonal expansion, and isotype switch:* at the germinal center
- *Postmutational stage:* selected B cells move to the periphery (post–germinal center) or to the recirculating pool (memory B cells), or undergo terminal differentiation (plasma cells)

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma (LPL) is a disease of adult life (median age in the 60s), usually presenting with generalized lymphadenopathy, constitutional symptoms, and splenomegaly.

Histologically, there is a diffuse interfollicular proliferation of small lymphocytes (many with plasmacytoid features) and plasma cells, with or without immunoglobulin (Ig)–filled intranuclear inclusions (Dutcher bodies) and sparing of the sinuses. An increased number of mast cells and iron-laden macrophages can be seen. Although many B-cell neoplasms occasionally show maturation to plasmacytoid or plasma cells with cytoplasmic Ig, the term LPL should be restricted to tumors lacking features of other well-defined entities, such as chronic lymphocytic leukemia (CLL) or mantle-cell lymphoma (MCL), which occasionally can manifest plasmacytoid differentiation. Many but not all patients with LPL may have clinical evidence of Waldenström macroglobulinemia (WM), which is based on the detection of an IgM monoclonal gammopathy of any concentration and is associated with bone marrow involvement by LPL (Chapter 80).

In LPL, cells have surface and cytoplasmic Ig, usually IgM (and usually lacking IgD), and express B cell–associated antigens (CD19, CD20, CD22, CD79a). They are generally negative for CD5 and cyclinD1, distinguishing LPL from CLL and MCL, respectively. CD25, CD10, or CD11c may be weakly expressed in some cases. The postulated normal counterpart is thought to be a postfollicular medullary cord B cell, based, in part, on the presence of somatic mutations in the Ig heavy-chain and light-chain variable region genes.

The recent identification of *MYD88* L265P mutation (found in approximately 90% of WM cases) has become a reliable marker supporting a diagnosis of LPL.[5] This mutation is also found in a significant proportion of IgM, but not IgG or IgA, monoclonal gammopathy of undermined significance (MGUS) cases.

Mantle-Cell Lymphoma

MCL usually presents in adults (median age 62; variable male predominance) with advanced-stage disease—involving lymph nodes, Waldeyer ring lymphoid tissue, spleen, bone marrow, and peripheral blood. Gastrointestinal (GI) tract involvement is common and is associated with a lymphomatous polyposis picture. Retrospective studies have shown a poor prognosis (median survival 3–5 years), with a high relapse rate following initial remission. MCL is composed of small lymphoid cells with slightly irregular nuclear contours, finely clumped chromatin, and scant cytoplasm. Specifically, blastoid and pleomorphic variants have been associated with a more aggressive clinical course. The postulated normal counterpart is a CD5$^+$ "naïve" sIgM$^+$ and sIgD$^+$ B cell, found in peripheral blood and in the mantles of reactive follicles.

MCL is characterized by a molecular hallmark, t(11;14)(q13;q32)—involving cyclin D1 (*CCND1*) and the *IGH* genes; an overexpression of *CCND1* is believed to be essential in the pathogenesis. Rare variants negative for *CCND1* but with similar immunomorphology and GEP have also been identified.[6] Half of the *CCND1* expression/rearrangement-negative forms have *CCND2* translocations, often with IGK or *IGL* as a partner locus, which could be of diagnostic utility.[7] SOX11 is overexpressed in most *CCND1*-positive and *CCND1*-negative cases.[8] Besides the *CCND1/IGH* translocation, additional alterations involving other cell cycle regulatory proteins (RB, p53, CDK inhibitors) have been described in the more aggressive forms of MCL.

In-situ mantle cell neoplasia (ISMCN) (according to new 2016 classification; previously "*in-situ*" MCL) describes clonal proliferation of cyclin D1-positive cells restricted to the inner mantle cuffs in an otherwise reactive lymph node/lymphoid tissue and usually represents an incidental finding. Some cases will eventually progress to overt MCL[2]; however, the risk of progression is difficult to ascertain, as the number of reported cases is few. Another newly identified nonnodal variant is characterized by a leukemic phase without nodal disease but often long-standing splenomegaly. These cases develop from IgHV-mutated SOX11-negative B cells, carry t(11;14) with few additional chromosomal abnormalities but lack expression of SOX11.[9]

The proliferation rate based on Ki67-positivity has been considered of prognostic relevance. More recently, GEP using genes involved in cell cycle progression and DNA synthesis has identified a proliferation signature—defining different prognostic groups and showing correlation with cytological subtype to some extent. For example, a high proliferation rate has been shown in the blastoid variant.

The treatment approach for newly diagnosed patients with MCL depends on their eligibility for stem cell transplantation (SCT). However, purging of the neoplastic cells is difficult to achieve because of frequent bone marrow involvement, and autologous SCT has not proven be curative. The incorporation of rituximab into chemotherapeutic regimens has become an evidence-based standard of care. Of the current drugs used for MCL, the application of the BTK inhibitor ibrutinib might change treatment paradigms by obviating the need for transplantation in younger patients and chemotherapy in older patients.[10] The patients with the nonnodal variant as described above do not appear to require aggressive chemotherapy.[9]

Follicular Lymphoma

Follicular lymphoma (FL) is the most common subtype of non-Hodgkin lymphoma (non-HL) in the United States and accounts for approximately 45% of all newly diagnosed cases. It has a peak incidence in the fifth and sixth decades and is rare under the age of 20 years. Both sexes are equally affected. Most patients have stage 3 or 4 disease at diagnosis, with generalized lymphadenopathy and bone marrow involvement. Approximately 10% of patients have circulating malignant cells; appropriate immunophenotypic or molecular analyses may reveal involvement of peripheral blood in a higher proportion of patients.

FL is composed of varying proportions of follicle center–type cells, centrocytes, and centroblasts, with centroblasts representing the proliferative component. According to the WHO classification, all low-grade FL are combined into a single category, grade 1/2—with an overall predominance of centrocytes and fewer than 15 centroblasts per high-power field (hpf). Grade 3 (with >15 centroblasts/hpf) is further subdivided into 3A and 3B, based on the presence or absence of background centrocytes. FL represents the neoplastic counterpart of the reactive germinal-center cells; intraclonal heterogeneity with high numbers of somatic and ongoing Ig mutations can be detected in the neoplastic cells, as in the normal counterparts. Biologically, grade 3B is more closely related to diffuse large B-cell lymphoma (DLBCL) compared with FL.

The vast majority of FL (approximately 90%) is associated with a t(14; 18) involving rearrangement of the *BCL2* gene. This translocation appears to result in constitutive expression of BCL2 protein, which is capable of inhibiting apoptosis in lymphoid cells. The cells of FL accumulate and are at risk for secondary mutations, which may be associated with histological progression. It is thought that the *BCL2* translocation occurs at a very early stage of B-cell development, during immunoglobulin gene rearrangement. Mutations in *BCL2* can lead to loss of BCL2 protein in the presence of the translocation; fluorescence *in situ* hybridization (FISH) studies for t(14; 18) in these cases are informative. Of note, t(14; 18) is not specific to FL and can be seen in CLL and other low-grade B-cell lymphomas as well. Grade 3B FL is less commonly associated with *BCL2* translocation and carries genetic aberrations more commonly seen in DLBCL. The neoplastic cells in FL have a mature B-cell phenotype with expression of the B-cell antigens (CD19, CD20, and CD22). Surface Ig is positive, most commonly with IgM expression, but IgG or IgA can also be seen in many cases. CD10 and BCL6 are positive, but CD5 is usually negative.

The 2008 WHO classification had recognized variants of FL, namely, *pediatric FL, GI tract FL,* and other *extranodal FL.* Pediatric-type FL (now a definite entity in the 2016 classification) is more common in males and presents as localized nodal disease. It typically has an expansile serpiginous pattern, with relatively monotonous, medium-sized, blastoid cellular composition. *BCL2, BCL6,* and *MYC* rearrangements are lacking. Complete remissions may be obtained with either surgical excision or local radiation therapy. Some studies have raised the possibility that pediatric-type FL might be a "benign clonal proliferation with low malignant potential."[11,12]

The WHO classification recognizes "FL *in situ*" (now termed *in-situ follicular neoplasia* [ISFN]) as a distinctive lesion. It should be distinguished from partial involvement of FL. ISFN shows involvement of germinal centers by CD10 and BCL2-positive cells carrying t(14;18) in an otherwise reactive lymph node, which is typically an incidental finding. Patients have a very low risk of progression, but ISFN may be detected in association with other forms of B-cell lymphoma, necessitating additional clinical assessment.[13] Fewer chromosomal abnormalities are noted in IFSN in comparison with partial or overt FL.[14] Patients lacking evidence of FL at staging have a low risk of developing the disease; this phenomenon appears to represent the tissue counterpart of circulating clonal B-cells carrying t(14;18) as detected in healthy individuals. A higher level of circulating t(14;18) positive lymphocytes ($>10^{-4}$ of total cells) indicates a higher risk for FL.

The new 2016 classification addresses GI tract FL as duodenal-type FL, as these can also be seen elsewhere in the GI tract and have features overlapping with ISFN and extranodal mucosa-associated lymphoreticular tissue (MALT) lymphoma.[14] These present as small mucosal polyps or nodules, and most cases are discovered incidentally on endoscopy. The lesions are usually low-grade and have an indolent clinical course, and most patients have been managed without therapy. Local recurrences in the intestine may occur, but spread beyond the small intestine is rare.

Primary cutaneous follicle center lymphoma frequently lacks the *BCL2* translocation and BCL2 expression. However, when BCL2 expression is detected, the possibility that this may represent a secondary site of involvement should be considered. These lesions are generally managed locally with conservative approaches and have a low risk of spread beyond the skin. The scalp is a common site of presentation.

Two recent variants or subtypes of FL have been described; one subtype described by Karube et al. occurring in older individuals showed a $CD10^-/MUM1^+$ immunophenotype that tends to show grade 3 morphology, usually lacks *BCL2* translocations, and often shows *BCL6* abnormalities.[15] This is in contrast to another recently described distinct new provisional entity of a low-stage large B-cell lymphoma with *IRF4* rearrangement common in children or young adults, typically involving the Waldeyer ring and/or the cervical lymph nodes. These cases show strong IRF4/MUM1 expression, usually with BCL6 and a high proliferative fraction, and are considered more aggressive than other pediatric-type FL; however, when treated, they show good response.[16] Another distinctive subtype described by Katzenberger et al.[17] is characterized by t(14;18)–negative nodal grade 1/2 FL with a high proliferation rate that predominantly shows diffuse growth pattern and deletions in the chromosomal region 1p36.

This entity usually presents with low clinical stage and large or localized inguinal tumors.[17]

FL is indolent but is still incurable with available therapeutic modalities. The occurrence of *BCL2* translocation at a very early stage of B-cell development might be contributory to the difficulty of eradicating the neoplastic clone with chemotherapy. Clinical parameters have been used to develop prognostic indexes (*e.g.,* the Follicular Lymphoma International Prognostic Index, adjusted from the International Prognostic Index for aggressive B-cell lymphoma). Recently, much has also been learned about the mutational landscape of FL. Mutations in *CREBBP, MLL2,* and *EZH2* have been shown as extremely common early events and may be potential therapeutic targets.[18] The natural history of the disease is associated with histological progression at both cellular composition and overall pattern levels (Fig. 79.2).

Mucosa-Associated Lymphoid Tissue Lymphomas

Most lymphomas of marginal zone derivation present in extranodal sites and have histopathological and clinical features that are part of the spectrum of MALT lymphomas. MALT lymphomas occur most frequently in the stomach, lung, thyroid gland, salivary gland, and lacrimal gland. Other less common sites of involvement include the orbit, breast, conjunctiva, bladder, kidney, and thymus. MALT lymphomas are characterized by a heterogeneous cellular composition, including centrocyte-like cells, monocytoid B cells, small lymphocytes, and plasma cells. In most cases, large transformed cells are uncommon, but reactive germinal centers are nearly always present. Historically, the distinction from reactive lesions has been problematic. Clonality can be established on the basis of light-chain restriction or molecular studies. Follicular colonization by the neoplastic cells can simulate FL. The clinical course is usually quite indolent. MALT lymphomas tend to relapse in other MALT-associated sites. MALT lymphomas of the salivary gland, thyroid gland, and mediastinum (thymus) are usually associated with a history of autoimmune diseases, predominantly Sjögren syndrome.

MALT lymphomas have several recurring cytogenetic abnormalities, including t(11;18)(q21;q21), t(1;14)(p22;q32), t(14;18)(q32;q21), t(3;14)(q27;q32), and t(3;14)(p14.1;q32); these abnormalities are observed with variable frequency, often depending on the anatomical site.[19] Although several genes are involved in these translocations, at least three of them—t(11;18), t(1;14), and t(14;18)—share a common pathway, leading to the activation of NFκB and its downstream targets.[20] By genome-wide DNA profiling integrated with GEP, differences were detected among the three main types of marginal zone lymphomas, lending support to the current WHO classification that separates these three entities.[18] The translocation t(11;18)(q21;q21) is associated exclusively with low-grade extranodal MALT and is not detected in cases with concurrent low-grade and high-grade tumors, or in primary extranodal large-cell lymphomas—raising doubts whether these primary extranodal lymphomas are, in fact, related to low-grade MALT. The term *extranodal marginal zone lymphoma* (MZL) of MALT type applies only to low-grade MALT; the term *high-grade MALT* should not be used for extranodal large B-cell lymphomas in a MALT site.

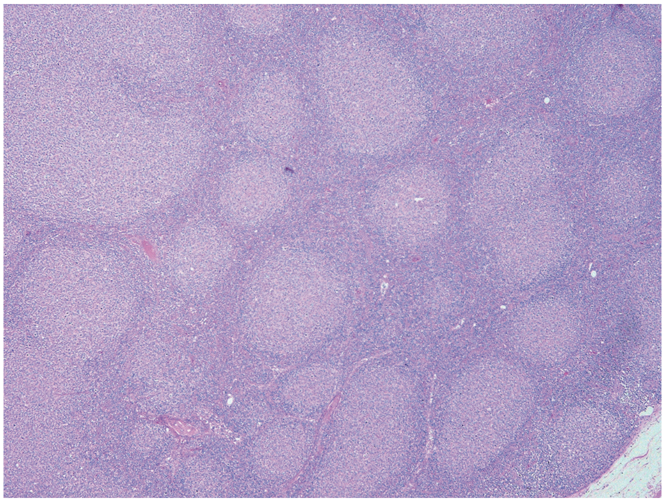


FIG 79.2 Follicular Lymphoma. The neoplastic follicles are similar in size and are partially surrounded by lymphoid cuffs. In contrast to reactive germinal centers, they lack polarization and tingible body macrophages ("starry-sky pattern").

There is a strong association between chronic infection with *Helicobacter pylori* and gastric MALT lymphoma. Other infectious agents have been described in MALT lymphomas involving skin (*Borrelia burgdorferi*), ocular adnexae (*Chlamydia psittaci*), and the small intestine (*Campylobacter jejuni*); however, a causal relationship has not yet been demonstrated. Chronic antigen stimulation is critical to both the development of a MALT lymphoma and the maintenance of the neoplastic state. Indeed, in some cases lacking aforementioned genetic aberrations, eradication of *H. pylori* by antibiotic therapy has led to the spontaneous remission of gastric MALT lymphoma. MALT lymphomas are positive for B cell–associated antigens but are usually negative for CD5 and CD10. BCL6 and CD10 are helpful markers to identify residual reactive germinal-center cells, especially in cases of follicular colonization. The putative cell of origin of MZL is a post–germinal-center memory B cell.

Nodal Marginal Zone Lymphoma

Nodal marginal zone lymphoma (NMZL), a primary nodal disease, resembles other marginal zone lymphomas, extranodal or splenic types. Adult patients often present with bone marrow involvement and tend to have a more aggressive clinical course compared with those with extranodal MALT. In contrast, when NMZL occurs in children, it shows a striking male predominance, presence of disrupted follicles with progressive transformation of germinal centers, presents with localized (head and neck) disease, and can be managed with local therapies.[19]

The neoplastic proliferation is mostly composed of small- to medium-sized B cells, often with pale cytoplasm. The immunophenotype is similar to that of other marginal zone B-cell lymphomas, $CD20^+$, $CD5^-$, $CD10^-$, with variable IgD expression. Some NMZLs have a morphology and immunophenotype similar to those of splenic marginal zone lymphomas (SMZLs) (see below), and in these cases, the tumor cells are IgD^+.

Splenic Marginal Zone Lymphomas

SMZLs present in adults and have a slight female gender predilection, usually with splenomegaly but without peripheral lymphadenopathy. Most patients have bone marrow involvement with modest lymphocytosis. Some evidence of plasmacytoid differentiation and the presence of a low level M-protein may also be seen. The course is reportedly indolent, and splenectomy may be followed by a prolonged remission.

Histologically, the spleen shows expansion of the white pulp with a characteristic biphasic pattern—central zone of small lymphocytes surrounded by a peripheral zone of larger cells resembling marginal zone cells. The residual polytypic mantle is not present in this instance. The abundant pale cytoplasm evident in tissue sections may also be seen in peripheral blood smears, and the cytological features may be mistaken for those of hairy-cell leukemia. The phenotype resembles other marginal zone B-cell lymphomas with a more frequent sIgD expression.

Deletion of 7q31 has been described in SMZL; although it can also be seen in isolated cases of splenic B-cell lymphoma or leukemia unclassifiable, it has not been detected in other splenic lymphomas.[21] Studies of the Ig variable genes and IgD expression have revealed two groups of naïve and memory B-cell origin.

CLINICAL PEARLS

Aggressive Lymphomas

- Natural history: survival measured in months.
- Successful therapy can be achieved with combination chemotherapy.
- Relapses from chemotherapy-induced remission may be cured with high-dose chemotherapy with hematopoietic support.
- In addition to the International Prognostic Index (IPI), gene expression profiling can be useful in predicting prognosis and survival of individual patients.

Diffuse Large B-Cell Lymphoma, Not Otherwise Specified

Diffuse large B-cell lymphoma, not otherwise specified (DLBCL, NOS) is one of the more common subtypes of non-HL, representing up to 40% of cases. This diagnosis is used for both primary DLBCL as well as for cases that transformed from a low-grade lymphoma. It may be nodal or involve extranodal sites, including bone, skin, the thyroid gland, the GI tract, and lungs.

DLBCL, NOS is composed of large transformed lymphoid cells with nuclei at least twice the size of a small lymphocyte (Fig. 79.3). The nuclei generally have vesicular chromatin, prominent nucleoli, and basophilic cytoplasm—resembling either centroblasts or immunoblasts, albeit with an overall greater cellular pleomorphism.

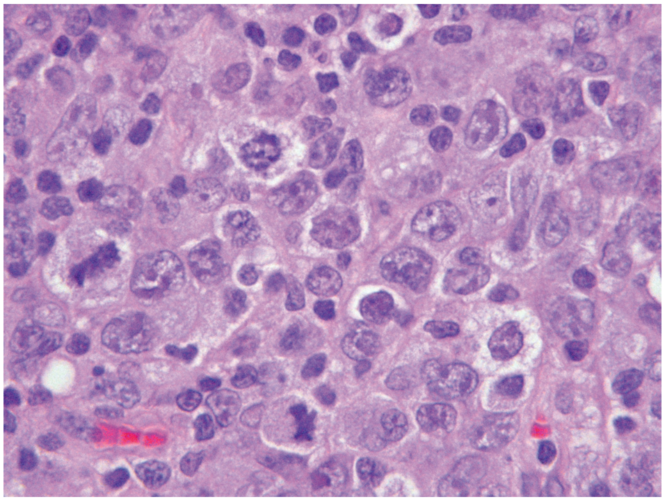

FIG 79.3 **Diffuse Large-Cell Lymphoma.** The neoplastic cells have large round to oval nuclei with vesicular chromatin and multiple eosinophilic nucleoli. Numerous mitoses are also present.

In terms of morphology and phenotype, DLBCL is one of the most heterogeneous categories in the WHO classification; currently, several morphological variants as well as specific subtypes are recognized.[2] There has been a great interest in identifying DLBCL features that might be prognostically relevant. To address issues traditionally not resolved by morphological or immunophenotypic features, DLBCL was among the first lymphomas to be analyzed by complementary DNA (cDNA) microarray. Based on the differential expression of a large set of genes by GEP, *germinal-center B cell–like* (GCB) group and *activated B cell–like* (ABC) group have been identified,[22] in addition to the previously recognized *primary mediastinal (thymic) large B-cell lymphoma* (PMBCL). GCB DLBCLs express a set of genes that are associated with normal germinal-center B cells, whereas ABC DLBCLs show downregulation of these genes and share similarities with post–germinal-center B cells.

The t(14;18) translocation involving *BCL2* and immunoglobulin heavy-chain gene has been detected in the GCB subtype, but not in the other subtypes. Previous studies have shown reduced disease-free survival in DLBCL cases with BCL2 overexpression, irrespective of the translocation. Although no absolute correlation between morphology and GEP has been established, interestingly, the majority of DLBCLs with centroblastic morphology falls into the GCB subtype, whereas those with immunoblastic morphology usually correlate with the ABC subtype.

DLBCL has an aggressive natural history but generally responds well to chemotherapy. The complete remission rate with modern regimens is 75–80%. Currently, with R-CHOP (rituximab–cyclophosphamide, doxorubicin, vincristine, and prednisone) regimen, the 10-year progression-free and overall survival rates for older patients with advanced-stage DLBCL are 36.5% and 43.5%, respectively.[23]

Immunophenotype-based algorithms using CD10/BCL6 positivity for GCB and MUM1/IRF4 expression for the ABC subtype have been proposed as surrogates for cDNA microarray; additionally, BCL2 and IPI are also informative to stratify the DLBCL cases. Because of the therapeutic impact, in the recent publication of the proposed changes in the WHO 2016 classification, it has been recommended that these two subtypes be identified, on the basis of either commonly used immunophenotype-based algorithms or GEP.

T cell/histiocyte–rich large B-cell lymphoma (THRLBCL) is a distinct clinicopathological entity, rather than a morphological variant. THRLBCL tends to occur in younger patients compared with other DLBCL, NOS, and often presents with advanced stage and bone marrow involvement with an aggressive clinical behavior.

The WHO classification recognizes that lymphomas arising from certain anatomical sites may have distinctive clinical and biological features. Among these are *primary DLBCL of the central nervous system* (CNS) and *primary cutaneous DLBCL, leg type.* Primary DLBCL of the CNS with some distinctive GEP features shares some similarities with DLBCL arising in other immune-privileged sites, such as the testis. Primary cutaneous DLBCL, leg type, has a GEP resembling the ABC subtype of DLBCL, presents most often in older females, and generally has an aggressive clinical course.

Several Epstein-Barr virus (EBV)–positive B-cell lymphoproliferations are often grouped with DLBCL. In the revised WHO 2016 classification, EBV-positive DLBCL, NOS[3] has now replaced a previous provisional entity "*EBV-positive DLBCL of the elderly*" in the 2008 WHO classification, since it may occur in younger patients with a broader morphological spectrum and better survival[24,25] as a consequence of decreased immune surveillance. These should be distinguished from EBV-associated atypical hyperplasia and lesions associated with iatrogenic or age-related immunosuppression, as well as those typified by an isolated and circumscribed cutaneous or mucosal presentation, with an indolent behavior and a self-limiting clinical course as EBV-positive mucocutaneous ulcer.[26] *Lymphomatoid granulomatosis* is an EBV-positive B-cell lymphoproliferative disorder (LPD) associated with an inflammatory background rich in T cells. The lung is nearly always involved; additionally, skin, kidneys, the liver, and the brain are frequently affected as well. *DLBCL associated with chronic inflammation* are EBV-driven large B-cell proliferations encountered in diverse clinical settings, usually associated with a confined anatomical space and a background of chronic inflammation. These cases appear to have a good prognosis if successfully resected.

Human herpes virus 6/Kaposi sarcoma herpes virus (HHV-8/KSHV)–associated LPDs are also documented. These include *primary effusion lymphoma* (PEL), *multicentric Castleman disease* (MCD), and lymphomas arising in the context of MCD. The cells of PEL are usually coinfected with EBV, and the disease is most often diagnosed in the setting of HIV infection and immunosuppression. Although pleural or peritoneal effusions are most common, extracavitary PEL can present as a tumor mass, usually in extranodal sites. PEL has a phenotype resembling terminally differentiated B cells (*i.e.,* plasmablastic).

Two other lymphomas with a plasmablastic phenotype include *plasmablastic lymphoma* (PBL) and *ALK-positive large B-cell lymphoma.* PBL is usually positive for EBV, most often extranodal, and is associated with immunosuppression from either human immunodeficiency virus (HIV) infection or advanced age. Recent studies have identified a high incidence of *MYC* translocation in PBL.[27] ALK-positive large B-cell lymphomas show overexpression of ALK, usually as a consequence of translocation. They mainly affect older individuals but can occur at any age.

Primary Mediastinal Large B-Cell Lymphoma

PMBCL has a distinct constellation of clinical and morphological features. PMBCL shows marked female gender predominance in adolescents and young adults. The clinical presentation is that of a rapidly growing anterior mediastinal mass with frequent superior vena cava syndrome and/or airway obstruction. Nodal involvement is uncommon at presentation and also at relapse. Frequent extranodal sites of involvement, particularly at relapse, include the liver, kidneys, adrenal glands, ovaries, the GI tract, and the CNS. The treatment approach includes aggressive systemic chemotherapy plus rituximab, along with radiation therapy used in some centers. A relatively abundant pale cytoplasm with distinct cytoplasmic membrane and fine compartmentalizing sclerosis are characteristic. The tumor appears to be derived from medullary B cells within the thymus gland. These cells express CD20 and CD79a, but not surface Ig. CD23 is frequently positive, and MUM-1/IRF4 coexpression is also common. A unique signature was identified by GEP in PMBCL that shared similarities with HL cell lines, including constitutive activation of the nuclear factor-κB and recurrent gains and amplification of c-Rel.[28] The expression of the *MAL* gene has been detected in PMBCL but not in other DLBCLs.

The 2008 WHO classification included borderline categories, one of which manifests features intermediate between DLBCL, especially PMBCL and classic HL (CHL) "gray-zone lymphomas."[29] A close relationship between PMBCL and CHL has been supported by GEP.[28] Tumor necrosis factor receptor–associated factor 1 expression and c-REL amplification also are seen in both types of neoplasms and could also be detected with appropriate immunohistochemical studies.

Gray-zone lymphomas are more common in males than females, present with bulky mediastinal masses, and appear to have a more aggressive clinical course compared with either PMBCL or CHL. Previously, methylation profiling showed a signature distinct from both CHL and PMBCL.[30] However, as shown by FISH studies, gray-zone lymphomas, PBMCL, and CHL all share a number of common cytogenetic aberrations, including gains at 2p16.1 (*REL/BCL11A* locus), 9p24.1 (*JAK2/PDL2*), and rearrangements of 16p13.13 (*CIITA*). DA-EPOCH R has been effective in both PMBL and DLBCL; however, it is not clear how these patients should be managed clinically, but they appear to benefit from combined modality therapy.[31,32]

CLINICAL PEARLS

Highly Aggressive Lymphomas

- More common in children
- Natural history similar to acute leukemia
- Successful treatment includes high-dose chemotherapy (induction, consolidation, and maintenance phases) with central nervous system prophylaxis

Burkitt Lymphoma

Burkitt lymphoma (BL) occurs most commonly in children and accounts for up to one-third of all pediatric lymphomas in the United States. Three clinical variants of BL are recognized—endemic, sporadic, and immunodeficiency-associated. The endemic cases are seen in equatorial Africa and mostly involve the jaw and other facial bones. African BL occurs in malaria-endemic regions. In non–malaria-endemic regions, such as the United States, extranodal sites are frequent, including the ileocecal region, ovaries, kidneys, or breasts. Bone marrow involvement is a sign of poor prognosis.

EBV has been shown to be a cofactor for the development of BL and shows varying degrees of positivity in the variant subtypes. BL is one of the more common tumors associated with HIV. It can present at any time during the clinical course and also can be the initial acquired immunodeficiency syndrome (AIDS)–defining illness. Recent GEP data have supported a common pathogenetic mechanism in cases of HIV infection and endemic malaria–related immunosuppression.

Cytologically, BL shows monomorphic medium-sized cells with round nuclei, multiple (2–5) basophilic nucleoli, and moderately abundant deeply basophilic cytoplasm. Cytoplasmic lipid vacuoles reflecting a high proliferation rate and apoptosis are frequent. It is the most rapidly growing of all lymphomas, with 100% of the cells in cell cycle at any time. The characteristic "starry sky" pattern of BL is a manifestation of the numerous benign macrophages that have ingested karyorrhectic or apoptotic tumor cells. BL has a mature B-cell phenotype, expressing CD19, CD20, CD22, CD79a, and monoclonal surface Ig, nearly always IgM. CD10 is positive in almost all cases, whereas CD5, CD23, and BCL2 are consistently absent.

The pathogenesis of BL is related to the *MYC* oncogene translocations seen in virtually 100% of cases. The *MYC* translocation is considered a primary event and often is the sole karyotypic abnormality detected. This is in contrast to other aggressive lymphomas, in which the *MYC* translocation occurs as a secondary event in a more complex karyotype.[33] Most of the translocations involve the *IGH* gene on chromosome 14 and, less commonly, the light-chain genes on chromosomes 2 and 22.

Recently, a subset with chromosome 11q alterations that morphologically, largely phenotypically, and by GEP resemble BL but lack *MYC* translocations has been described[34] as a new provisional entity "Burkitt-like lymphoma with 11q aberration" in the revised classification. Mutations in the transcription factor *TCF3* or its negative regulator *ID3* are present in approximately 70% of sporadic and immunodeficiency-related BL and 40% of endemic cases.

Few cases show GEP of BL but carry additional *BCL2* or *BCL6* cytogenetic abnormalities. These "double-hit" or "triple-hit" lymphomas have an aggressive clinical course and poor prognosis and are now reclassified from the previous borderline category of the 2008 WHO classification now as HGBL with and without *MYC* and *BCL2* or *BCL6* translocations (except for those fulfilling the criteria for follicular or lymphoblastic lymphoma).[3] Of note, the "double-hit" lymphoma are usually of GCB subtype, whereas "double expressors" are of the ABC subtype. However, this category should not be utilized for otherwise typical DLBCLs with a *MYC* translocation.

T-CELL AND NK-CELL NEOPLASMS

Overview of the Classification of T-Cell Neoplasms

Peripheral T-cell lymphomas (PTCLs) are uncommon, representing fewer than 10% of all non-HLs. The classification of PTCL has always been controversial. The genetic landscape of many entities has only recently been defined, and immunophenotypic markers are less specific for apparently distinct disease entities. For these reasons, the WHO classification relied, to a considerable extent, on clinical presentation to subdivide these tumors.[2]

Extranodal NK/T-Cell Lymphoma, Nasal Type

Extranodal NK/T-cell lymphoma, nasal type, is a distinct clinicopathological entity highly associated with EBV. It affects adults (median age 50 years), and the most common clinical presentation is a destructive nasal or midline facial lesion. Palatal destruction, orbital swelling, and edema can be prominent. NK/T-cell lymphomas have been reported in other extranodal sites, including skin, soft tissue, testes, the upper respiratory tract, and the GI tract. It is much more common in Asians and indigenous populations of the Americas than in those of European background, and this indicates that genetic factors play a role in the pathogenesis of these lymphomas.

Extranodal NK/T-cell lymphoma, nasal type, is characterized by a broad cytological spectrum. Although the cells express some T cell–associated antigens, most commonly CD2, other T-cell markers, such as surface CD3, are usually absent. Cytoplasmic CD3 is positive, but most cases lack clonal T-cell gene rearrangement. In favor of an NK-cell origin, the cells are nearly always CD56$^+$, although CD16 and CD57 are usually negative. EBV is invariably positive as shown by *in situ* hybridization.

The clinical features and treatment response of nonnasal extranodal NK/T-cell lymphoma are different from of those of nasal presentation of this lymphoma in that the addition of radiotherapy in early-stage nasal cases may offer a survival benefit.[35] A hemophagocytic syndrome is a common clinical complication and adversely affects survival. Emerging oncogenic pathways have been identified by GEP.

Aggressive NK-cell leukemia is a closely related entity with a similar phenotype, EBV association, and epidemiology. It presents at a younger age than extranodal NK/T-cell lymphoma, is associated with systemic disease, and has a fulminant clinical course.

There are other EBV$^+$ T-cell and NK-cell proliferations seen mainly in Asian children and in indigenous populations from Central and South Americas and Mexico. These show a broad range of clinical manifestations from indolent, localized forms involving skin, such as *hydroa vacciniforme-like lymphoproliferative disorder* (name changed from lymphoma) and *mosquito bite allergy,* the latter usually being derived from NK cells, to *systemic EBV$^+$ T-cell lymphoma* (name changed from lymphoproliferative disease),[3] a more systemic form characterized by fever, hepatosplenomegaly and lymphadenopathy with or without cutaneous manifestations[36] and a fulminant clinical course, and hemophagocytic lymphohistiocytosis.

Nodal T-Cell Lymphoma With T_{FH} Phenotype: Angioimmunoblastic T-Cell Lymphoma

Recently angioimmunoblastic T-cell lymphoma (AITL) has been grouped under an umbrella category "nodal T-cell lymphoma with T follicular helper cell (T_{FH}) phenotype" to highlight a spectrum of nodal lymphomas with T_{FH} phenotype, including follicular T-cell lymphoma and other nodal PTCLs with a T_{FH} phenotype, in addition to AITL.[3]

AITL presents in adults with generalized lymphadenopathy and prominent systemic symptoms, including fever, weight loss, and skin rash. Polyclonal hypergammaglobulinemia is usually seen.

Histologically, the nodal architecture is generally effaced, but peripheral sinuses are often open or dilated. Proliferation of high endothelial venules (HEVs) is often prominent. Follicles are regressed, but a proliferation of dendritic cells (DCs) often entrapping HEVs is typically seen. The atypical lymphoid cells have clear cytoplasm and are admixed with small lymphocytes, immunoblasts, plasma cells, and histiocytes, with or without eosinophils. A relationship to T_{FH} has been confirmed by GEP. The atypical T cells are usually positive for CD4, CD10, and PD-1, a phenotype characteristic of T_{FH}. Chemokine ligand-13 (CXCL-13), a chemokine involved in B-cell trafficking into the germinal centers, is also expressed. In keeping with an established derivation from T_{FH}, B-cell proliferation, including marked polyclonal plasmacytosis, is often seen. In some cases, the plasma cells may be monoclonal. Background EBV$^+$ B cells are almost constant, and progression to EBV$^+$ B-cell lymphoma may occur. The exact role of EBV in AILT is uncertain; however, plausible theories include expansion resulting from decreased immune surveillance. The majority of cases show clonal rearrangements of T-cell receptor (TCR) genes, but proliferation of B cells also contributes to the histological and clinical picture. Patients may initially respond to steroids or mild cytotoxic chemotherapy, but progression usually occurs. More aggressive combination chemotherapeutic regimens have led to a higher remission rate, but patients are prone to secondary infectious complications. The median survival is usually less than 5 years.

New genetic insights have shown recurrent mutations, including *TET2, IDH2, DNMT3A, RHOA,* and *CD28,* as well as gene fusions, such as *ITK-SYK* or *CTLA4-CD28,* which affect a significant proportion of PTCL, NOS cases with a T_{FH} phenotype, and AITL cases.

Peripheral T-Cell Lymphomas, Not Otherwise Specified

Peripheral T-cell lymphomas, not otherwise specified (PTCL, NOS) most often present in adults with generalized lymphadenopathy, hepatosplenomegaly, and frequent bone marrow involvement. It is a diagnosis of exclusion with most cases being nodal in origin. PTCLs are characterized by cytological and phenotypical heterogeneity. Most cases have a mature T-cell phenotype and express one of the major subset antigens, with CD4 expression seen more frequently than CD8. These are not clonal markers, and antigen expression can change over time. Loss of one of the pan-T-cell antigens (CD3, CD5, CD2, or CD7) is seen in two-thirds of cases, with loss of CD7 being most frequent.

Recently, GEP has shown a global signature close to one of the activated T lymphocytes and has identified at least three subtypes characterized by overexpression of *GATA3, TBX21,* and cytotoxic genes associated with a different clinical behavior and response to therapy. The clinical course is generally aggressive, especially with a high proliferation signature, with a lower response rate than that seen for aggressive B-cell lymphomas.

Anaplastic Large-Cell Lymphoma

Anaplastic large-cell lymphoma (ALCL) is most common in children and young adults, and more common in males than in females. Nodal presentations are most common; however, a variety of extranodal sites can be involved.

ALCL is characterized by pleomorphic or monomorphic cells that have a propensity to invade lymphoid sinuses. The cells of classic ALCL have large, often lobulated nuclei with small basophilic nucleoli. In some cases, the nuclei may be round. The cytoplasm is usually abundant and amphophilic and has distinct cytoplasmic borders, and a prominent Golgi region is generally visible.

The expression of the CD30 antigen is a hallmark of this disease. However, CD30 expression is not specific for ALCL and may also be seen in other forms of malignant lymphoma, including CHL. ALCL-ALK$^+$ is associated with a characteristic chromosomal translocation, t(2;5)(p23;q35), involving the *ALK* and *NPM* genes, respectively. A variety of other *ALK* partners have been identified and monoclonal antibodies to the ALK protein have been able to identify tumor cells regardless of the underlying translocation. The neoplastic cells show both nuclear and cytoplasmic staining in the majority of cases; the presence of cytoplasmic staining for ALK is suggestive of a variant translocation.

Immunohistochemistry is indispensable in the correct diagnosis of ALCL. The prominent Golgi region usually shows intense staining for CD30 and epithelial membrane antigen (EMA). The cells exhibit an aberrant phenotype with loss of many of the T cell–associated antigens. Both CD3 and CD45RO, the most widely used pan-T-cell markers, are negative in >50% of cases. CD2 and CD4 are positive in the majority, whereas CD8 is usually negative. ALCL cells, despite the CD4$^+$/CD8$^-$ phenotype, often express the cytotoxic-associated antigens (TIA-1, granzyme B, and perforin). In addition, clusterin is generally present in ALCL and represents another useful diagnostic marker. Molecular studies in most cases demonstrate TCR rearrangement, confirming a T-cell origin.

Improved criteria now exist for the recognition of ALK-negative ALCL as a separate entity. It occurs in an older age group compared with the ALK-positive cases. Recently, a unique form of ALK-negative ALCL arising in association with breast implants has been identified,[37] with a medial interval from time of implant to lymphoma of about 10 years. Confinement of the neoplastic cells to the seroma fluid without capsule invasion portends a favorable prognosis.

Recently GEP studies have shown that ALK-negative ALCLs have a signature close to that of ALK-positive counterparts, but distinct from other NK/T-cell lymphomas. Genetic studies have shown convergent mutations and kinase fusions leading to constitutive activation of the JAK/STAT3 pathway. The overall survival and disease-free survival are significantly better in ALK-positive cases than in ALK-negative cases. Clinical or prognostic variations exist in ALK-negative ALCLs—a subset with rearrangements at the *DUSP22* and *IFR4* locus on 6p25 has a superior prognosis, whereas a small subset with *TP63* rearrangements is very aggressive.

Primary Cutaneous ALCL

Primary cutaneous ALCL is closely related to lymphomatoid papulosis (LyP) and differs at the clinical, immunophenotypic, and molecular levels from the systemic form. Indeed, LyP and cutaneous ALCL represent a histological or clinical continuum of CD30$^+$ cutaneous lymphoproliferative diseases. Small lesions are likely to regress, whereas patients with large tumor masses may develop disseminated disease with lymph node involvement—a period of observation is usually warranted before the institution of any chemotherapy for isolated lesions. Most patients with primary cutaneous ALCL have multiple skin lesions, but it is a more indolent disease compared with other T-cell lymphomas of the skin. Cutaneous ALCL is CD30$^+$ but is usually ALK-1– and EMA-negative, and it also lacks the t(2;5) translocation. More recently, LyP variants D-E and LyP with 6p25 have been described; appreciation of these variants is important as they can mimic aggressive T-cell lymphoma histologically but clinically are similar to other forms of LyP A-C.

Subcutaneous Panniculitis-Like T-Cell Lymphoma

Subcutaneous panniculitis-like T-cell lymphoma (SPTCL) usually presents with subcutaneous nodules primarily affecting the extremities. In its early stages, the infiltrate may appear deceptively benign, and lesions are often misdiagnosed as panniculitis. However, histological progression usually occurs, and subsequent biopsies show more pronounced cytological atypia.

The neoplastic cells are CD8$^+$ cytotoxic α/β T cells. They are also positive for the cytotoxic proteins perforin, granzyme B, and TIA-1 that may be responsible for the cellular destruction seen in these tumors. EBV is negative. Some PTCL of γ/δ T-cell derivation may show similar features but differ from SPTCL in their clinical behavior (more aggressive) and histological pattern, as they are often not confined to the subcutis.

Some patients have a history of autoimmune disease, and in particular, the differential diagnosis of SPTCL with lupus profundus panniculitis can be challenging. Unlike SPTCL, lupus panniculitis usually contains abundant plasma cells, a mixture of CD4$^+$ and CD8$^+$ cells, and a relative increase of γ/δ T cells and plasmacytoid DCs.

A hemophagocytic syndrome can be a complication of SPTCL but is more often associated with γ/δ T-cell lymphomas involving the subcutaneous tissue. Patients present with fever, pancytopenia, and hepatosplenomegaly. It is most readily diagnosed in bone marrow aspirate smears, where histiocytes containing erythrocytes, platelets, and other blood elements may be observed. The hemophagocytic syndrome usually heralds a fulminant downhill clinical course.

Primary Cutaneous γ/δ T-Cell Lymphomas

Primary cutaneous γ/δ T-cell lymphomas are clinically aggressive tumors that can present with involvement of the subcutis and the dermis or with epidermal infiltration. Skin is the most common presenting site, however, similar lymphomas of γ/δ T-cell origin can present in other extranodal sites, including the GI tract and lungs. The cells have a cytotoxic phenotype and express cytotoxic molecules, and like normal γ/δ T cells, lack CD5. They may be CD8^{+} or, more often, double-negative for CD4 and CD8. Few cutaneous γ/δ T-cell lymphomas appear to be TCR silent (negative for both TCR-β and TCR-γ) but share the same aggressive clinical behavior. Recurrent mutations of *STAT5B* can be seen in T-cell lymphomas of γ/δ origin.[38]

Mycosis Fungoides and Sézary Syndrome

Mycosis fungoides (MF) and Sézary syndrome (SS) are closely related and often considered together from a clinical and biological standpoint but are now regarded as separate diseases. Both are primary cutaneous T-cell malignancies derived from mature skin homing CD4 T cells. Epidermotropism is the hallmark of MF; infiltration of the epidermis produces characteristic Pautrier microabscesses. The cutaneous lesions are categorized as patches, plaques, and tumors, based on the extent of the infiltrate. A γ/δ indolent variant of MF has also been described. SS presents with exfoliative erythroderma and circulating cerebriform lymphocytes known as *Sézary cells.* Clinically, SS is more aggressive than MF.

Enteropathy-Associated T-Cell Lymphoma

Enteropathy-associated T-cell lymphoma (EATL) is highly associated with celiac disease on a worldwide basis. This disease occurs in adults; the majority has either overt or clinically silent gluten-sensitive enteropathy (Chapter 75). Ulcerative jejunitis may precede the development of overt EATL and may share a common clonal T-cell population as with the subsequent lymphoma. The small bowel usually shows ulceration with frequent perforation, with or without a mass. EATL shows a cytological composition of variably sized or polymorphic atypical lymphoid cells. The adjacent small bowel usually shows villous atrophy associated with celiac disease. The neoplastic cells are CD3^{+}, CD7^{+} T cells that also express the homing receptor CD103. Anaplastic cells strongly positive for CD30 can be present. The cells express cytotoxic molecules, a feature shared by nearly all extranodal T-cell lymphomas. The majority belong to the α/β TCR subset, whereas only a minority expresses the γ/δ TCR. Other PTCLs can present with intestinal disease, including EBV^{+} extranodal T/NK-cell lymphomas and γ/δ T-cell lymphomas, and should be distinguished from EATL. The clinical course is aggressive.

The disease previously known as *EATL type II* has been now been formally designated as *monomorphic epitheliotropic intestinal T-cell lymphoma* (MEITL); it shows no association with celiac disease and appears to have an increased incidence in Asian and Hispanic populations. Unlike classic EATL, MEITL is monomorphic, usually positive for CD8, CD56, and MAPK.[39] *STAT5B* mutations are common in MEITL cases, many of which are of γ/δ T-cell origin.

Hepatosplenic T-Cell Lymphoma

Hepatosplenic T-cell lymphoma (HSTCL) shows a marked male gender predominance, and most patients are young adults. The clinical presentation is that of marked hepatosplenomegaly in the absence of lymphadenopathy.

The liver and the spleen show marked sinusoidal infiltration, with sparing of both portal triads and white pulp, respectively. The homing pattern manifested by the malignant cells is similar to that of normal γ/δ T cells, which also populate the sinusoidal areas of the spleen. The neoplastic cells have a phenotype that resembles normal γ/δ T cells, usually expressing neither CD4 nor CD8. CD56 is often positive. The cells are positive for the cytotoxic protein TIA-1, but are not activated and generally lack granzyme B and perforin. *In situ* hybridization for EBV is negative. The recognition of the atypical cells in bone marrow is greatly aided by immunohistochemical stains showing a sinusoidal pattern of infiltration.

Isochromosome 7 is a consistent cytogenetic abnormality, usually seen in conjunction with trisomy 8. Rare cases derived from α/β T cells but with similar morphological and biological features can be seen. Recurrent mutations of *STAT5B* and less often *STAT3* are seen in HSTCL of γ/δ origin.[38]

Clinically, HSTCL is aggressive. Although patients may respond initially to chemotherapy, relapse occurs in the vast majority of cases. The median survival is less than 3 years. Allogeneic bone marrow transplantation is required for sustained remission.

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma (ATLL) is a distinct form of T-cell lymphoma associated with the retrovirus human T-lymphotropic virus-1 (HTLV-1). The highest number of cases is seen in Southwestern Japan and the Caribbean basin. The disease has a long latency, and affected individuals are usually exposed to the virus very early in life. The virus may be transmitted in breast milk and through exposure to blood or blood products. The cumulative incidence of ATLL is estimated to be 2.5% among HTLV-1 carriers. The virus is monoclonally integrated into tumor DNA. Different clinical variants of ATLL, including the acute, lymphomatous, chronic, and smoldering types, have been recognized. Cutaneous involvement is seen in the majority of patients.

Peripheral blood involvement is very common, often without bone marrow disease. The atypical cells are often markedly polylobated and have been referred to as "flower" cells. The cells have a characteristic phenotype that resembles T-regulatory cells (Tregs)—CD3^{+}, CD4^{+}, and CD25^{+}. FoxP3 is expressed in a minority of tumor cells. The function of the tumor cells as Tregs may correlate with the associated immunodeficiency.

Somatic gain of function *CCR4* mutations have been implicated in the pathogenesis of ATLL.[40] Recent integrated molecular analysis has shown frequent intragenic deletions and mutations of key T-cell signaling molecules in ATLL.[41]

CLINICAL PEARLS

Hodgkin Lymphoma

- B-cell lineage established in nearly all cases
- Reed-Sternberg cell, the hallmark of the disease, represents a "crippled" germinal-center B cell
- Nodular lymphocyte-predominant Hodgkin lymphoma considered a related but distinct entity
- Eighty percent of patients are curable with current therapy
- Stage of disease guides the choice of therapy; even patients with advanced-stage disease may be cured
- Late complications from treatment include acute leukemia (alkylating agents with extended-field radiation therapy), second solid tumors (radiation therapy), and premature atherosclerotic coronary artery disease (radiation therapy)
- Cause of death in the first 5–10 years is mainly Hodgkin lymphoma; after 10 years, mainly secondary malignant tumors

HODGKIN LYMPHOMAS

HL and non-HL have long been regarded as distinct disease entities on the basis of their differences in pathology, phenotype, clinical features, and response to therapy. It is now accepted that the malignant cell of HL is an altered B cell. Therefore it is not surprising that biological and clinical overlap occurs between these two lymphoma groups, as also shown by GEP in PMBCL and classic Hodgkin cell lines. In spite of the close histogenetic relationship (hence the name *Hodgkin lymphoma*), these disorders are still treated with different modalities.

The diagnosis of classic HL (CHL) depends on the identification of Hodgkin/Reed–Sternberg (HRS) cells in an appropriate inflammatory background composed of small T lymphocytes, plasma cells, histiocytes, and granulocytes (often eosinophils). All cases of CHL share certain immunophenotypic and genotypic features. The phenotype is $CD30^+$, $CD15^{+/-}$, $CD45^-$, and EMA^-. Expression of B cell–associated antigens is seen in up to 75% of cases; however, when present, CD20 staining is usually weaker or more variable than that seen in normal B cells. CD79a is usually negative. Ig and TCR genes are usually germline because of the paucity of tumor cells in the inflammatory background; however, microdissection can enable amplification for clonal rearrangement of the Ig genes by polymerase chain reaction (PCR). In addition, the presence of somatic mutations indicates transit through the germinal center.

Sufficient evidence has emerged in recent years to warrant the recognition of nodular lymphocyte-predominant HL as a distinct entity. Although it resembles other types of HL in having a minority of putative neoplastic cells in a background of benign inflammatory cells, it differs morphologically, immunophenotypically, and clinically from CHL. The preferred term *Hodgkin lymphoma,* versus *Hodgkin disease,* reflects current knowledge concerning the nature of the neoplastic cell as a lymphocyte.

Nodular Lymphocyte-Predominant Hodgkin Lymphoma

Nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) occurs at all ages but is more common in adult males. It usually involves peripheral lymph nodes with sparing of the mediastinum and is localized at diagnosis, although rarely it may be disseminated. NLPHL usually has a nodular growth pattern, with or without diffuse areas. The number of infiltrating reactive T cells is variable, and various patterns have been described on the basis of the cellular composition and growth pattern.[42] The atypical cells have vesicular, polylobated nuclei and small nucleoli. These had been called *lymphocytic and/or histiocytic (L&H) cells,* or “popcorn” cells, but the term *lymphocyte-predominant (LP) cell* is now preferred. LP cells differ from classic HRS cells. The background is composed predominantly of lymphocytes with or without clusters of epithelioid histiocytes. Plasma cells are infrequent; eosinophils and neutrophils are also rare. The atypical cells are $CD45^+$, positive for B cell–associated antigens (CD19, CD20, CD22, CD79a), $CDw75^+$, $EMA^{+/-}$ $CD15^-$, $CD30^{-/+}$ and usually sIg^-, as shown by routine techniques. Small lymphocytes in the nodules are predominantly B cells with a mantle zone phenotype. However, numerous T cells are present, with $CD279^+$ T cells “rosetting” the LP cells. The proportion of T cells tends to increase over time in sequential biopsies. A prominent follicular DC meshwork is present within the nodules. LP cells, when microdissected, have shown to have clonally rearranged immunoglobulin genes with evidence of somatic hypermutation.

Survival for localized cases with or without treatment is long. However, cases with variant histology are more likely to have advanced stage disease with a higher relapse rate.[43] Moreover, patients with advanced-stage disease respond poorly to HL regimens, such as adriamycin, bleomycin, vinblastine, dacarbazine (ABVD), and benefit from treatment for aggressive B-cell lymphoma.[44] Although considered two separate entities with major differences, NLPHL shares immunomorphological similarities with THRLBCL; these similarities have also been shown by GEP and array comparative genomic hybridization. Two forms of histological progression can be seen, either to DLBCL or to a process resembling THRLBCL.

Classic Hodgkin Lymphoma, Nodular Sclerosis

This variant of HL, classic Hodgkin lymphoma, nodular sclerosis (CHLNS) is most commonly seen in adolescents and young adults but can occur at any age. Female cases equal or exceed those in males. The mediastinum is commonly involved; stage and bulk of disease have prognostic importance.

The tumor has at least a partially nodular pattern, with fibrous bands separating the nodules in most cases. Diffuse areas with necrosis may be present. The characteristic cell is the “lacunar-type” Reed-Sternberg (RS) cell, which may be very numerous. Diagnostic RS cells are usually also present. The background contains lymphocytes, histiocytes, plasma cells, eosinophils, and neutrophils. Grading (I and II) is based on the proportion of the tumor cells and the presence of necrosis but is considered optional. The immunophenotype and genotype are characteristic of CHL. However, EBV is infrequently positive— less than 15% of cases.

CHLNS is often curable; however, in long-term survivors, the risk of secondary malignancies is increased, especially in those receiving both chemotherapy and radiation. CHLNS of the mediastinum is thought to be closely related to PMBCL, and both types of tumors can be seen in the same patient, either as composite malignancy or sequentially.

Classic Hodgkin Lymphoma, Mixed Cellularity

Classic Hodgkin lymphoma, mixed cellularity (CHLMC) is predominantly seen in male adults. A bimodal age distribution, with peaks in young children and later in older adults can be present. Both CHLMC and the lymphocyte-depleted form (see below) can be associated with underlying HIV infection. The infiltrate is diffuse without band-forming sclerosis, although fine interstitial fibrosis may be present (Fig. 79.4). HRS cells are of the classic type. It is often EBV-positive, seen in up to 75% of cases. The stage is often advanced at diagnosis. The clinical course is moderately aggressive, but is often curable.

Classic Hodgkin Lymphoma, Lymphocyte Depletion

Classic Hodgkin lymphoma, lymphocyte depletion (CHLLD) is the least common variant of CHL and is most common in older people, in HIV-positive individuals, and in populations of nonindustrialized countries. It frequently presents with abdominal lymphadenopathy, and spleen, liver, and bone marrow involvement, but without peripheral adenopathy. The infiltrate is diffuse and often appears hypocellular because of the presence of diffuse fibrosis and necrosis. A large number of HRS cells and occasional bizarre “sarcomatous” variants are seen relative to the fewer number of normal lymphocytes and scarce other inflammatory cells. The immunophenotype is characteristic of CHL. Since the

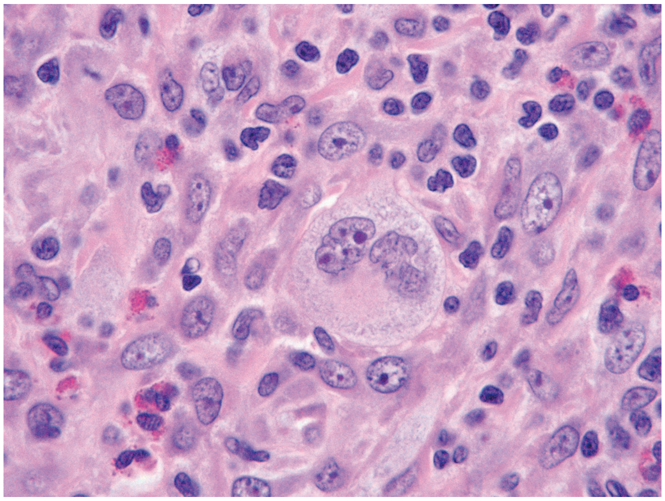

FIG 79.4 **Classic Hodgkin Lymphoma, Mixed Cellularity Subtype.** A classic Reed-Sternberg cell is shown in a mixed inflammatory background with eosinophils, plasma cells, histiocytes, and small lymphocytes.

histological differential diagnosis often includes B- or T-large-cell lymphoma or ALCL, immunohistochemistry should be performed in most cases. EBV is positive in the majority of cases. The stage is usually advanced at diagnosis.

Classic Hodgkin Lymphoma, Lymphocyte-Rich

Classic Hodgkin lymphoma, lymphocyte-rich (CHLLR) may be nodular or diffuse and contains relatively infrequent classic HRS cells. Eosinophils and plasma cells are rare. In the nodular form, the HRS cells are seen at the periphery of B cell–rich nodules, mainly in the marginal zone. CHLLR has some features that are intermediate between other CHL and NLPHL.[45] Immunophenotypically, the neoplastic cells resemble classic HRS cells, but morphological distinction from LP cells may be difficult in some cases. Thus, in the past, many cases were misdiagnosed as NLPHL. However, patients usually present with localized disease and tend to be older than patients with NLPHL. The genetic features are similar to other variants of CHL.

ON THE HORIZON

- In recent years, there has been a greater appreciation of early events in lymphoid neoplasia.
- These early lesions in some ways can be considered equivalent to benign neoplasms in the epithelial system.
- These are clonal proliferations of B or T cells that carry genetic aberrations associated with specific forms of lymphoid neoplasia: chronic lymphocytic leukemia, multiple myeloma, follicular lymphoma, mantle cell lymphoma.
- Examples include monoclonal gammopathy of undermined significance, monoclonal B-lymphocytosis, *in situ* mantle cell neoplasia, *in situ* follicular neoplasia, lymphomatoid papulosis, patch stage of mycosis fungoides.
- Early lesions appear to lack the secondary and tertiary "hits" seen in lymphoid neoplasms that are clinically significant, and most patients have a very low risk of clinical progression.
- Current focus is to define the precise genetic features that distinguish early lesions from lymphoma, assess the risk of clinical progression, and determine their clinical management.

MULTIPLE-CHOICE QUESTIONS

1. In the diagnostic workup of a diffuse large B-cell lymphoma, which markers are helpful in the identification of the cell of origin?
   A. CD10/BCL6/MUM1
   B. CD10/P53/MIB-1
   C. CD10/BCL2/MUM1
   D. CD10/BCL6/MIB1

2. The presence of MYD88 L265P mutation is associated with the diagnosis of:
   A. Mantle cell lymphoma
   B. Follicular lymphoma
   C. Chronic lymphocytic leukemia
   D. Lymphoplasmacytic lymphoma
   E. Multiple myeloma

3. Which of the following lymphomas are typically associated with Epstein-Barr virus (EBV) positivity?
   A. Enteropathy-associated T-cell lymphoma
   B. Extranodal natural killer (NK)-/T-cell lymphoma, nasal type
   C. Hepatosplenic T-cell lymphoma
   D. Anaplastic large-cell lymphoma, ALK positive
   E. Anaplastic large-cell lymphoma, ALK negative

Monoclonal Gammopathies

Kazunori Murata, Samuel McCash, C. Ola Landgren

Monoclonal gammopathies are a group of disorders characterized by the proliferation of a single clone of plasma cells. These plasma cells produce an immunologically homogeneous immunoglobulin, or parts thereof, also known as an M (for monoclonal) protein.

This chapter covers 12 recognized types of monoclonal gammopathies: monoclonal gammopathy of undetermined significance (MGUS); multiple myeloma (MM); smoldering multiple myeloma (SMM); nonsecretory/oligosecretory myeloma; plasma cell leukemia (PCL); solitary plasmacytoma of bone (SPB); solitary extramedullary plasmacytoma (SEP); polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes (POEMS) syndrome; Waldenström macroglobulinemia (WM); heavy chain disease (HCD); light chain amyloidosis (AL); and monoclonal immunoglobulin deposition disease. These disorders differ in the types of monoclonal proteins that are generated by the diseased cell. The proteins involved include immunoglobulin (Ig)-G, IgA, IgM, IgD, IgE, kappa or lambda light chains only, and immunoglobulin heavy chains only.

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

MGUS is a clinically asymptomatic premalignant clonal plasma cell or lymphoplasmacytic proliferative disorder. It is defined by the presence of the following characteristics: the presence of an M-protein in the serum at a concentration <3 g/dL, bone marrow with <10% monoclonal plasma cells, and the absence of end-organ damage related to the lymphoproliferative process. There are three distinct clinical types of MGUS: non-IgM MGUS, IgM MGUS, and light chain MGUS (LC-MGUS).

Epidemiology

MGUS occurs in approximately 1–2% of adults and >2% of the general Caucasian population above the age of 50. The mean age at diagnosis is 70 years with <2% of patients diagnosed before the age of 40. The incidence increases with age, and the prevalence of MGUS in persons ≥50, ≥70, and ≥85 years of age is 3.2%, 5.3%, and 7.5%, respectively.[1]

Men are at higher risk of developing MGUS compared with women (4.0% versus 2.7%). The incidence of MGUS in men is estimated to be 120/100 000 at age 50, increasing to 530/100 000 by the age of 90, whereas the incidence rate for women is estimated to be 60/100 000 at age 50, increasing to 370/100 000 by the age of 90. Race is also a risk factor, with the incidence of MGUS being 1.5- to 3-fold higher in Africans and African Americans compared with Caucasians.[1]

Most cases of MGUS are sporadic. However, relatives of persons with MGUS (or MM) have an increased risk of developing MGUS and related diseases. Acquired angioedema is closely associated with MGUS, being identified in approximately one-third of acquired angioedema patients.[1]

Clinical Presentation and Laboratory Findings

By definition, all patients with MGUS have no myeloma-associated symptoms attributable to the proliferation of plasma cells or the presence of the monoclonal protein. Non-IgM and IgM MGUS are characterized by the presence of an M-protein produced and secreted by clonal plasma cells. These proteins can be detected in serum using either protein electrophoresis or immunofixation electrophoresis as well as in a sample from a 24-hour urine collection using the same methods.

The quantity of monoclonal protein in all cases of MGUS is defined as <3 g/dL in the serum. Serum immunofixation electrophoresis (SIF) is used to confirm the presence of an M-protein and to determine its type. The clonal immunoglobulin distribution in MGUS varies according to isotype: IgG 69%, IgM 17%, IgA 11%, IgD <1%, and biclonal 3%.[2]

IgD MGUS is extremely rare with only two cases having been reported. Thus finding an IgD M-protein is almost always associated with the diagnosis of MM, light chain amyloid, or PCL. Biclonal MGUS is also uncommon, representing only 3% of patients with MGUS. Approximately one-third of MGUS patients will have a decrease in the concentration of the uninvolved immunoglobulin isotypes (e.g., IgM and IgA in the case of IgG MGUS), with many demonstrating a reduction in the normal polyclonal circulating immunoglobulins.[1]

Serum free light chain (sFLC) assays can detect low concentrations of monoclonal free light chain in patient serum. This technique can be used to diagnose light chain MGUS and to predict the risk of the progression of MGUS. A monoclonal light chain can also be found in the urine of approximately 20% of MGUS patients.[1]

The complete blood count and peripheral smear are typically normal. Infrequently, rouleaux formation (the phenomenon in which red cells take on the appearance of stacked coins in diluted suspensions of blood) is seen, and this is typically observed in those MGUS patients with elevated serum protein levels. Circulating plasma cells of the same isotype can be seen in peripheral blood of some patients with MGUS using a slide-based immunofluorescence assay or flow cytometry.[1]

By definition, a bone marrow aspirate and biopsy must demonstrate fewer than 10% clonal plasma cells. For IgM

MGUS, clonal lymphoplasmacytic cells must constitute <10% infiltration.

Conventional cytogenetics are normal in patients with MGUS due to technical limitations, a low proliferative rate, and the small number of plasma cells within the bone marrow samples. However, studies using more sensitive methods have shown that chromosomal abnormalities are very common in the clonal cells found in MGUS. Analysis by interphase fluorescent *in situ* hybridization (FISH) demonstrate chromosomal aneuploidy, in particular hyperdiploidy, in approximately 50% of patients with MGUS.[1]

Diagnosis

Diagnostic criteria for each of the individual types of MGUS are determined by the International Myeloma Working Group (IMWG) and are detailed in Table 80.1.[3]

Clinical Course

The clinical course of MGUS depends largely on the specific type.[4] In non-IgM MGUS a minority of cases will progress to the more advanced premalignant stage SMM and to symptomatic MM. Less frequently, these patients progress to light chain amyloidosis, light chain deposition disease (LCDD), or another lymphoproliferative disorder. IgM MGUS can progress to smoldering WM (SWM) and to symptomatic WM. IgM MGUS also infrequently progresses to IgM MM. LC-MGUS may progress to idiopathic Bence-Jones proteinuria, light chain MM, AL amyloidosis, or LCDD.

TABLE 80.1 IMWG Diagnostic Criteria for MGUS by Type

Non-IgM MGUS

1. The presence of a serum monoclonal protein (M-protein, whether IgA, IgG, or IgD) at a concentration <3 g/dL.
2. Fewer than 10% clonal plasma cells in the bone marrow.
3. The absence of lytic bone lesions, anemia, hypercalcemia, and renal insufficiency related to the plasma cell proliferative process.

IgM MGUS

1. The presence of a serum IgM monoclonal protein at a concentration <3 g/dL.
2. Fewer than 10% clonal lymphoplasmacytic/plasma cells in the bone marrow.
3. The absence of end-organ damage such as anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly related to the plasma cell proliferative process.

Light Chain MGUS

1. The presence of an abnormal free light chain ratio (*i.e.*, ratio of kappa to lambda free light chains <0.26 or >1.65).
2. Increased level of the appropriate involved light chain (*e.g.*, increased kappa FLC in patients with a ratio >1.65 and increased lambda FLC in patients with a ratio <0.26).
3. No monoclonal immunoglobulin heavy chain (IgG, IgA, IgD, or IgM).
4. Fewer than 10% clonal lymphoplasmacytic cells in the bone marrow.
5. The absence of lytic bone lesions, anemia, hypercalcemia, and renal insufficiency related to the plasma cell proliferative process.

Source: International Myeloma Working Group. Criteria for the classification of monoclonal gammopathies, multiple myeloma and related disorders: a report of the International Myeloma Working Group. Br J Haematol 2003;121(5):749–57. PubMed PMID: 12780789.

Patients with MGUS progress to a symptomatic plasma cell proliferative disorder or lymphoproliferative disorder at a rate of 1% per year. However, not all persons with MGUS have the same risk of disease progression. The risk of progression to a more serious disease ranges widely from 0.6–3.4%/year based on the initial value of serum monoclonal protein as well as from 0.25–2.9%/year according to a risk stratification model.[4] Three adverse risk factors have been combined to create a risk stratification model that is useful in predicting progression of MGUS (non-IgM and IgM) to MM or a related malignancy[5]: The findings that generate a less favorable outcome include serum monoclonal protein level ≥1.5 g/dL, non-IgG MGUS, and abnormal serum free light chain ratio (kappa/lambda free light chain ratio <0.26 or >1.65).

The stratified absolute chance of disease progression over 20 years is 58% for high-risk MGUS associated with all three risk factors, 37% for high- or intermediate-risk MGUS based on two risk factors, 21% for low- or intermediate-risk MGUS associated with one risk factor, and 5% for low-risk MGUS based on no risk factors.[5] Risk factors for progression of LC-MGUS have yet to be defined.

KEY CONCEPTS

MGUS

- A premalignant clonal plasma cell/lymphoplasmacytic proliferative disorder.
- Asymptomatic by definition.
- Defined by the presence of a monoclonal protein (M-protein) in the serum or bone marrow with <10% monoclonal plasma cells and absence of end-organ damage related to the proliferative process.
- Three types of MGUS: non-IgM MGUS, IgM MGUS, and light chain MGUS.
- Progresses to a symptomatic plasma cell proliferative disorder or lymphoproliferative disorder at a rate of 1% per year.
- Patients with MGUS should not be treated but instead monitored for signs of progressive disease.

Management and Prognosis

Patients with MGUS should be followed over time with history and physical examination for signs and symptoms of progressive disease. Treatment of MGUS has not been shown to have any effect on mortality, and, as noted above, only a minority of patients will progress to symptomatic disease over a set time interval.[4] All other patients are followed with annual serum and urinary M-protein, complete blood count, creatinine, and serum calcium.[4] It has been observed that patients with MGUS are at increased risk of fracture and thromboembolic disease. Patients with MGUS should be evaluated for osteoporosis with a dual-energy X-ray absorptiometry (DEXA) scan and have their vitamin D and calcium intake optimized.[4]

MULTIPLE MYELOMA

MM is the neoplastic proliferation of a single clone of plasma cells producing an M-protein. The difference between MM and MGUS lies in the presence of detectable end-organ damage caused by the proliferation of plasma cells and/or the overproduction of M-protein. The proliferation of plasma cells in MM causes skeletal bone destruction, primarily in the axial skeleton, and may also result in anemia. Myeloma patients often present with pain and hypercalcemia caused by osteolytic lesions and/or pathological fractures. Overproduction of M-protein over time can contribute to renal failure, hyperviscosity syndrome, and/or recurrent bacterial infections.

Epidemiology

MM accounts for approximately 1% of all cancers and slightly more than 10% of hematological malignancies in the United States. The annual incidence in the United States is approximately 4 to 5 per 100 000. The incidence of MM in people of African background is two to three times that in Caucasians, whereas the risk is lower in Japanese and in Mexicans. MM is also slightly more frequent in men than in women with an incidence ratio of approximately 1.4 : 1. The median age at diagnosis is 66 years; only 10% and 2% of patients are diagnosed before 50 and 40 years, respectively. The risk of developing MM is approximately 3.7-fold higher for persons with a first-degree relative diagnosed with MM.[6]

Clinical Presentation

Most patients with MM present with signs and symptoms related to the infiltration of plasma cells into the bone or other organs as well as kidney damage from excess light chains. Patients often complain of fatigue and display pallor upon physical examination.[6]

Bone pain, particularly in the back or chest, and less often in the extremities, is present at the time of diagnosis in approximately 60% of patients. The pain is usually induced by movement and does not occur at night except with change of position. The patient's height may be reduced by several inches as a result of vertebral collapse. Plasmacytomas of the ribs occur and can present either as expanding costal lesions or soft-tissue masses.[6] Radiculopathy, usually in the thoracic or lumbosacral area, is the most common neurological complication of MM and is due to compression of the nerve by a paravertebral plasmacytoma or, in rare instances, by the bone collapse itself.[6]

Extramedullary plasmacytomas (EP) are seen in approximately 7% of patients with MM at the time of diagnosis. An additional 6% of patients will develop EP later during the course of disease, and these can present as large, purplish subcutaneous masses. Spinal cord compression from an extramedullary plasmacytoma or a bone fragment due to fracture of a vertebral body occurs in approximately 5% of patients. Intracranial plasmacytomas are rare and almost always represent extensions of myelomatous lesions of the skull or plasmacytomas involving the clivus or base of the skull.[6] Patients with MM are at increased risk for infection with *Streptococcus pneumoniae* and gram-negative organisms representing the most frequent pathogens.[6]

Laboratory Findings

Biochemical Tests

The serum creatinine concentration is increased in almost one-half of patients at diagnosis. Hypercalcemia was found in 28% of one series of patients with MM at the time of diagnosis. Serum calcium greater than 11 mg/dL has been found in 13% of patients and can require emergent treatment. Elevation of the serum calcium may be due to binding of the monoclonal protein to calcium. A low anion gap may be present due to severe hypercalcemia and the presence of a cationic IgG molecule.[6]

The vast majority (97%) of patients with MM will have an M-protein produced and secreted by the malignant plasma cells. M-proteins can be detected by protein electrophoresis of the serum (SPEP) and/or of urine (UPEP) from a 24-hour collection combined with SIF and urine (UIF).[6] SPEP will demonstrate a localized band or peak in 82% of patients with myeloma (Figs. 80.1 and 80.2).

Addition of serum protein immunofixation electrophoresis increases the sensitivity to 93%. Adding either the sFLC assay or urine monoclonal protein studies (UPEP and UIF) increases the diagnostic sensitivity to 97% or more. The very rare patient who lacks detectable M-protein by any of these tests is considered to have "nonsecretory myeloma." Among the 20% with no localized band on SPEP, hypogammaglobulinemia is seen in approximately one-half, with no apparent abnormality in the remainder.[6]

SIF confirms the presence of an M-protein and determines its type. The malignant plasma cells can produce a complete clonal immunoglobulin molecule consisting of heavy and light chains, light chains alone, or neither, with the following frequencies on serum immunofixation electrophoresis: IgG 52%, IgA 21%, IgD 2%, IgM 0.5%, biclonal 2%, kappa or lambda light chain only 16%, and negative 17%.[7]

Kappa is the predominant light chain compared with lambda by a ratio of 2 to 1, with the exception that lambda light chains are more common in IgD myeloma and myeloma associated with amyloidosis. The level of one of the major uninvolved immunoglobulins (*i.e.*, IgM or IgA in the case of IgG myeloma) is reduced in 91% of patients overall, and both isotypes are reduced in 73%. Up to 20% of myeloma patients have only monoclonal light chains in the serum or urine. Approximately 3% of patients with MM have no M-protein in the serum or urine on immunofixation at the time of diagnosis. In approximately 60% of patients with myeloma who have a normal serum and urine immunofixation, monoclonal sFLC can be detected in the serum using FLC assays.[6] M-proteins can increase the serum viscosity and erythrocyte sedimentation rate (ESR). The ESR is >20 mm/h in 84% and >100 mm/h in one-third of patients with MM.

The sFLC assay measures kappa and lambda light chains that are unbound to heavy chains in the serum. These assays typically report out three values: quantitation of free kappa chains, quantitation of free lambda chains, and the kappa/lambda ratio. The kappa/lambda ratio is obtained by dividing the free kappa value by the free lambda quantitation (For example, the kappa/lambda ratio of a patient with a kappa value of 6.32 mg/dL and a lambda value of 0.51 mg/dL would have a kappa/lambda ratio of 12.4). The kappa/lambda ratio currently plays a key role in the diagnosis and management of patients with monoclonal gammopathies. The normal kappa/lambda FLC ratio is 0.26 to 1.65. Abnormal FLC ratios outside this range are usually seen in clonal plasma cell disorders when there is excess production of one type of light chain (kappa or lambda). Abnormal FLC ratios are seen in approximately 90% of patients with MM. Patients with otherwise asymptomatic myeloma who have an involved/uninvolved FLC ratio of 100 or greater have a risk of progression to end-organ damage in the next 2 years of approximately 80%. For this reason, an involved/uninvolved FLC ratio of 100 or more is now considered diagnostic of MM.[6]

Hematology

A normocytic, normochromic anemia (hemoglobin ≤12 g/dL) is present in 73% at diagnosis and in 97% at some time during the course of MM. Macrocytosis (mean corpuscular volume >100 fL) has been shown to be present in 9% of patients. The most frequent findings on peripheral smear are rouleaux formation,

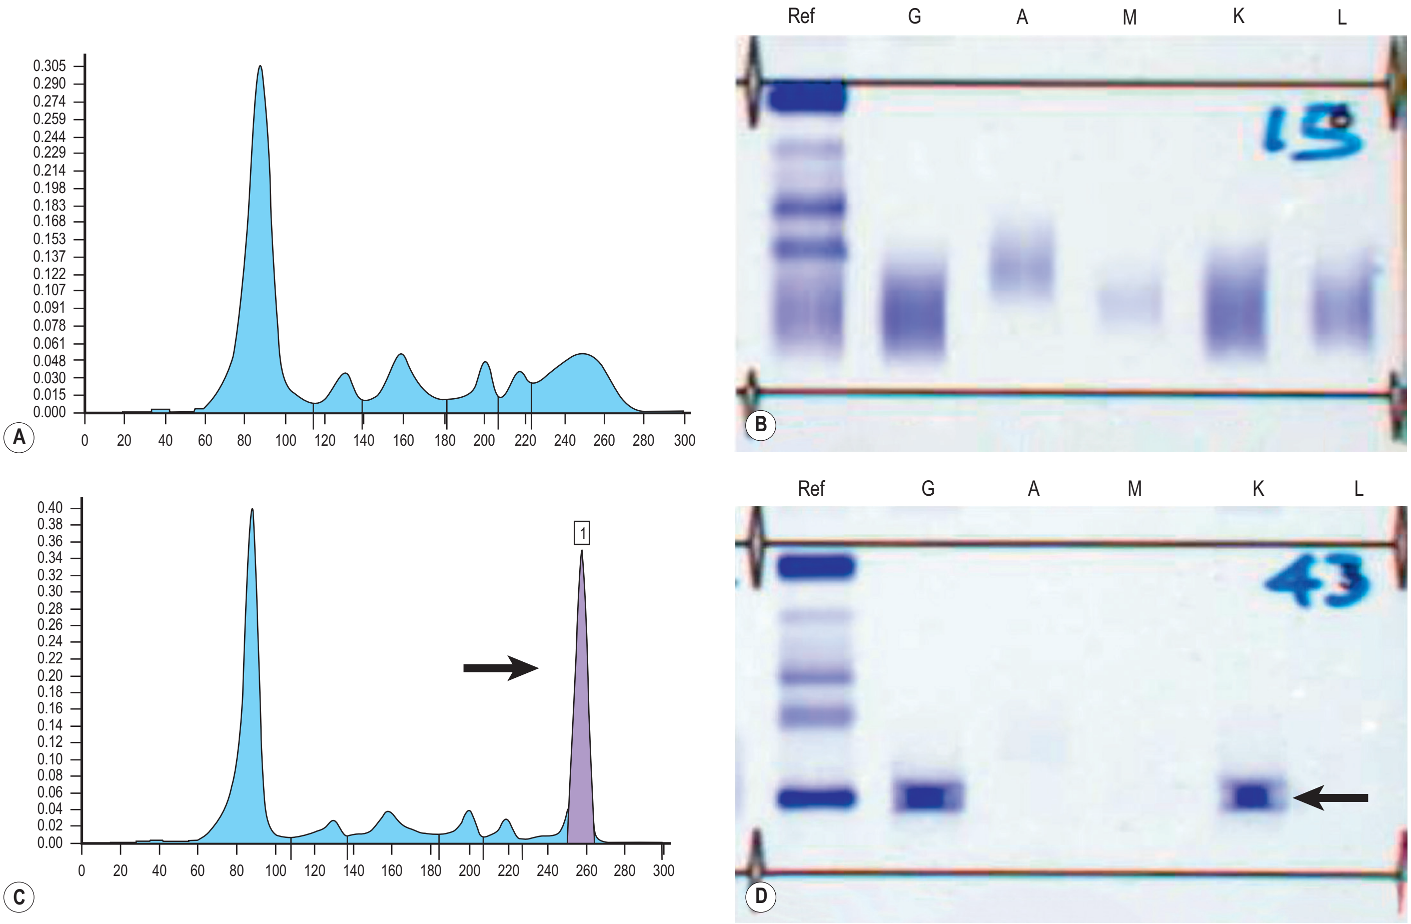

FIG 80.1 Electropherogram (A) and Immunofixation Electrophoresis (B) of Serum from a Normal Patient and a Myeloma Patient (C) and (D). Note the M-spike in the gamma region of the electropherogram and the immunoglobulin G (IgG) kappa band visible in the immunofixation of the myeloma patient specimen.

leukopenia, and thrombocytopenia. Rouleaux formation is particularly common in patients with elevated serum protein levels, as noted in the discussion of MGUS. Monoclonal plasma cells are rarely seen in the peripheral smear in patients with MM; a detectable absolute peripheral blood plasma cell count ≥100 cells/μL (≥0.1 × 10/L) is found in approximately 10%. Evaluation for circulating monoclonal plasma cells utilizes a slide-based immunofluorescence assay, a two-color immunoassay technique (ELISPOT), or flow cytometry by gating on CD38$^+$/CD45$^-$ cells.[6]

Bone Marrow Evaluation

Bone marrow aspirates and biopsies are key to the diagnosis of MM. The bone marrow plasma cell percentage should be estimated from a core biopsy specimen. However, if the percentage of plasma cells in the aspirate and core biopsy differ, the higher value should be used. Flow cytometry is not used to determine bone marrow plasma cell percentage for diagnostic purposes. Clonality can be established by demonstrating kappa/lambda light chain restriction using flow cytometry, immunohistochemistry, or immunofluorescence.[6]

The bone marrow of the vast majority of patients contains 10% or more clonal plasma cells. However, due to patchy bone marrow involvement, a bone marrow aspirate and biopsy may show less than 10% plasma cells in approximately 4% of patients.[6]

Mature plasma cells are oval with abundant basophilic cytoplasm. The nucleus is round and eccentrically located with a marked perinuclear cytoplasmic clearing, termed a hof. 80. The nucleus contains “clock face“ or “spoke wheel“ chromatin without nucleoli. Immature plasma cells have dispersed nuclear chromatin, prominent nucleoli, and a high nuclear to cytoplasmic ratio (Fig. 80.3).[6] The cytoplasm of myeloma cells may contain condensed or crystallized cytoplasmic immunoglobulin resulting in the following unusual findings, which are not limited to MM: multiple pale bluish-white, grapelike accumulations, cherry-red refractive round bodies, vermilion staining glycogen-rich IgA, overstuffed fibrils, and crystalline rods.

Immunohistochemical staining, immunofluorescent studies, and flow cytometry detect either kappa or lambda light chains, but not both, in the cytoplasm of bone marrow plasma cells in patients with MM while surface immunoglobulin is absent. The normal kappa/lambda ratio in the bone marrow is 2:1. A ratio of more than 4:1 or less than 1:2 is considered to meet the definition of kappa or lambda monoclonality, respectively.[6] As with normal plasma cells, myeloma cells express CD79a, p63, CD138, and CD38. In contrast to normal plasma cells, myeloma cells infrequently express CD19. Approximately 70% of myeloma cells express CD56, which is typically negative in normal plasma cells and in PCL.[6]

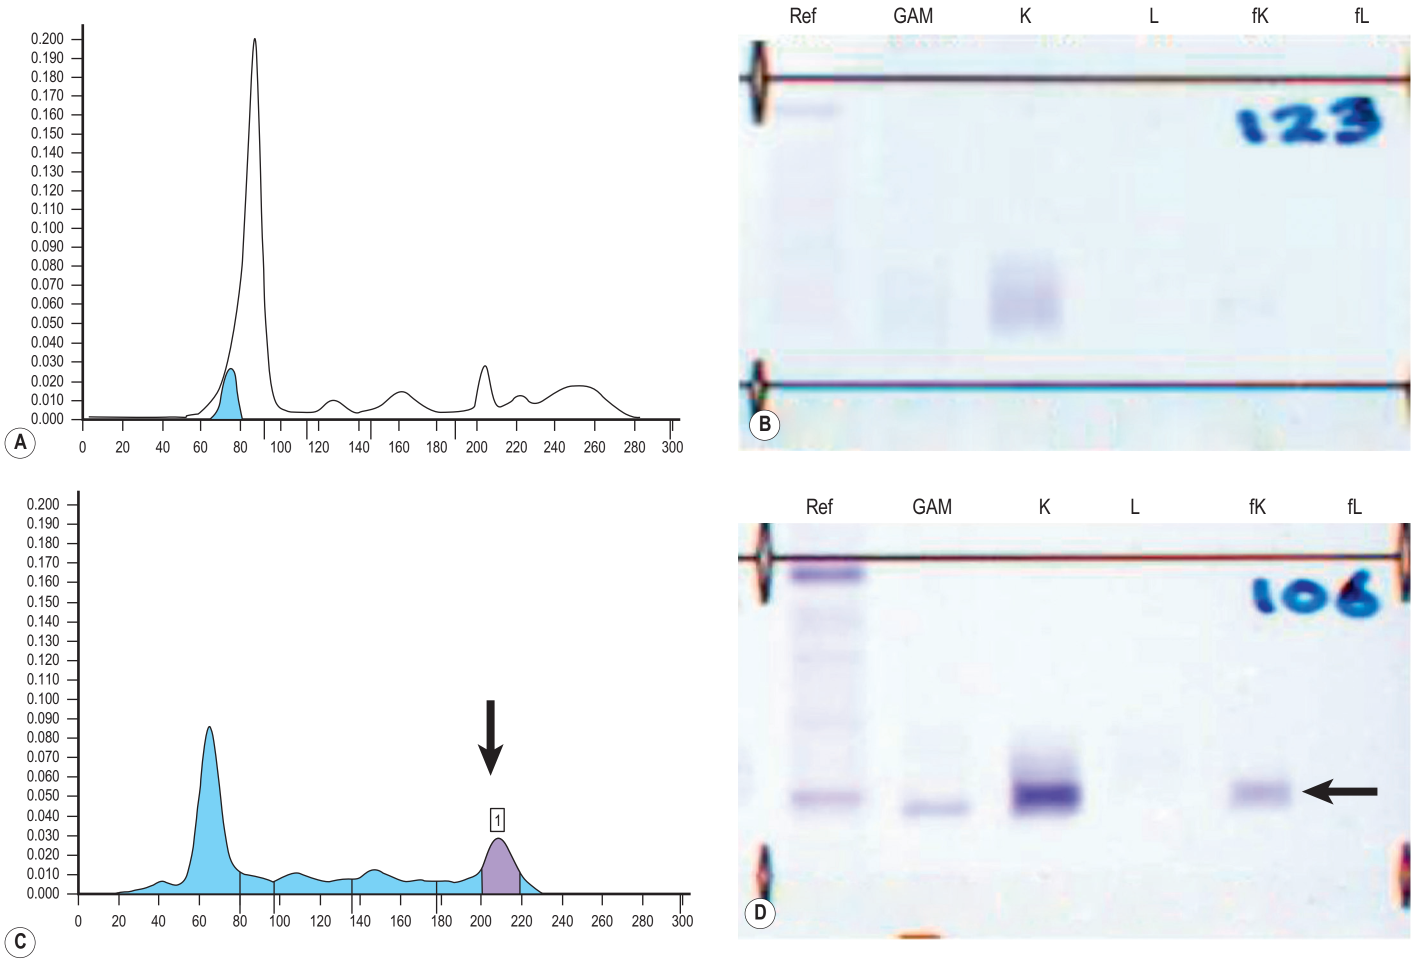

FIG 80.2 Electropherogram (A) and Immunofixation Electrophoresis (B) of Urine from a Normal Patient and a Myeloma Patient (C and D). Note the M-spike in the gamma region seen in the myeloma patient specimen. Both a monoclonal free kappa band as well as a monoclonal intact immunoglobulin band is visible in the urine immunofixation of the myeloma patient, indicating the presence of both monoclonal free kappa light chains (Bence-Jones protein) and monoclonal immunoglobulin M-protein in the patient's urine.

There is no specific cytogenetic abnormality that is typical or diagnostic of MM. The majority of myeloma tumors have genetic abnormalities that can be detected with sensitive molecular genetic techniques, such as interphase FISH. In contrast, only 20–30% of patients will have cytogenetic abnormalities detected in bone marrow plasma cells by conventional karyotyping; this is due to the low number of metaphases in myeloma cells.[6]

Radiography

A metastatic bone survey with plain radiographs including the humeri and femurs is a key component to the evaluation of a patient suspected of having MM (Fig. 80.4). The skeletal survey for patients with MM includes a posteroanterior view of the chest; anteroposterior and lateral views of the cervical spine, thoracic spine, lumbar spine, humeri, and femurs; anteroposterior and lateral views of the skull; and anteroposterior view of the pelvis. Symptomatic areas are also imaged. Conventional skeletal surveys reveal punched-out lytic lesions, diffuse osteopenia, or fractures in nearly 80% of patients with MM at the time of diagnosis.

Focal lytic lesions are found in nearly 60% of patients; osteoporosis, pathological fractures, or compression fractures of the spine each occur in approximately 20%. The most frequent sites of involvement include areas with active hematopoiesis, such as the vertebral bodies, skull, thoracic cage, pelvis, and proximal humeri and femurs.[6]

Low-dose whole-body computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET)/CT scans are helpful in patients who have bone pain but no abnormalities on routine roentgenograms (Fig. 80.5). MRI can detect diffuse and focal bone marrow lesions in patients with MM without osteopenia or focal osteolytic lesions on standard metastatic bone surveys, and bone surveys can detect lesions not found on MRI of the axial skeleton. PET/CT scanning using fluorine-18-labeled fluorodeoxyglucose (FDG) appears to correlate with areas of active lytic bone disease.[6]

Diagnosis

The physical examination, laboratory tests, and imaging studies recommended by the IMWG for the diagnosis of MM are outlined in Table 80.2.[8] The 2015 IMWG criteria for the diagnosis of MM require the fulfillment of criteria as outlined in Table 80.3.[8]

KEY CONCEPTS

Multiple Myeloma

- A cancer of plasma cells.
- Organ damage due to plasma cell proliferation and M-protein overproduction.
- Pathophysiology of multiple myeloma consists mainly of CRAB: hyperCalcemia, Renal, Anemia, and Bone.
- History and physical examination, laboratory tests, bone marrow testing, and imaging all play key roles in the diagnosis and management of myeloma.
- Prognosis and treatment vary depending on risk stratification.

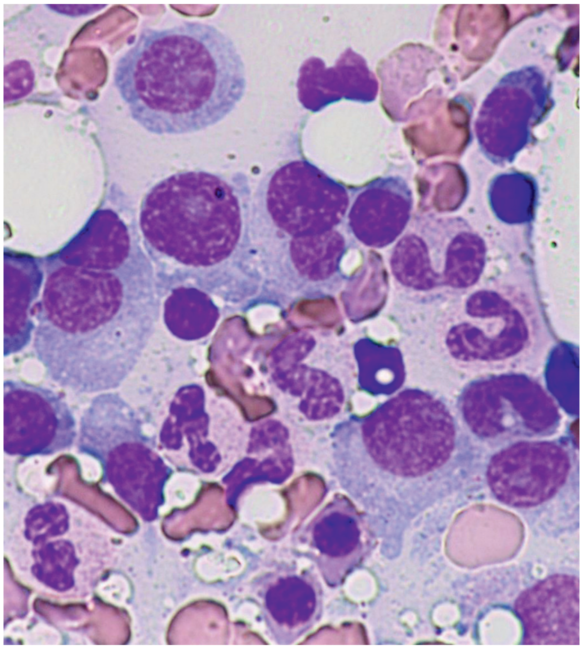

FIG 80.3 Photomicrograph of Plasma Cells in a Bone Marrow Biopsy From a Myeloma Patient. Plasma cells show atypical features, including visible nucleoli, multinucleation, high nuclear/cytoplasmic ratios, and increased size. (Courtesy Dr. Mikhail Roshal, Department of Pathology, Memorial Sloan Kettering Cancer Center.)

Management

Patients who have end-organ damage attributable to the underlying plasma cell disorder have MM and require therapy. The following findings, if attributable to the underlying plasma cell disorder, are clear indications for treatment: anemia, hypercalcemia, renal insufficiency, lytic bone lesions or severe osteopenia, and extramedullary plasmacytoma (excluding SEP).[9] Asymptomatic patients who have one of the following biomarkers are also considered to have MM that requires therapy: ≥60% clonal plasma cells in the bone marrow, involved/uninvolved FRL ratio of ≥100, more than one focal bone lesion on MRI.[9]

High-dose chemotherapy with autologous hematopoietic stem cell transplantation (HSCT) is the preferred therapy for patients with standard- or intermediate-risk myeloma. Patients eligible for HSCT receive induction therapy for 2–4 months prior to stem cell collection to reduce the number of tumor cells in the bone marrow and peripheral blood, to lessen symptoms, and to mitigate end-organ damage.[9] The preferred induction chemotherapy regimen depends on the risk stratification.

Patients ineligible for HSCT receive induction lenalidomide plus dexamethasone. In contrast, those receiving alkylator- or bortezomib-based regimen are treated for approximately 12 to 18 months and then observed until progression.[9] Patients with high-risk MM do poorly with all conventional treatment options. All patients should be evaluated before each treatment cycle to determine the degree of disease response.

Patients with one or more lesions on skeletal radiographs and those with osteopenia should be given bisphosphonate therapy. Pneumococcal and influenza vaccines should also be given to all patients. Patients with MM frequently develop complications related to their disease, including hypercalcemia, renal insufficiency, infection, and skeletal lesions, which require specific treatment.[9]

Almost all patients with MM who survive initial treatment will eventually relapse and require further therapy. Treatment options for patients with relapsed or refractory MM include HSCT, a reinitiation of the previous chemotherapy regimen, or a trial of a new regimen.[9]

Prognosis

MM is a heterogeneous disease. Some patients progress rapidly despite treatment, and others remain stable without therapy for a number of years. Myeloma patients are typically staged using the Revised International Staging System (R-ISS). This system stratifies patients with MM into three main risk categories at time of diagnosis.[10]

- High-Risk Myeloma: Patients with t(14;16), t(14;20), or del17p13 by FISH are considered to have high-risk myeloma. These patients have a median survival of approximately 2–3 years despite standard treatment. Patients with lactate dehydrogenase (LDH) ≥2 times the institutional laboratory upper limit of normal and those with features of primary are also considered to have high-risk MM.
- Intermediate-Risk Myeloma: Patients with t(4;14) or 1q+ by FISH or deletion 13/hypodiploidy are considered to have intermediate-risk MM.
- Standard-Risk Myeloma: All other patients with MM who lack any of the high- or intermediate-risk cytogenetic abnormalities or features are considered to have standard-risk MM; this includes patients with trisomies, t(11;14) and t(6;14).

THERAPEUTIC PRINCIPLES

Current Treatment of Multiple Myeloma (MM)

- Patients with standard- or intermediate-risk myeloma: High-dose chemotherapy with autologous hematopoietic stem cell transplantation (HSCT) with induction chemotherapy regimen dependent on risk stratification.
- Patients ineligible for HSCT: induction lenalidomide plus dexamethasone.
- Patients with high-risk MM do poorly with all conventional treatment options.
- Patients should be evaluated before each treatment cycle to determine degree of disease response.
- Patients with one or more lesions on skeletal radiographs and those with osteopenia should be given bisphosphonate therapy.
- Almost all patients with MM who survive initial treatment will eventually relapse and require further therapy.

SMOLDERING MULTIPLE MYELOMA

SMM is defined as follows: M-protein ≥3 g/dL in serum and/or 10–60% bone marrow plasma cells, no end-organ damage (lytic lesions, anemia, renal disease, or hypercalcemia) attributable to

TABLE 80.2 Exams, Tests, and Imaging Studies Recommended by the International Myeloma Working Group for the Diagnosis of Multiple Myeloma

1. History and Physical Examination
2. Routine Testing
   - Complete blood count with differential and peripheral blood smear review.
   - Chemistry panel including calcium and creatinine.
   - Serum protein electrophoresis, immunofixation electrophoresis.
   - Nephelometric quantitation of immunoglobulins.
   - Routine urinalysis, 24-hour urine collection for proteinuria, electrophoresis, and immunofixation electrophoresis.
   - Quantification of both urine M-component level and albuminuria.
3. Bone Marrow Testing: Obtain an aspirate plus trephine biopsy with testing for cytogenetics, fluorescent in situ hybridization (FISH), and immunophenotyping.
4. Imaging
   - Bone survey including spine, pelvis, skull, humeri, and femurs.
   - The IMWG now recommends the use of low-dose whole-body CT (LDWBCT) or MRI in the workup of smoldering multiple myeloma (SMM) and solitary plasmacytoma.
   - The IMWG now recommends that one of PET/CT, LDWBCT, or MRI of the whole body or spine be done in all patients with suspected smoldering myeloma, with the exact imaging modality determined by availability and resources.
   - Clear evidence of one or more sites of osteolytic bone destruction (≥5 mm in size) seen on CT (including LDWBCT) or PET/CT does fulfill the criteria for bone disease in multiple myeloma and should be regarded as meeting the CRAB (hyperCalcemia, Renal, Anemia, and Bone) requirement, whether or not the lesions can be visualized on skeletal radiography.
   - Increased uptake on PET/CT alone is not adequate for the diagnosis of multiple myeloma; evidence of underlying osteolytic bone destruction is needed on the CT portion of the examination.
   - Bone densitometry studies are not sufficient to determine the presence of multiple myeloma.
   - The IMWG no longer recommends the presence of osteoporosis or vertebral compression fractures in the absence of lytic lesions as being sufficient evidence of bone disease for purposes of the diagnostic criteria.

Source: Rajkumar SV, Dimopoulos MA, Palumbo A, Blade J, Merlini G, Mateos MV, et al. International Myeloma Working Group updated criteria for the diagnosis of multiple myeloma. Lancet Oncol 2014;15(12):e538–48. doi: 10.1016/S1470-2045(14)70442-5. PubMed PMID: 25439696.

TABLE 80.3 IMWG Criteria for the Diagnosis of Multiple Myeloma

Clonal bone marrow plasma cells ≥10% or biopsy-proven bony or extramedullary plasmacytoma and any one or more of the following CRAB (hyperCalcemia, Renal, Anemia, and Bone) features and myeloma defining events (MDEs):

1. Evidence of end-organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically:
   - Hypercalcemia: serum calcium >0.25 mmol/L (>1 mg/dL) higher than the upper limit of normal or >2.75 mmol/L (>11 mg/dL)
   - Renal insufficiency: creatinine clearance <40 mL per minute or serum creatinine >177 µmol/L (<2 g/dL [20 g/L])
   - Anemia: hemoglobin value of >20 g/L below the lowest limit of normal, or a hemoglobin value <10 g/dL (100 g/L)
   - Bone lesions: one or more osteolytic lesions on skeletal radiography, CT, or PET/CT. If bone marrow has <10% clonal plasma cells, more than one bone lesion is required to distinguish from solitary plasmacytoma with minimal marrow involvement
2. Any one or more of the following biomarkers of malignancy (MDEs):
   - 60% or greater clonal plasma cells on bone marrow examination
   - Serum-involved uninvolved free light chain ratio of 100 or greater, provided the absolute level of the involved light chain is at least 100 mg/L (a patient's "involved" free light chain—either kappa or lambda—is the one that is above the normal reference range; the "uninvolved" free light chain is the one that is typically in, or below, the normal range)
   - More than one focal lesion on MRI that is at least 5 mm or greater in size

Source: Rajkumar SV, Dimopoulos MA, Palumbo A, Blade J, Merlini G, Mateos MV, et al. International Myeloma Working Group updated criteria for the diagnosis of multiple myeloma. Lancet Oncol. 2014;15(12):e538–48. doi: 10.1016/S1470-2045(14)70442-5. PubMed PMID: 25439696.

the underlying plasma cell disorder, and no amyloidosis. SMM is differentiated from MGUS by the quantity of M-protein in serum (≥3 g/dL), urine (≥500 mg/24 h), and/or the percentage of clonal bone marrow plasma cells (10–60%).

Prognosis and Management

Patients with SMM will progress to symptomatic MM or AL amyloidosis at an approximate rate of 10%/year for the first 5 years, 3%/year for the next 5 years, and 1–2%/year for the following 10 years. The majority of patients with SMM will progress, with a median time to progression of 4.8 years.[11] The following factors are associated with an increased risk of progression: abnormal free light chain κ/λ ratio (<0.125 or >8.0), bone marrow clonal plasma cells 50–60%, serum M-protein ≥3 g/dL (or progressive increase in M-protein level), IgA SMM, immunoparesis, high-risk genetic features, increased circulating plasma cells, abnormal plasma cell immunophenotype, and abnormalities on imaging (MRI or PET/CT).[11,12] Patients with SMM should not be treated but instead closely monitored with follow-up every 3–4 months with treatment initiated upon progression to MM.[11]

NONSECRETORY MYELOMA

Approximately 3% of patients with MM have no M-protein in the serum or urine based on immunofixation electrophoresis at the time of diagnosis. Patients with myeloma who have normal serum and urine immunofixation electrophoresis as well as a normal serum FLC ratio are considered to have true nonsecretory myeloma. Of these, approximately 85% will have M-protein that can be detected in the cytoplasm of the neoplastic plasma cells by immunohistochemistry; however, they have impaired secretion of this protein. The other 15% do not have immunoglobulin detectable in the plasma cells.[6]

Patients with true nonsecretory myeloma need to be monitored mainly on the basis of imaging tests and bone marrow studies. Patients with nonsecretory MM are not at risk for myeloma kidney as long as light chains cannot be detected in the urine, but they are at risk for other complications of MM.[6]

OLIGOSECRETORY MYELOMA

Approximately 5–10% of patients with MM have oligosecretory myeloma at the time of diagnosis as defined by the absence of measurable disease in serum or urine using the following parameters: serum M-protein <1 g/dL and urine M-protein <200 mg/24 hours.[6]

Monitoring these patients is difficult using the standard serum and urine electrophoretic tests. In most of these patients, the serum FLC assay can be used to monitor the disease, provided that the serum FLC ratio is abnormal and the involved (affected) FLC level is ≥10 mg/dL. Patients with oligosecretory disease may need to be monitored with imaging and bone marrow studies, particularly if the baseline FLC levels are unmeasurable (<10 mg/dL).

PLASMA CELL LEUKEMIA

PCL is a very rare and aggressive variant of MM. It is characterized by high levels of plasma cells circulating in peripheral blood. PCL may originate de novo (primary PCL) or as a secondary transformation of MM (secondary PCL). The incidence of PCL in Europe has been estimated at 4 cases/10 000 000 persons/year. Secondary PCL occurs as a progression of disease in 1–4% of all cases of MM.[13]

Clinical Presentation and Diagnosis

Patients with PCL typically present with signs and symptoms similar to those seen in MM as well as in other leukemias.[13] The diagnosis of PCL is based upon the evaluation of peripheral blood smear, bone marrow aspirate and biopsy, and protein electrophoresis. PCL diagnosis is confirmed when a monoclonal population of plasma cells is present in the peripheral blood with an absolute plasma cell count exceeding 2000/μL and 20% of the peripheral blood white cells.[13]

Management and Prognosis

Treatment generally consists of induction therapy followed by HSCT, if eligible for HSCT, and chemotherapy alone for those ineligible for HSCT.[13] The prognosis of PCL is poor with a median survival of 7–11 months. Median survival for PCL occurring after refractory or relapsing MM is 2–7 months.[13]

SOLITARY PLASMACYTOMA OF BONE

SPB is a localized tumor in the bone comprised of a single clone of plasma cells in the absence of other features of MM. Approximately 5% of all cases of plasma cell disorders are SPB. The incidence of SPB is approximately 0.15 cases/100 000 person-years with approximately 450 new cases per year in the United States. The incidence is highest in patients of African background and lowest in Asians and Pacific Islanders. Men are diagnosed twice as frequently as women. The median age at diagnosis is 55–65 years compared with a median age at diagnosis of 71 years for patients with MM.[14]

Clinical Presentation

Most patients present with skeletal pain or a pathological fracture of the affected bone. Patients with vertebral involvement may have severe back pain or neurological compromise. Less commonly, SPB can extend into the surrounding soft tissue, resulting in a palpable mass. The most common bones involved are those with active hematopoiesis; the axial skeleton is more commonly involved than is the appendicular skeleton, and involvement of the distal appendicular skeleton below the knees or elbows is extremely rare.[14] By definition, patients with SPB do not have anemia or renal insufficiency attributable to the underlying plasma cell disorder.

Diagnosis

The diagnosis of SPB requires the following: biopsy-proven solitary tumor of bone with evidence of clonal plasma cells, metastatic bone survey and either CT (PET/CT) or MRI of the spine and pelvis showing no other lytic lesions, bone marrow aspirate, and biopsy that contains no clonal plasma cells as well as no findings attributable to clonal plasma cell proliferative disorder (anemia, hypercalcemia, or renal insufficiency).[8] The presence of an M-protein does not exclude the diagnosis of SPB, as a low level of M-protein may be present in 30–75% of cases. This M-protein may or may not disappear with treatment.

Management and Prognosis

The primary treatment for patients with SPB is localized radiation therapy (RT). Surgery may be required for patients with structural instability of the bone, retropulsed bone, or rapidly progressive symptoms from cord compression. Bisphosphonates are not recommended for patients with SPB, except in the setting of underlying osteopenia.[14]

The median overall survival of patients with SPB is approximately 10 years. Overall survival rates at 5 and 10 years are approximately 75% and 45%, respectively, with corresponding disease-free survival rates of 45% and 25%. A little more than half of patients with SPB will eventually develop overt MM. Patients with true SPB who meet the strict criteria listed above have a recurrence/progression rate of approximately 10% within 3 years.[14]

SOLITARY EXTRAMEDULLARY PLASMACYTOMA

SEPs are plasma cell tumors that arise outside the bone marrow. SEP refers to a solitary nonosseous plasma cell neoplasm in the absence of any other sign of MM. The SEP lesions are most often located in the head and neck region, mainly in the upper aerodigestive tract, but may also occur in the gastrointestinal tract, urinary bladder, central nervous system, thyroid, breast, testes, parotid gland, lymph nodes, and skin. The median age at diagnosis for SEP is 55 to 60 years; approximately two-thirds of patients are male, and SEP accounts for approximately 3% of plasma cell malignancies.[15]

Clinical Presentation

Most patients present with symptoms related to the location of the mass. Approximately 80% involve the upper respiratory tract (*i.e.*, oronasopharynx and paranasal sinuses) and cause epistaxis, nasal discharge, or nasal obstruction. Less common sites of involvement include the gastrointestinal tract, liver, lymph nodes, testes, skin, and central nervous system. Primary plasmacytoma of the lung often presents as a pulmonary nodule or hilar mass with or without hemoptysis.[15]

Diagnosis

By definition, patients with SEP do not have anemia, hypercalcemia, renal insufficiency, or bone lesions attributable to the underlying plasma cell disorder. The diagnosis of SEP requires the following: biopsy-proven extramedullary tumor with evidence of clonal plasma cells, metastatic bone survey and either MRI or PET/CT of the spine and pelvis that show no lytic lesions, bone marrow aspirate and biopsy without clonal plasma cells, and absence of anemia, hypercalcemia, or renal insufficiency attributable to a clonal plasma cell proliferative disorder.[16]

Some patients may have a small amount of M-protein, usually IgA, in the serum or urine, which often disappears after treatment. The bone marrow of patients with SEP does not have clonal plasma cells, whereas some patients with a solitary extramedullary lesion may demonstrate up to 10% clonal plasma cells, in which case the diagnosis is SEP with minimal marrow involvement.[15]

Management and Prognosis

The treatment of choice for SEP is RT. Small lesions may be cured with surgery alone; no adjuvant RT is indicated unless there is suspicion of residual local disease.[15]

Less than 7% of patients with SEP will develop a local recurrence after tumoricidal radiation. Approximately 10–15% of patients ultimately will develop MM; the progression rate is higher (20%) in patients with SEP with minimal marrow involvement. Five-year overall survival rates range from 40–85%.[15]

POEMS SYNDROME

POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes) syndrome is characterized by the presence of a monoclonal plasma cell disorder, peripheral neuropathy, and one or more of the following features: osteosclerotic myeloma, Castleman disease, increased levels of serum vascular endothelial growth factor (VEGF), organomegaly, endocrinopathy, edema, typical skin changes, and papilledema. The cause of POEMS syndrome is unknown, although chronic overproduction of proinflammatory and other cytokines such as VEGF appears to be a major feature of this disorder. POEMS syndrome is a rare disorder, but the exact incidence is unknown. POEMS syndrome commonly presents in the fifth to sixth decade.[17]

Clinical Presentation

By definition, all patients have peripheral neuropathy and a monoclonal plasma cell disorder, almost always of the lambda light chain type. In addition, almost all patients have osteosclerotic lesions, whereas Castleman disease is present in approximately 15%.[17]

Diagnosis

The IMWG has developed a series of criteria required for the diagnosis of POEMS syndrome; other signs and symptoms that do not fall into these criteria may also be present, as outlined in Table 80.4.[8]

TABLE 80.4 IMWG Diagnostic Criteria for the Diagnosis of POEMS Syndrome

Both Mandatory Criteria:

1. Polyneuropathy
2. Monoclonal plasma cell proliferative disorder

Plus at Least One Major Criterion:

3. Osteosclerotic or mixed sclerotic/lytic lesion visualized on plain films or computed tomography (CT)
4. Castleman disease
5. Elevated serum or plasma vascular endothelial growth factor (VEGF) levels (at least three to four times the upper limit of normal)

Plus at Least One Minor Criterion:

1. Organomegaly (splenomegaly, hepatomegaly, or lymphadenopathy)
2. Extravascular volume overload (peripheral edema, ascites, or pleural effusion)
3. Endocrinopathy (adrenal, thyroid, pituitary, gonadal, parathyroid, or pancreatic disorder excluding diabetes mellitus or hypothyroidism)
4. Skin changes (hyperpigmentation, hypertrichosis, glomeruloid hemangiomata, plethora, acrocyanosis, flushing, white nails)
5. Papilledema
6. Thrombocytosis or polycythemia

POEMS, polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes.

Source: Rajkumar SV, Dimopoulos MA, Palumbo A, Blade J, Merlini G, Mateos MV, et al. International Myeloma Working Group updated criteria for the diagnosis of multiple myeloma. Lancet Oncol 2014;15(12):e538–48. doi: 10.1016/S1470-2045(14)70442-5. PubMed PMID: 25439696.

Management and Prognosis

There is no standard treatment for POEMS syndrome. Those with limited disease may be treated with RT. Patients with widespread bone lesions may be treated with therapy similar to that used for MM.[17] POEMS syndrome is chronic, and patients with POEMS syndrome survive three times longer than those with MM. The natural history is one of progressive peripheral neuropathy until the patient is bedridden. Death usually occurs from inanition or a terminal bronchopneumonia.[17]

WALDENSTRÖM MACROGLOBULINEMIA

WM is a rare clinicopathological entity demonstrating 10% or greater infiltration of the bone marrow by clonal lymphoplasmacytic cells and a monoclonal IgM gammopathy in the blood. WM is a rare disorder with an incidence of approximately 3/million people/year, with 1400 new cases diagnosed in the United States each year. The median age at diagnosis is 64 years; less than 1% of patients are diagnosed under 40 years of age, and approximately 60% are males. WM is more common in Caucasians than in other ethnic groups, and familial predisposition is present in up to 20%.[18]

Clinical Presentation

Patients usually present in their seventh decade with symptoms related to the infiltration of the hematopoietic tissues or to the effects of monoclonal IgM in the blood. WM most commonly presents with pallor, oronasal bleeding, systemic complaints (weakness, fatigue, weight loss, fever, night sweats), and organomegaly (enlarged lymph nodes, spleen, and/or liver). Involvement of the bone or kidneys is uncommon.[18]

An important presentation includes central nervous system signs and symptoms due to the hyperviscosity syndrome (blurring or loss of vision, headache, ataxia, dementia, stroke, or coma). A classic finding in WM associated with hyperviscosity is the presence of dilated, segmented, and tortuous retinal veins. Another major presentation involves neurological symptoms such as paresthesias and weakness as well as cranial nerve palsies and sudden deafness. Patients with WM who are asymptomatic are considered to have SWM.[18]

Laboratory Findings and Diagnosis

Patients with WM must have 10% or greater infiltration of the bone marrow by clonal lymphoplasmacytic cells and a monoclonal

IgM gammopathy in the blood. The diagnosis of WM is made when the following two criteria are met: (i) presence of an IgM monoclonal paraprotein on serum immunofixation and (ii) 10% or more of the bone marrow biopsy sample demonstrates infiltration by small lymphocytes that exhibit plasmacytoid or plasma cell differentiation (lymphoplasmacytic features or lymphoplasmacytic lymphoma) with an intertrabecular pattern. This infiltrate should express a typical immunophenotype (*e.g.*, surface IgM^{+}, CD5$^{+/-}$, CD10^{-}, CD19^{+}, CD20^{+}, CD22^{+}, CD23^{-}, CD25^{+}, CD27^{+}, FMC7^{+}, CD103^{-}, CD138^{-}).[19] WM must be differentiated from IgM MGUS, MM, chronic lymphocytic leukemia (CLL), and mantle-cell lymphoma.

Management and Prognosis

Many patients with WM are asymptomatic and can be observed for months to years after the diagnosis is established before requiring treatment. Asymptomatic patients with adequate hemoglobin and platelet levels are followed every 6 months with complete blood counts and monoclonal protein levels.[20] Treatment is indicated in those who meet one or more of the conditions presented in Table 80.5.[21]

Symptomatic WM is treated with a regimen that incorporates rituximab in combination with other agents. Symptomatic patients with low tumor burden and minimally symptomatic patients may be treated with the single agent rituximab. Patients who present with symptoms due to hyperviscosity should undergo immediate therapeutic plasmapheresis, followed by chemotherapy for control of the malignant clone.[21] Median survival in WM is approximately 5–8 years from the time of diagnosis. However, outcomes are highly variable. A staging system for WM has been developed based on a prospective multicenter observational study outlined in Table 80.6.[22]

TABLE 80.5 Clinical and Laboratory Indications for Initiation of Treatment for Waldenström Macroglobulinemia (WM)

Clinical Indications for Therapy Initiation:

- Recurrent fever, night sweats, weight loss, fatigue
- Hyperviscosity
- Lymphadenopathy that is either symptomatic or bulky (≥5 cm in maximum diameter)
- Symptomatic hepatomegaly and/or splenomegaly
- Symptomatic organomegaly and/or organ or tissue infiltration
- Peripheral neuropathy due to WM

Laboratory Indications for Therapy Initiation:

- Symptomatic cryoglobulinemia
- Cold agglutinin anemia
- Immune hemolytic anemia and/or thrombocytopenia
- Nephropathy related to WM
- Amyloidosis related to WM
- Hemoglobin ≤10 g/dL
- Platelet count <100 × 10^{9}/L

Treatment recommendations for patients with Waldenstrom macroglobulinemia (WM) and related disorders: IWWM-7 consensus. Blood 2014;124(9):1404–11. doi: 10.1182/blood-2014-03-565135. PubMed PMID: 25027391; PubMed Central PMCID: PMC4148763.

HEAVY CHAIN DISEASES

The HCDs are rare B-cell proliferative disorders characterized by the production of an M-protein consisting of a portion of the immunoglobulin heavy chain without a bound light chain. Three types of HCD are recognized, based upon the class of immunoglobulin heavy chain produced by the malignant cell:

1. Alpha HCD is a form of mucosa-associated lymphoreticular tissue (MALT) lymphoma that is also called immunoproliferative small intestinal disease (IPSID), Mediterranean lymphoma, or Seligmann disease.
2. Gamma HCD (Franklin disease) is typically associated with the presence of a systemic lymphoma, often of mixed lymphoid-plasmacytic character.
3. Mu HCD has clinical features resembling small lymphocytic lymphoma/CLL, often with distinctive vacuolated lymphocytes/plasma cells in the bone marrow.

Clinical Presentation

The clinical presentation of the HCDs is that of a patient with a low-grade B-cell malignancy. Alpha HCD is a form of MALT lymphoma, with the same histological features of MALT-type gastrointestinal lymphomas with marked plasma cell differentiation. It is the most common form of HCD and occurs in patients from the Mediterranean region or Middle East, usually young males, and is often associated with relatively poor sanitation. The gastrointestinal tract is most commonly involved in alpha HCD, resulting in abdominal pain, malabsorption with chronic diarrhea, steatorrhea, and loss of weight. Growth retardation, digital clubbing, and mesenteric lymphadenopathy may also be present.[23]

Patients with gamma HCD typically present with systemic symptoms, lymphadenopathy, splenomegaly, and/or anemia, and occasionally with palatal and uvular swelling. The median age of patients with gamma HCD is 60 to 70 years, although the condition has been noted in persons younger than age 20. Autoimmune manifestations are seen in about one-third of patients.[23]

Mu HCD is the least common of the HCDs and has features resembling CLL/small lymphocytic lymphoma, although peripheral adenopathy is less common than in CLL. Osteolytic lesions or pathological fractures occasionally have been reported in patients. Unlike those with alpha and gamma HCD, some patients

TABLE 80.6 Staging System for Waldenström Macroglobulinemia

Stage	Risk	Characteristics	Five-Year Survival	Five-Year Progression-Free Survival
A	Low	B2M <3 mg/L and Hgb ≥12.0 g/dL	87%	83%
B	Medium	B2M <3 mg/L and Hgb <12.0 g/dL	63%	55%
C	Medium	B2M ≥3 mg/L and serum IgM ≥4.0 g/dL	53%	33%
D	High	B2M ≥3 mg/L and IgM <4.0 g/dL	21%	12%

B2M, Beta 2 microglobulin.

Source: Dhodapkar MV, Jacobson JL, Gertz MA, Rivkin SE, Roodman GD, Tuscano JM, et al. Prognostic factors and response to fludarabine therapy in patients with Waldenstrom macroglobulinemia: results of United States intergroup trial (Southwest Oncology Group S9003). Blood 2001;98(1):41–8. PubMed PMID: 11418461.

with mu HCD have increased free light chain secretion, and they may develop cast nephropathy or amyloidosis.[23]

Diagnosis

The diagnosis of the HCDs can be made on histopathological examination of affected tissues and/or analysis of serum or urine samples by electrophoresis and immunofixation electrophoresis. A typical M-spike in the serum or urine may not always be present. On serum or urine immunofixation electrophoresis or immunohistochemical staining of affected tissues, the abnormal protein consists of a heavy chain without an associated light chain. Immunohistochemical staining of affected tissue shows the presence of a clonal population of cells staining positively for a heavy chain but negative for both kappa and lambda light chains.[23]

Alpha HCD most commonly involves infiltration of the jejunal mucosa with plasmacytoid cells, whereas the duodenum and ileum are affected less often. The diagnosis depends upon the recognition of a monoclonal alpha heavy chain without an associated light chain in the serum, urine, intestinal secretions, or the cells infiltrating the intestinal mucosa. The serum protein electrophoretic pattern is normal in one-half of cases, and in the remainder an unimpressive broad band may appear in the alpha-2 or beta mobility regions. The amount of alpha heavy chain in the urine is small.[23]

Gamma HCD is typically associated with a polymorphous infiltrate, including admixtures of lymphocytes, plasmacytoid lymphocytes, plasma cells, immunoblasts, and eosinophils. The electrophoretic pattern often shows a broad-based band more suggestive of a polyclonal increase, but the gamma chains are monoclonal. The diagnosis is established by immunofixation electrophoresis, which shows that the abnormal protein consists only of gamma heavy chains without associated light chains.[23]

Mu HCD is characterized by vacuolated plasma cells or lymphoid cells observed in the bone marrow, together with panhypogammaglobulinemia. The serum protein electrophoretic pattern is usually normal, except for hypogammaglobulinemia.[23]

Management and Prognosis

Initial treatment of alpha HCD consists of eradication of any concurrent infection with appropriate antibiotics. Those with symptomatic disease who do not respond adequately to antibiotics may be treated with chemotherapy similar to that used for non-Hodgkin lymphoma, such as the CHOP regimen.[23] Treatment of gamma HCD is indicated only for symptomatic patients. Appropriate chemotherapy includes melphalan plus prednisone or regimens used to treat B-cell lymphoma, such as the combination of cyclophosphamide, vincristine, and prednisone, with or without doxorubicin, or rituximab if the abnormal cells express CD20.[23] Treatment for symptomatic patients with mu HCD is similar to that employed in patients with CLL (*e.g.*, glucocorticoids, alkylating agents, fludarabine).[23]

In the absence of therapy, alpha HCD typically is progressive and fatal. The prognosis of gamma HCD is variable and ranges from the asymptomatic presence of a stable monoclonal heavy chain in the serum or urine (*e.g.*, MGUS) to a rapidly progressive downhill course over a short duration (*e.g.*, highly aggressive lymphoma). Median survival is 7.4 years with an extremely wide range from 1 month to more than 21 years.[23] The course of mu HCD is variable, and survival ranges from a few months to many years.[23]

LIGHT CHAIN AMYLOIDOSIS

Amyloidosis refers to the deposition of fibrils composed of low-molecular-weight subunits of normal serum proteins. AL amyloidosis is a specific form of amyloidosis caused by the deposition of monoclonal light chains. These light chains undergo transformation to a beta-pleated fibrillar configuration. Deposition of these light chains in various organs results in organ failure.

AL amyloidosis is an uncommon disorder of older adults, and the exact incidence is unknown. In the United States, the incidence is approximately 6–10 cases per million person-years. Age-specific incidence rates increase in each decade of life after age 40 years. The median age at diagnosis is 64 years, and less than 5% of patients are under the age of 40. There is a male predominance, with men accounting for 65–70% of patients. AL amyloidosis occurs in all races and all geographic locations.[24]

Clinical Presentation

AL amyloidosis is a systemic disorder that can present with a variety of symptoms, including significant proteinuria, edema, hepatosplenomegaly, otherwise unexplained heart failure, and carpal tunnel syndrome. Although virtually all patients have multisystem amyloid deposition, it is not uncommon for a patient to present with evidence of mainly one organ involvement.

Nonspecific systemic symptoms, including fatigue and unintentional weight loss, are common in patients with AL amyloidosis. Renal involvement occurs in approximately 70% of patients and most often presents as asymptomatic proteinuria or nephrotic syndrome. Cardiac involvement is seen in approximately 60% of patients and typically is characterized by thickening of the interventricular septum and ventricular wall. This can lead to systolic or diastolic dysfunction with symptoms of heart failure. Other manifestations that may be seen include sudden death or syncope due to arrhythmia or heart block and, rarely, angina or infarction due to accumulation of amyloid in the coronary arteries.[24]

Hepatomegaly with or without splenomegaly is seen in as many as 70% of patients. Potential gastrointestinal manifestations include bleeding, gastroparesis, constipation, bacterial overgrowth, malabsorption, and intestinal pseudo-obstruction resulting from dysmotility.[24]

Mixed sensory and motor peripheral neuropathy and/or autonomic neuropathy is a prominent feature in AL amyloidosis. Symptoms of numbness, paresthesia, and pain are frequently noted, as in peripheral neuropathy of many other causes. Compression of peripheral nerves, especially the median nerve within the carpal tunnel, can cause more localized sensory changes. Symptoms of bowel or bladder dysfunction and findings of orthostatic hypotension may be due to autonomic nervous system damage.[24]

Amyloid infiltration of skeletal muscles may cause visible enlargement. Macroglossia, or lateral scalloping of the tongue from impingement on the teeth, is characteristic of AL amyloid. Arthropathy may be due to amyloid deposition in joints and surrounding structures. The “shoulder pad“ sign is visible enlargement of the anterior shoulder due to fluid in the glenohumeral joint and/or amyloid infiltration of the synovial membrane and surrounding structures.[24]

Purpura, characteristically elicited in a periorbital distribution (raccoon eyes) by a Valsalva maneuver or minor trauma, is present in only a minority of patients, but it is highly characteristic of AL amyloidosis. Other signs of skin involvement include waxy thickening, easy bruising, and subcutaneous nodules or plaques. Amyloidosis may also be directly associated with a bleeding diathesis. Approximately 10% of patients have coexisting MM.[24]

KEY CONCEPTS

Light Chain Amyloidosis

- A specific form of amyloidosis caused by tissue deposition of monoclonal light chains.
- A systemic disorder with multisystem amyloid deposition causing a variety of nonspecific symptoms.
- Demonstration of amyloid deposition in affected organs is key to diagnosis.
- Poor long-term prognosis due to organ dysfunction caused by amyloid deposition.

Laboratory Findings and Diagnosis

Demonstration of amyloid fibrils upon histological evaluation of an affected organ or a surrogate site is required for the diagnosis of AL amyloidosis. Kidney or liver biopsy is positive for amyloid deposition in over 90% of cases; however, a high success rate can also be achieved by less invasive procedures, such as abdominal fat pad aspirate, rectal biopsy, bone marrow biopsy, or skin biopsy.[24]

Amyloid appears as a pink, amorphous, waxy substance with a characteristic "cracking" artifact on hematoxylin and eosin–stained biopsies (Fig. 80.6a). The presence of amyloid fibrils can be confirmed by their characteristic appearance on electron microscopy and by their ability to bind Congo red or thioflavin-T (Fig. 80.6b and 80.6c).[24]

Staining for kappa and lambda light chains, transthyretin, and serum amyloid A can determine the type of amyloidosis. Positive staining for kappa or lambda indicates AL amyloidosis.[24] Immunofluorescence microscopy using light chain–specific antisera and other specialized techniques may show deposition of a monoclonal (lambda or kappa) light chain in the kidney or other affected tissues. Laser microdissection of tissue followed by analysis by tandem mass spectrometric proteomic analysis

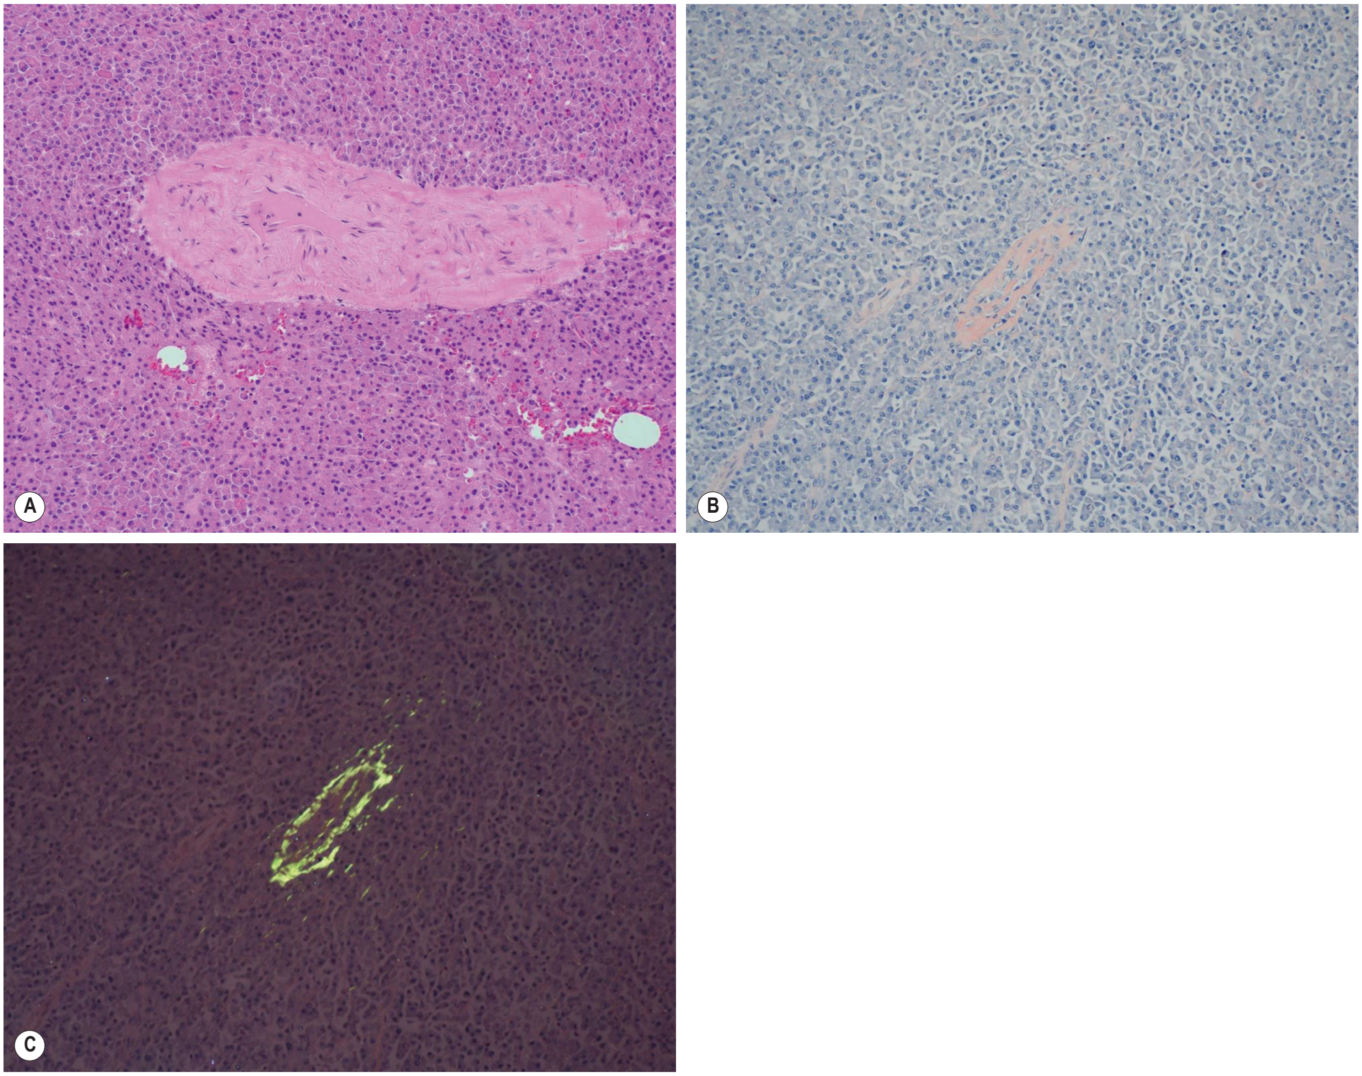

FIG 80.6 **Photomicrograph of Plasmacytoma With AL Amyloid Deposition.** (A) Hematoxylin and eosin stain, (B) Congo red staining without polarization, (C) Congo red staining under polarized light. (Courtesy Dr. Mikhail Roshal, Department of Pathology, Memorial Sloan Kettering Cancer Center.)

may be helpful in identifying the type of amyloid protein (*e.g.*, monoclonal light chain versus other forms of amyloid proteins). An alternative to mass spectrometry is to use immunoelectron microscopy, if available.[24]

Patients with AL amyloidosis frequently have chromosomal abnormalities, but there is no single chromosomal change that is diagnostic of this disease. Chromosomal abnormalities reported with moderate to high frequency in patients with AL amyloidosis include t(11;14)(q13;q32), del(13q14), and gain of 1q21.[24]

Most patients with AL amyloidosis have little or no intact monoclonal immunoglobulin, but are characterized by the presence of monoclonal free light chain. The monoclonal light chain type is lambda in approximately 70% of cases, kappa in 25%, and biclonal in 5%. SPEP demonstrates a localized band or peak in less than 50% of patients with AL amyloidosis. Immunofixation electrophoresis detects a serum or urinary monoclonal protein in nearly 90% of cases of AL amyloidosis. When serum and urine immunofixation electrophoresis is combined with serum free light chain ratio analysis, a monoclonal protein can be detected in virtually all cases.[24]

Bone marrow biopsy specimens typically demonstrate a slightly increased percentage of plasma cells that may appear morphologically normal. Less commonly, the bone marrow demonstrates overt myeloma or lymphoplasmacytic lymphoma. A clonal excess of plasma cells (lambda or kappa) can also be demonstrated by immunoperoxidase staining or flow cytometric analysis of specimens of involved bone marrow.[24] Diagnostic criteria for AL amyloidosis have been developed by the Mayo Clinic and the IMWG that require the presence of the four criteria outlined in Table 80.7.[8] Approximately 2–3% of patients with AL amyloidosis will not meet the requirement for evidence of a monoclonal plasma cell disorder listed.

Management and Prognosis

Amyloidosis patients meeting the criteria in Table 80.8 are considered to be eligible for autologous HSCT.[25] Those eligible for HSCT may be treated with melphalan followed by autologous HSCT. Those not eligible for HSCT may be treated with melphalan/dexamethasone or a bortezomib-based regimen.[25]

AL amyloidosis typically has poor long-term prognosis. Death is typically due to organ dysfunction, with major causes of death due to cardiac or hepatic failure as well as infection. There is, however, significant variability in median survival, depending on the nature, number, and extent of organ involvement. Median survival may range from 4 to 6 months in patients diagnosed at an advanced stage, to in excess of 5 years in patients with limited organ involvement. Two key prognostic factors include the presence and severity of cardiac involvement and the presence of concurrent myeloma.[26]

TABLE 80.7 IMWG Diagnostic Criteria for the Diagnosis of Light Chain Amyloidosis

1. Presence of an amyloid-related systemic syndrome (*e.g.*, renal, liver, heart, gastrointestinal tract, or peripheral nerve involvement). To be included as a diagnostic criterion, the organ damage must be felt to be related to amyloid deposition and not to another common disease, such as diabetes or hypertension.
2. Positive amyloid staining by Congo red in any tissue (*e.g.*, fat aspirate, bone marrow, or organ biopsy) or the presence of amyloid fibrils on electron microscopy.
3. Evidence that the amyloid is light chain–related is established by direct examination of the amyloid using spectrometry-based proteomic analysis or immunoelectron microscopy.
4. Evidence of a monoclonal plasma cell proliferative disorder (*e.g.*, presence of a serum or urine M-protein, abnormal serum free light chain ratio, or clonal plasma cells in the bone marrow).

MONOCLONAL IMMUNOGLOBULIN DEPOSITION DISEASES

Monoclonal immunoglobulin deposition diseases are a nonamyloid monoclonal immunoglobulin chain deposition disease that is caused by a clonal plasma cell proliferative disorder. These diseases are characterized by the deposition of immunoglobulin light or heavy chain fragments, leading to organ dysfunction. There are two types of immunoglobulin deposition diseases: heavy chain deposition disease (HCDD) and LCDD. They are differentiated from light chain and heavy chain amyloidosis in that the light chain fragments do not have the necessary biochemical characteristics to form amyloid fibrils.

Clinical Presentation

HCDD is extremely rare, with 37 cases reported in the literature from 1992 to 2011. The majority of patients present with hypertension, progressive renal dysfunction, anemia, and nephrotic syndrome with microhematuria.[27] Patients with LCDD usually present with renal, cardiac, or hepatic involvement and may have underlying MM or a lymphoproliferative disorder.[24]

Laboratory Findings

In LCDD, a population of clonal plasma cells produces monoclonal light chain fragments that are deposited as granules in the tissues. The deposits in LCDD are almost always composed of kappa light chains; they are granular, not fibrillar, and do not bind Congo red, thioflavin-T, or serum amyloid P component. Tissue deposits of fragments of monoclonal light chains are commonly seen and can occur in a variety of organs, including the kidney, heart, liver, and small intestine. Routine electrophoretic techniques may not demonstrate a monoclonal protein in the serum or urine in some patients, but it may be detectable by serum free light chain analysis.[26]

TABLE 80.8 Eligibility Criteria for Autologous HSCT in Light Chain Amyloidosis Patients

1. Physiological age ≤70
2. Troponin T <0.06 ng/mL
3. N-terminal pro-brain natriuretic peptide (NT proBNP) <5000 ng/L
4. Creatinine clearance ≥30 mL/min (unless on chronic stable dialysis)
5. Eastern Cooperative Oncology Group (ECOG) performance status ≤2
6. New York Heart Association functional status Class I or II
7. No more than two organs significantly involved (liver, heart, kidney, or autonomic nerve)
8. No large pleural effusions
9. No dependency on oxygen therapy

In HCDD, a population of clonal plasma cells produces both light and heavy monoclonal immunoglobulin chains or only short (truncated) heavy chains that are unable to form amyloid fibrils but are deposited as granules in the tissues. HCDD can be identified by immunofluorescence staining of biopsy tissue with anti–heavy chain antibodies.[26]

Management and Prognosis

The therapeutic approaches for both LCDD and HCDD are similar to those employed for patients with MM. Serial free light chain assays can be used to monitor response to treatment in LCDD.[26] The prognoses of LCDD and HCDD vary considerably, depending on the nature, number, and extent of organ involvement.[26]

ON THE HORIZON

- Two monoclonal antibody drugs (mAb) have recently been approved by the FDA for the treatment of multiple myeloma, with more on the way.
- Caution is warranted when monitoring myeloma patients on mAb drugs, as these biologicals may cause false positive results by protein electrophoresis of the serum and immunofixation electrophoresis (IFE).

MULTIPLE-CHOICE QUESTIONS

1. Which of the following is a "myeloma defining event" according to the 2014 International Myeloma Working Group (IMWG) guidelines?
   A. One focal 4-mm lesion on magnetic resonance imaging
   B. M-protein >0.5 g/dL
   C. Back pain
   D. Clonal bone marrow plasma cells ≥60%

2. Which one of these is a risk factor for progression from monoclonal gammopathy of undetermined significance (MGUS) to multiple myeloma or a related malignancy?
   A. Immunoglobulin G (IgG) MGUS
   B. Abnormal serum free light chain ratio
   C. M-protein ≥0.3 g/dL
   D. Patient age >50

3. Which one of these differentiates Waldenström macroglobulinemia (WM) from IgM MGUS?
   A. IgM M-protein ≥1 g/dL
   B. ≥10% plasma cells in bone marrow
   C. Renal damage
   D. Patient age <50

Concepts and Challenges in Organ Transplantation: Rejection, Immunosuppression, and Tolerance

Kathryn J. Wood, Sushma Shankar, Joanna Hester, Fadi Issa

The clinical era of transplantation began on December 23, 1954, when Dr. Joseph Murray and colleagues performed the first successful renal transplant on the genetically identical Herrick twins.[1] Solid organ transplantation (SOT) has since transformed the landscape of modern medicine, offering dramatic improvements in patient survival and quality of life in many end-stage diseases. The development of powerful immunosuppressive regimens and cutting-edge biological agents represents an elegant proof of concept, translating seminal work from the laboratory bench to the patient's bedside. However, this ground-breaking field within clinical immunology is not free of setbacks. Rejection of transplanted organs and tissues can result in devastating problems for the patient, and potent immunosuppression is associated with substantial comorbidity, including exposure to infection, malignancy, and cardiovascular risks that may be fatal. Theoretically, immunosuppression withdrawal and allograft-specific protection against host responses is the ultimate treatment to offer a transplant recipient. Although this is undoubtedly a challenging goal, it is being realized in defined subgroups of recipients. This chapter examines the rejection response, outlines the mainstay of current immunosuppressive therapy, and discusses the latest advances in the search for transplantation tolerance.

REJECTION

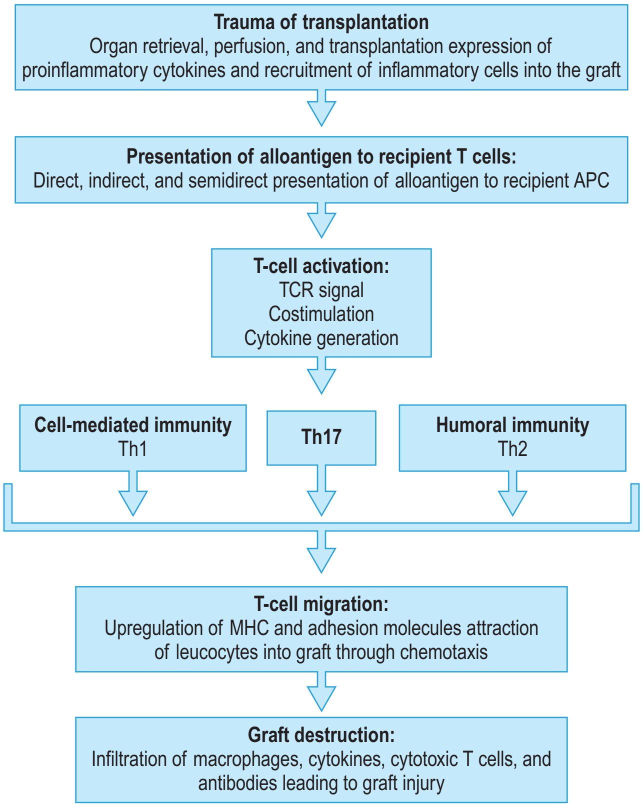
The immune system is complex and has evolved to protect the individual from harm. This harm may be either in the form of foreign pathogenic microorganisms or premalignant mutations in the individual's own cells. To achieve this safely, the immune system must have the ability to distinguish "self" from "non-self" or "altered-self" to avoid damaging the host itself. Any immune response that is generated must also be proportional to the threat, and thus antigens encountered in the context of inflammation will prime T cells and evoke a more aggressive immune response. Although an effective immune response is essential to survival in the context of infection or malignancy, it can represent significant management challenges in the transplantation setting.

Some elements of the immune system respond to the general trauma associated with organ retrieval, perfusion, and surgery, whereas others respond after specific recognition of antigenic differences between the donor and the recipient. If this process continues in an uncontrolled manner, it inevitably leads to destruction of the graft. Thus isografts or syngeneic grafts (grafting of tissue between two genetically identical individuals such that there are no antigenic differences) do not typically result in rejection, whereas allografts (transplantation of tissues from genetically different individuals) usually evoke an aggressive immune response as a result of the antigenic differences between the donor and the recipient. Tissue transplanted between species, or xenografts, are also possible but not yet in clinical use in cell and organ transplantations because these usually trigger a more rapid and aggressive immune response compared with an allograft. This section considers the processes involved in allorecognition and graft destruction.

Innate Immunity and Ischemia-Reperfusion Injury

Trauma to the graft is initiated during, or even before, retrieval because death of the donor brainstem induces hemodynamic and neuroendocrine responses; in addition, organs obtained from donors after their cardiac death suffer a period of warm ischemia. During cold storage, loss of intracellular potassium and cell injury continues. This leads to graft damage through cell swelling and a buildup of toxic metabolites, leaving the graft susceptible to further ischemia–reperfusion injury on rapid warming following revascularization. Efforts are made during storage and organ implantation surgery to reduce the metabolic rate through storage on ice and perfusion with specialized fluids. This approach aims to minimize the accumulation of toxic metabolites and the resultant pH changes to reduce the effect of cold ischemic time on posttransplantation outcomes, such as delayed graft function.[2]

Tissue injury leads to the expression of damage-associated molecular patterns (DAMPs), such as heparin sulfate, heat shock proteins (HSPs), nucleic acids, and high-mobility group box-1 (HMGB1) protein. These are identified by invariant pattern-recognition receptors (PRRs) of the innate immune system, for example, Toll-like receptors (TLRs) (Chapter 3). This process results in the local production of inflammatory mediators, such as interleukin (IL)-1 and -6, chemokines, and the expression of adhesion molecules within the graft. These early innate responses are seen in autografts as well as isografts and are generally not alloantigen specific, although a subcategory of innate cells does display a limited degree of alloantigen reactivity. In turn, this triggers activation of macrophages and dendritic cells (DCs) via cell-surface and internal PRRs,[3] causing both cell types to show greater antigen-presenting capacity and to enter a cytocidal state. Endogenous signals, such as stress, can also activate the complement cascade to generate several products, including complement component C3 in the graft, which promotes DC maturation and subsequently their ability to activate T cells. DCs are also activated



Trauma of transplantation
Organ retrieval, perfusion, and transplantation expression of proinflammatory cytokines and recruitment of inflammatory cells into the graft
Presentation of alloantigen to recipient T cells:

FIG 81.1 **Mechanisms Leading to Graft Injury.** Interplay of innate and adaptive immune responses results in eventual graft destruction.

by interferon-γ (IFN-γ) produced by natural killer (NK) cells. In one or more of these ways the innate immune system, activated by local tissue injury, promotes the initiation of adaptive immune responses when there are antigenic differences between the donor and the recipient. Activation of the adaptive immune system results in a series of effector mechanisms, both cell and antibody mediated, that lead to further graft injury (Fig. 81.1).

A severely damaged graft will initiate a more aggressive immune response, and this may explain the superior outcomes in living donor grafts compared with deceased donor grafts (as the former are subject to a lower degree of ischemic injury), even in the presence of significant major histocompatibility complex (MHC) mismatches.[4] The immune response evoked by the damaged tissue also accounts for the higher rates of rejection observed in individuals with delayed graft function.[5]

Initiation of the Adaptive Immune System

Recognition of differences between donor and recipient major and/or minor histocompatibility (miH) molecules or antigens by T cells is central to the adaptive immune response. The extensive polymorphism of MHC genes (Chapter 5) makes complete matching of unrelated individuals rare, and therefore, almost inevitably, transplantation of cells or organs between genetically unrelated individuals occurs across an MHC mismatch. Knowledge of the MHC and of the structure of MHC molecules has contributed significantly to our understanding of how rejection is triggered and has facilitated the development of novel immunosuppressive drugs. Additionally, transplantation between MHC-identical siblings has shown that differences in miH antigens can also be significant, particularly in bone marrow transplantation (BMT), where activation of the adaptive immune system of the donor may result in graft-versus-host disease (GvHD). These miH antigens may be derived from a wide variety of polymorphic proteins and are encoded for a vast array of genes distributed throughout the genome.

Signal 1: Recognition of Alloantigen

Class I MHC molecules are cell surface glycoproteins expressed on most nucleated cells and are recognized by the T-cell receptors (TCRs) of CD8 T cells. Class II MHC molecules are not expressed by every cell in the body; rather they are found on DCs, B lymphocytes, macrophages, and, in humans, endothelial cells. MHC class II molecules are recognized by T cells bearing the CD4 surface glycoprotein. Expression of both class I and II MHC molecules can be increased or, in the latter case, induced during inflammation, in particular by IFN-γ.

Class I and II MHC proteins contain a highly polymorphic groove or cleft, which can bind peptides, formed on a platform of beta strands, flanked by two α helices. Antigen processing within antigen-presenting cells (APCs) results in the production of peptides that can bind in these grooves producing a MHC–peptide complex that can be recognized by T cells (Chapter 6). These peptides may be of self origin or derived from foreign molecules (*e.g.*, from an allograft after transplantation or from a virus after an infection). In general, peptides derived from molecules present inside the cell are processed and loaded into MHC class I molecules, whereas molecules present outside the cell in the extracellular environment are processed into peptides that load into class II molecules. However, cross-presentation can also occur, whereby some APCs, notably DCs, process extracellular proteins such that they can be loaded onto MHC class I molecules and presented to CD8 T cells, leading to "cross-priming."[6]

The TCR is composed of two chains that confer MHC–peptide specificity and is associated with a complex of polypeptides referred to collectively as CD3 (Chapter 4). On antigen recognition by a TCR, CD3 delivers intracellular signals to the T cell (Chapter 12). Recognition of antigen by the TCR–CD3 complex is the first step in T-cell activation and commonly referred to as "signal 1." This initial meeting between host naive and memory T cells and alloantigen from the foreign transplant is believed to take place in secondary lymphoid organs rather than in the transplanted graft itself.[7] The inflammatory response triggered in the allograft by retrieval and implantation of the organ or tissue, as outlined above, not only initiates the migration of donor-derived passenger leukocytes but also their maturation into functional APCs expressing high levels of donor MHC molecules.

The presentation of intact allogeneic MHC molecules by donor-derived passenger leukocytes to T cells is known as the direct pathway of allorecognition. This is the dominant pathway through which the immune reaction to the graft is initiated, and T cells responding to direct antigen presentation constitute a vast majority of the alloreactive immune repertoire, estimated at 10% of T cells.[8] After a time, the donor lymphocytes transplanted with the graft are depleted; however, this does not abrogate rejection. The immune response against an allograft is maintained by recipient APCs, largely consisting of DCs and B cells, which process and present peptides derived from allogeneic MHC molecules shed from the graft (soluble MHC molecules or apoptotic cells) as well as miH antigens. This route of allorecognition is known as the *indirect pathway.* Experimental models have

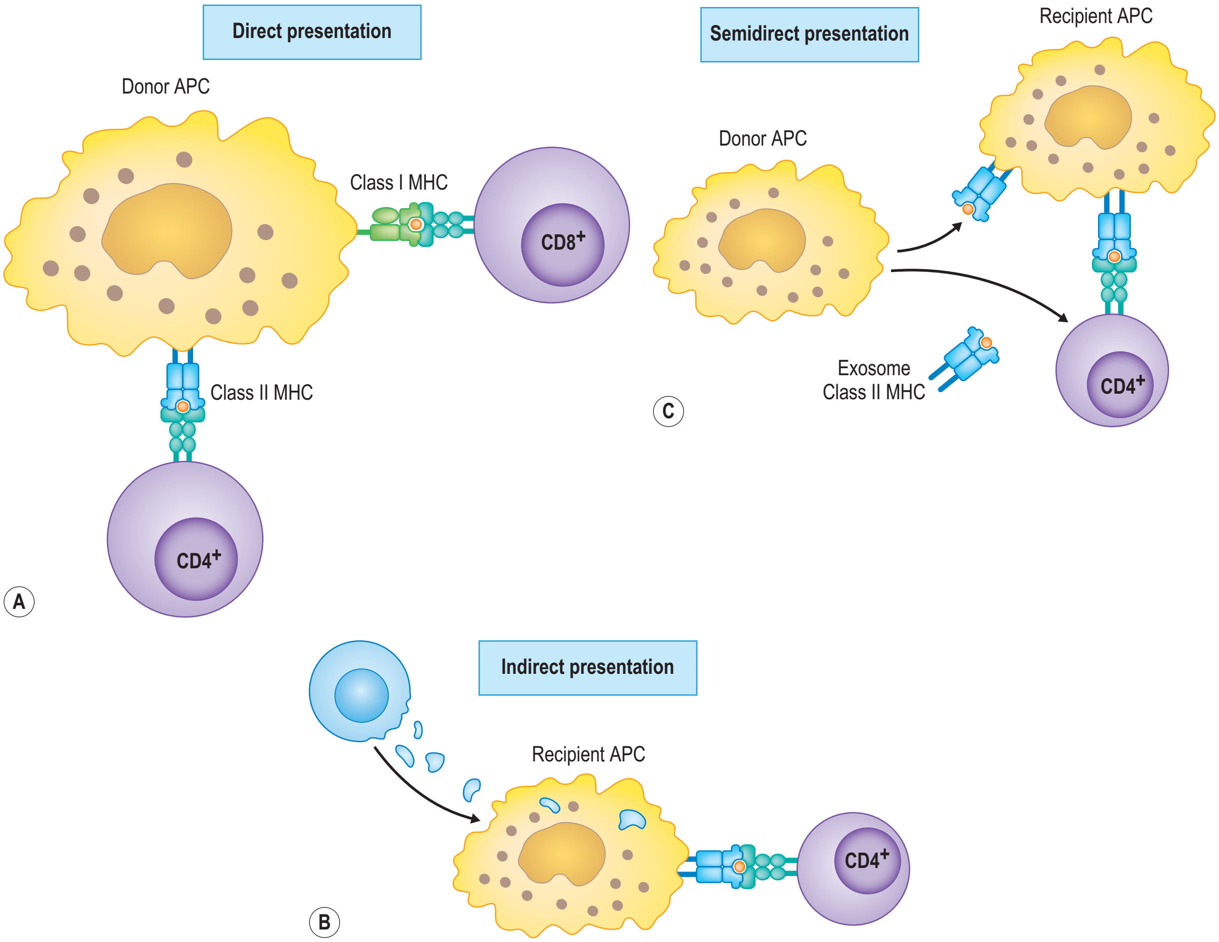

FIG 81.2 Antigen Presentation. (A) Direct presentation: passenger donor antigen-presenting cells (APCs) present alloantigen to recipient T cells in lymphoid tissue. (B) Indirect presentation: alloantigen from donor cells is processed and presented by recipient APCs via major histocompatibility complex (MHC) class II to recipient $CD4^+$ cells. (C) Semidirect presentation: donor MHC class I and class II may be transferred to the surface of recipient APCs enabling presentation of alloantigen to recipient T cells.

suggested that indirect presentation of donor antigens may play a greater role in rejection than direct presentation overall, as it continues for as long as the graft remains *in situ*.[9] It is also now known that the direct and indirect pathways of allorecognition interact as a third pathway referred to as the *semidirect pathway* of antigen presentation. In the semidirect pathway of allorecognition, donor MHC proteins are transferred intact to recipient APCs (through membrane transfer or the exosomal route), enabling them to present allogeneic MHC–peptide complexes to recipient T cells. This MHC transfer is temperature and energy dependent and requires close cell-to-cell contact. Both MHC class I and class II may be transferred, although class II MHC appears to be transferred more efficiently.[10] These three modes of antigen presentation are illustrated in Fig. 81.2.

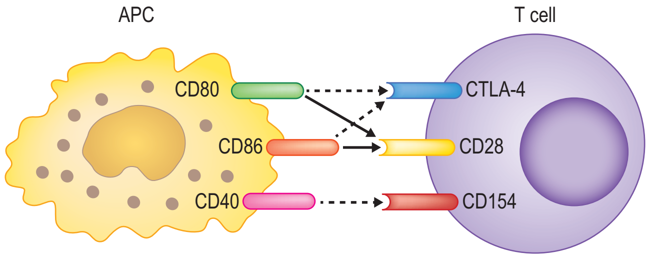

FIG 81.3 Costimulation. Costimulation follows binding to major histocompatibility complex (MHC) class I and class II on antigen-presenting cells (APCs) and involves signal transduction via intracellular proteins and increased interaction affinity via the binding of several cell surface proteins. Several costimulatory molecule pairs have been identified.

Signal 2: Costimulation

T lymphocyte activation relies not only on contact of the TCR–CD3 complex with its specific MHC–peptide complex (“signal 1”) but also on signals delivered by the interaction of several costimulatory receptors and their ligands, known collectively as “signal 2” (Fig. 81.3). During T-cell activation, the membrane of the T cell reorganizes such that the TCR–CD3 complex and costimulatory molecules are brought together in the cell membrane to form the immunological synapse. Signal 1 is specific for the antigen involved, whereas costimulation is not.

Costimulatory receptors fall into two major families, the B7 family (*e.g.,* CD28 and CD152) and the tumor necrosis factor (TNF) family (*e.g.,* CD154 and CD70) (Chapter 12). Although several costimulatory molecule pairs have been identified, the CD28 and CD154 pathways have been the most clearly defined to date. CD80 and CD86 are receptor ligands on the surface of DCs and other cells that can bind to CD28 on T cells, resulting in the activation of additional signal–transduction pathways within the T cell. This has a number of effects: lowering the threshold for T-cell activation; increasing glucose metabolism, as well as cytokine and chemokine expression, including IL-2 production; reducing T-cell death through apoptosis; and expanding the number of T cells that respond through proliferation. CD80 and CD86 are also linked to an inhibitory receptor, CD152 or cytotoxic T lymphocyte antigen-4 (CTLA-4), which inhibits T-cell activation possibly by competing with CD28 to bind with CD80 or CD86. CTLA-4 has a 10-fold higher receptor affinity compared with CD28 and is rapidly upregulated following T-cell activation. Additionally, CD152 activates tryptophan catabolism in DCs, which results in the inhibition of proliferation and promotes apoptosis of the responding T cells. Related to this pathway are other pathways involving members of the B7–CD28 family of molecules, including ICOS/B7h, PD1/PD-L1/PD-L2, and B7-H3. Each of these can play a role in T-cell costimulation and later coinhibition, but for the early phase of the response, the CD28 pathway dominates. CD40 belongs to the TNF receptor family, expressed on all APCs, and binds to CD154 (CD40L), which is present on activated CD4 cells, a subset of CD8 cells and NK cells. CD40 stimulation causes triggering signals for antibody production and induces MHC expression on APCs, thus amplifying antigen presentation.[11]

In clinical transplantation, treatment with calcineurin inhibitors (CNIs) to block signal 1 and/or the use of T cell–depleting agents has been highly successful in the prevention and reversal of rejection episodes. More recently, blockade of costimulatory pathways has also been shown to be effective. These approaches are discussed in the “Immunosuppression” section.

Signal 3: Proliferation and Differentiation of Effector T Cells

Following alloantigen recognition by the TCR–CD3 complex and costimulation, a process begins resulting in “signal 3.” This is the complex process involving the recruitment and phosphorylation of a series of signaling molecules, which induce intracellular biochemical processes that lead to the activation of three signal–transduction pathways: the calcium–calcineurin pathway, the Ras- and Rac-mitogen–activated protein kinase pathways, and the protein kinase C nuclear factor κB (NF-κB) pathway. These pathways interact with inositol triphosphate (IP3) and diacylglycerol (DAG), formed from the hydrolysis of phosphatidylinositol 4,5-bisphosphonate, to activate transcription factors: nuclear factor of activated T cells (NFAT), activating protein-1 (AP-1), and NF-κB, respectively. These transcription factors cause the expression of many genes leading to upregulation of growth factors and cytokines, in particular, IL-2 and CD25 (IL-2Rα). Growth signals are then delivered through the phosphoinositide-3-kinase (PI3K) and mechanistic target of rapamycin (mTOR) pathways to promote cell cycle progression, and initiation of clonal expansion and differentiation of activated T cells to express effector functions. These mechanisms are targeted by various immunosuppressive agents discussed in the “Immunosuppression” section and illustrated in Fig. 81.5.

The pattern of cytokine production through the interaction of the combination of signaling processes determines the nature of the response, in which either cell-mediated or antibody-mediated immunity is seen to dominate (Chapter 16). The T cells known to promote a cell-mediated response, and the cytokines they produce, are termed T-helper 1 (Th1) cells. These cells are associated with the production of IFN-γ. T cells promoting a humoral response are referred to as Th2 and are associated with the generation of IL-4, -5, and -6. Additionally, a Th17 population that has been identified is characterized by the production of IL-17 and promoting the infiltration of neutrophils.[12] Th22 cells, which express IL-13, IL-22, and TNF-α, have also been described. A subset of CD4 cells called *regulatory T cells* (Tregs) can also be induced following antigen exposure in the periphery (pTregs; Chapter 18).[13] These cells secrete IL-10 or transforming growth factor (TGF) and have suppressive or regulatory functions against effector cells and APCs. The balance of these responses results in either graft injury or the induction of tolerance (discussed below).

Memory T Cells

Following exposure to an antigen, antigen-specific memory T and B cells are generated. These memory cells are then able to produce a more rapid and intense immune reaction if the antigen is encountered on a second occasion because they have a lower activation threshold and are less dependent on costimulation. Transplant recipients, particularly older patients or those who have had previous antigen exposure through previous transplantation, blood transfusion, or pregnancy, may therefore have specific anti-donor memory cells. Memory-type responses may also occur as a result of antigen receptor cross-reactivity known as *heterologous immunity.*

Cell Migration

After activation, chemotactic cytokines, or chemokines, generated at the site of inflammation attract leukocytes that have been primed in secondary lymphoid tissues to the graft (Chapter 10). Once activated, leukocytes upregulate chemokine receptors, thus enabling their migration along a chemokine gradient. Vessels in proximity to the graft become dilated, allowing increased blood flow, and the endothelium becomes activated. Activated endothelial cells externalize Weibel-Palade bodies containing P-selectin, and chemokines generated in the graft, such as IL-8, RANTES, and MCP-1, stick to the vascular endothelium (Chapter 11). This signals the passing leukocytes in postcapillary venules to leave laminar flow of blood and move closer to the vessel edge so that they can interact with the activated endothelial cells. Extravasation then occurs in a multistep process, involving molecules on the surface of activated leukocytes called *Sialyl-Lewis moieties,* which interact with endothelial P-selectin, forming temporary bonds that form and break causing the leukocytes to “roll.” Chemokines on the endothelial surface then induce a conformational change in leukocyte integrin molecules, allowing high-affinity binding to endothelial adhesion molecules, such as intercellular adhesion molecule-1 (ICAM-1). When this occurs, the leukocytes stop rolling, and this allows them to extravasate and follow the chemokine gradient further into the graft, where damage then occurs.

The Effector Response and Graft Destruction

The immune system generates many different effector mechanisms, depending both on the challenge it meets and the microenvironments that are present. In transplantation, the type of transplanted tissue, graft site, and immune status of the recipient at time of transplantation may modify this response. Although initiation of rejection in a nonsensitized recipient is principally T-cell dependent, many components of the immune system contribute to the subsequent destruction of the transplanted tissue. Graft destruction may be alloantigen specific, or there may be bystander tissue destruction. The nature of the immune cells involved in the effector response is reflected in the characteristics of the resulting damage and in the speed of onset of tissue destruction.

Acute Antibody-Mediated Rejection

Alloantigen-specific antibodies, or alloantibodies, are secreted by plasma cells. Alloantibodies are produced after alloantigen-driven B-cell activation in the presence of T-cell help, such as can occur during rejection or following a blood transfusion. Antibodies that cross-react with alloantigens can also be generated as a result of infections that result in heterologous immunity. In the former, in addition to DCs, the B cells themselves may act as APCs. MHC class II molecules are presented to and bind immunoglobulins (Igs) on the surface of B cells, enabling the B cell to internalize the alloantigen and process it into peptides that are presented at the cell surface within MHC class II molecules (Chapter 6). The subsequently activated T cells produce cytokines that activate B cells enabling them to differentiate into alloantibody-producing plasma cells. When allospecific antibodies encounter their specific antigen, antibody-mediated rejection occurs. Antibodies function through a number of effector mechanisms. Antibody binding activates endothelial cells within the graft, resulting in the expression of adhesion molecules, cytokines, and chemokines as well as the synthesis of tissue factor. Antibody binding can trigger complement activation, which can result in cell lysis and graft damage directly or indirectly by the binding of complement components to the graft and the recruitment of macrophages and neutrophils. Additionally damage is caused by a mechanism whereby effector cells, such as NK cells and macrophages, bind to the Fc non–antigen-specific portion of the antibody. This encourages NK cells and macrophages to kill any target cells with antibody bound to their surface. This is a nonspecific process termed *antibody-dependent cellular cytotoxicity* (ADCC) and can contribute to graft rejection.[14]

When donor-specific alloantibodies (DSAs) exist in a recipient prior to transplantation (*e.g.,* as a result of previous transplantation, blood transfusion, or pregnancy), a dramatic response is seen upon perfusion of the transplanted graft. Coagulation and complement cascades are activated, resulting in extensive thrombosis and graft infarction within minutes. This so-called hyperacute rejection is now very rarely seen in clinical practice because of the advances in screening and cross-matching techniques as well as desensitization techniques, such as plasmapheresis and intravenous immunoglobulin (IVIG).

Acute Cellular Rejection

As described above, following the non–antigen-specific innate response to organ retrieval and implantation, an inflammatory environment is created within the graft, thus promoting an adaptive cellular response over the ensuing days. Naïve cytotoxic T cells, activated by CD4 cells clustering with APCs, migrate to the graft, where they recognize allogeneic class I MHC molecules. This causes them to release cytotoxic molecules, such as perforin and granzyme B; upregulate surface Fas ligand; and secrete soluble mediators, such as TNF-α. Perforins insert into the target cell membrane to form pores, allowing granzyme to enter the cell, and this causes proteolysis and activates the caspase cascade. Fas ligand binds to Fas on the target cell and also initiates the caspase cascade. These processes induce target cell apoptosis and acute cellular rejection and typically occur 1 week to 3 months after transplantation.

Additionally a nonspecific delayed-type hypersensitivity response occurs, usually mediated by CD4 cells that are attracted to the graft and involving the release of multiple proinflammatory cytokines, including IL-1, IFN-γ, and TNF-α. This leads to the recruitment and activation of further leukocytes, affects graft cell permeability and vascular smooth muscle tone, thus affecting graft physiology and contributing to acute and chronic rejection. CD4 alloreactive T cells responding to donor-derived peptides bound to recipient MHC class II molecules have also been correlated with chronic allograft dysfunction.[15]

As acute allograft rejection is initiated by the recognition of polymorphic donor MHC molecules by recipient T cells, it follows that transplantation of MHC incompatible tissues will elicit a strong, T cell–dependent immune response to donor tissues. In general, mismatches for only class I MHC result in slower rates of rejection compared with grafts with differences in class II MHC or both class I and II.[16] Rejection can still occur when transplantation has taken place between MHC-matched siblings because of T-cell recognition of minor histocompatibility antigens.

Delayed Allograft Rejection and Dysfunction

Rejection later after transplantation, which is often referred to as chronic rejection or chronic allograft dysfunction, comprises a number of mechanisms. It is characterized by a cellular infiltrate constituted of macrophages, eosinophils, NK cells, and T cells, where the primary target is the vascular endothelium.[17] Damaged endothelium allows platelet deposition on the arterial wall and growth factor production. This, in turn, leads to smooth muscle proliferation in the arterial wall media. Proliferating muscle cells invade the intima and contribute to intimal fibrosis. These changes are concentric, affecting all graft arteries. In heart transplants, this may appear as transplant arteriosclerosis. Chronic rejection therefore manifests in an organ-specific manner. For example, within renal glomeruli glomerulosclerosis and interstitial fibrosis may develop, whereas in lungs, bronchiolitis obliterans develops. The underlying mechanistic processes remain similar.

Clinical Implications

To prevent hyperacute rejection, patients on transplant waiting lists are monitored routinely for the development of anti–human leukocyte antigen (HLA) antibodies as a marker of sensitization. Immediately before transplantation, a further check is performed by mixing recipient serum and donor splenocytes and observing for cell lysis.[18] The extent of the risk of hyperacute rejection is determined by the antibody target and quantitative titer of the anti-donor antibodies.[19] Highly sensitized recipients can remain on waiting list for extended periods but may have successful transplantations after desensitization, as mentioned previously, by removal of existing antibodies through plasma exchange or adsorption or by depletion of B cells with immunosuppressive agents, such as rituximab or proteasome inhibitors. Despite the extensive screening performed to detect donor HLA antibodies before transplantation, preformed antibodies against donor non-MHC antigens may exist and have the ability to induce

1. Normal

2. Antibody-mediated rejection
Acute antibody-mediated rejection

I. ATN-like – C4d+, minimal inflammation
II. Capillary - margination and/or thromboses, C4d+
III. Arterial – v3, C4d+

Chronic active antibody-mediated rejection
Glomerular double contours and/or peritubular capillary basement membrane multilayering and/or interstitial fibrosis/tubular atrophy and/or fibrous intimal thickening in arteries, C4d

3. Borderline changes: 'suspicious' for acute T-cell-mediated rejection
This category is used when no intimal arteritis is present, but there are foci of tubulitis

4. T-cell-mediated rejection
Acute T-cell-mediated rejection

IA. Cases with significant interstitial infiltration (>25% of parenchyma affected, i2 or i3) and foci of moderate tubulitis (t2)
IB. Cases with significant interstitial infiltration (>25% of parenchyma affected, i2 or i3) and foci of severe tubulitis (t3)
IIA. Cases with mild to moderate intimal arteritis (v1)
IIB. Cases with severe intimal arteritis comprising >25% of the luminal area (v2)
III. Cases with 'transmural' arteritis and/or arterial fibrinoid change and necrosis of medial smooth muscle cells with accompanying lymphocytic inflammation (v3)

Chronic active T-cell-mediated rejection
'Chronic allograft arteriopathy' (arterial intimal fibrosis with mononuclear cell infiltration in fibrosis, formation of neo-intima)

5. Interstitial fibrosis and tubular atrophy, no evidence of any specific etiology

I. Mild interstitial fibrosis and tubular atrophy (<25% of cortical area)
II. Moderate interstitial fibrosis and tubular atrophy (26–50% of cortical area)
III. Severe interstitial fibrosis and tubular atrophy/loss (>50% of cortical area) (may include nonspecific vascular and glomerular sclerosis, but severity graded by tubulointerstitial features)

6. Other: Changes not considered to be due to rejection-acute and/or chronic

FIG 81.4 **Banff Diagnostic Criteria for Renal Allografts.** Histological criteria have been developed and are regularly reviewed to aid diagnosis of the cause of chronic allograft dysfunction. Determining the cause of dysfunction aids decision making with regard to pathology and management. C4d, complement degradation product C4d.

vascular rejection. There is increasing interest in determining the impact of such antibodies on graft outcome.

Acute graft rejection is suspected when there is a sudden deterioration in allograft function. Biopsy of the transplanted tissue and histological evaluation are performed, resulting in diagnosis of rejection and numerical grading of severity. Grading schemes, such as the Banff criteria shown in Fig. 81.4, which provide semiquantitative measures for histopathological assessment of the inflammatory response, have been developed for specific organs and form the basis on which further clinical management is guided; decisions to treat with high-dose steroids or other immunosuppressive medications can thus be made after structured analysis of a biopsy specimen of the transplant.

In addition to the diagnosis of cell-mediated rejection, modern staining techniques have enabled the identification of complement component 4d (C4d) in biopsy specimens from rejecting tissues, thus providing indirect evidence of antibody deposition and complement fixation in not only late rejection but also early rejection. Antibody-mediated rejection (ABMR) is frequently seen following heart, lung, and kidney transplantations; however, liver allografts are relatively protected.[20] Nevertheless ABMR is increasingly recognized as a cause of graft damage in liver transplantation. This is explored further in the discussion below on tolerance in the liver (Fig. 81.6).

Although improved immunosuppression regimens have led to a reduction in the occurrence of acute rejection, chronic rejection has become more evident and remains a significant contributor to late graft loss. Nonimmunological factors, including CNI-induced toxicity, advanced donor age, ischemic injury during implantation, hypertension, and infection, also contribute to chronic allograft dysfunction, and modifying these factors can improve graft outcome.[21] However, immunological processes play a significant role with increased levels of pretransplantation anti-HLA antibodies, *de novo* posttransplantation donor-specific antibodies and antibodies against non-HLA antigen MHC class

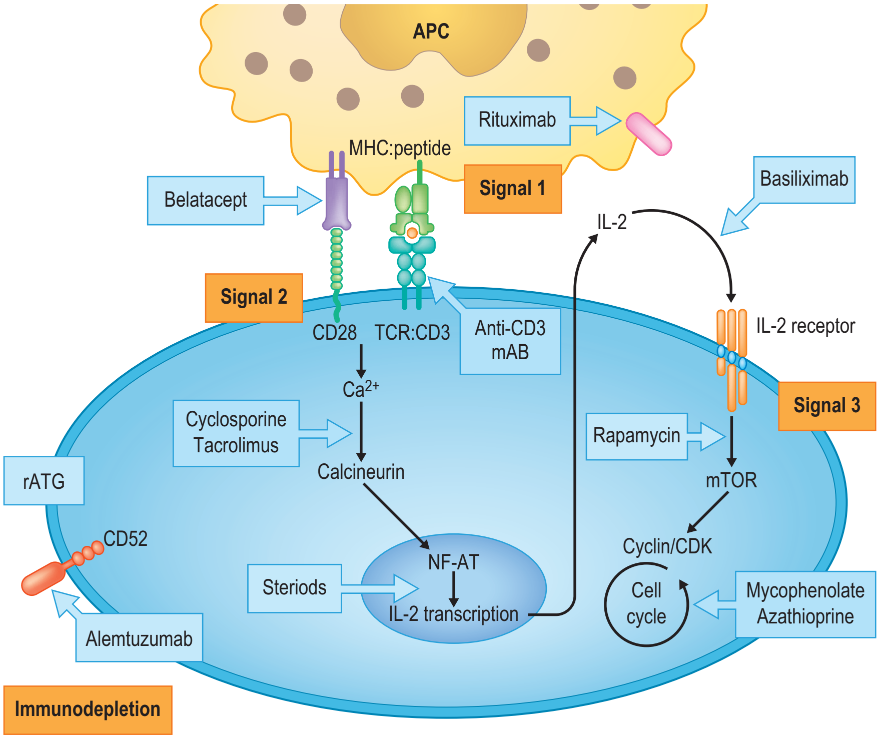

FIG 81.5 **Immunosuppressive Drugs and Their Targets.** Signal 1 results from major histocompatibility complex (MHC): antigen recognition through the T-cell receptor (TCR)–CD3 complex, a process blocked by anti-CD3 mAbs and indirectly by rituximab. Signal 2 results in costimulation, a process which can be blocked by belatacept. Costimulation results in full activation of the TCR–CD3 complex, initiating signal transduction, Signal 3: Downstream signaling pathways result in calcineurin activation, a stage which can be inhibited by tacrolimus and cyclosporine. Activated calcineurin dephosphorylates nuclear factor of activated T cells (NFAT), allowing interleukin-2 (IL-2) transcription, a process that can be inhibited by steroids. IL-2 receptor stimulation, a step which can be blocked by basiliximab, activates the mechanistic target of rapamycin (mTOR) signaling cascade, which can be inhibited by sirolimus. This pathway induces the T cell to enter cell cycle and proliferate, which, in turn, can be blocked by mycophenolate and azathioprine. Rabbit antithymocyte globulin (rATG) exerts polyclonal effects, and alemtuzumab binds to CD52, both resulting in immunodepletion,

I polypeptide-related sequence A (MICA) being seen to affect allograft survival.

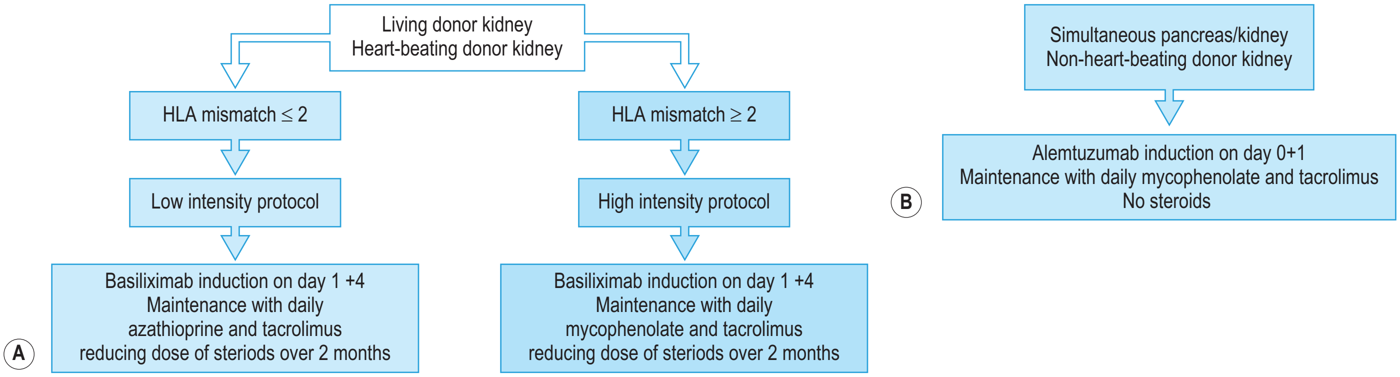
The correlation among late acute rejection, chronic allograft dysfunction, and graft loss has been consistently reported, and there is increasing evidence that subclinical rejection may represent an important factor in predicting graft loss.[22] Establishing a clear link between subclinical rejection and development of chronic allograft dysfunction may be difficult, however, because of the interplay of other factors, including CNI toxicity.[21]

IMMUNOSUPPRESSION

In recent years, substantial advances in immunosuppressive strategies and their translation to routine clinical practice have revolutionized management and outcomes in solid organ transplantation (SOT)—an option that has become the therapy of choice for many end-stage organ diseases. Short-term outcomes, such as patient and allograft survival at 1 year, acute rejection rates, and time-course of disease progression and symptom control have steadily improved since the first successful transplantations performed over 50 years ago.

Clinical regimens implemented today are focused on targeting the steps involved in the T cell–mediated immune response to alloantigen. As outlined earlier, there are three main stages in this pathway: recognition of alloantigen or self antigen; costimulation; and proliferation/differentiation of effector T cells. The current clinical paradigm is based on blockade of at least one of these stages and/or by total immunodepletion therapy as well as by alterations in lymphocyte trafficking (see Fig. 81.5).

The risk of acute graft rejection is greatest during the initial three months following transplantation; therefore current immunosuppression strategies are primarily based on a potent induction regimen using a monoclonal antibody (mAb) or polyclonal antibody, followed by "maintenance immunosuppression" often consisting of calcineurin inhibitors (CNIs, cyclosporine or tacrolimus), an antiproliferative agent (mycophenolate mofetil, MMF), and low-dose corticosteroids (prednisolone). Provided there are no episodes of acute rejection, the doses of these agents are gradually reduced, and then maintenance immunosuppression is continued indefinitely (Fig. 81.6). This dose reduction is based on the concept that as graft inflammation subsides and



Living donor kidney
Heart-beating donor kidney
HLA mismatch ≤ 2
HLA mismatch ≥ 2
Low intensity protocol
High intensity protocol
Basiliximab induction on day 1 +4
Maintenance with daily
azathioprine and tacrolimus
reducing dose of steroids over 2 months
Basiliximab induction on day 1 +4
Maintenance with daily
mycophenolate and tacrolimus
reducing dose of steroids over 2 months
A
Simultaneous pancreas/kidney
Non-heart-beating donor kidney
Alemtuzumab induction on day 0+1
Maintenance with daily mycophenolate and tacrolimus
No steroids
B

FIG 81.6 **Examples of Immunosuppressive Protocols in Clinical Use.** (A) Patients receiving a renal transplant from a living donor or heart-beating donor are stratified according to human leukocyte antigen (HLA) mismatch. When HLA mismatch ≤2, the patient is treated with a low intensity protocol; when HLA mismatch ≥2, the patient is treated with a high intensity protocol. (B) Pancreas and non–heart-beating donor kidneys have higher immunogenicity, and so induction is with a potent monoclonal antibody, alemtuzumab; therefore steroids are not required.

TABLE 81.1 Immunosuppressive Therapies in Transplantation: Maintenance and Induction Agents

Drugs	Mechanisms	Adverse Effects
Maintenance Agents		
Azathioprine	Inhibits purine and DNA synthesis, inhibits cell proliferation	Bone marrow depression, opportunistic infection, macrocytosis, liver toxicity
Cyclosporine	Binds to cyclophilin, inhibits calcineurin-phosphatase, blocks NFAT dephosphorylation, blocks IL-2 transcription and & T-cell activation	Hypertension, hyperlipidemia, nephrotoxicity, hepatotoxicity, pancreatitis, peptic ulcers, thrombotic microangiopathy, opportunistic infection, neurotoxicity, tremor, gingival hyperplasia, hirsutism
Mycophenolate mofetil	Inhibits inosine-monophosphate-dehydrogenase, inhibits purine synthesis and blocks cell proliferation	Gastrointestinal symptoms, bone marrow depression, opportunistic infection in particular CMV and BK nephropathy
Rapamycin	Binds to FKBP12, inhibits mTOR and blocks IL-2–driven cell proliferation	Delayed graft function, delayed wound healing, mouth ulcers, pneumonitis, increased proteinuria, peripheral edema, hyperlipidemia
Steroids	Induces phospholipase A_2 inhibitory proteins, inhibits arachidonic acid synthesis, inhibits prostaglandins and leukotrienes	Diabetes, delayed wound healing, peptic ulcers, psychosis, osteoporosis, infection, blurred vision, fluid retention, weight gain, acne, constipation
Tacrolimus	Binds to FKBP12, inhibits calcineurin-phosphatase and blocks T-cell activation	Posttransplantation diabetes mellitus, nephrotoxicity, thrombotic microangiopathy, neurotoxicity
Induction Agents		
Antithymocyte globulin	Polyclonal effects not well characterized; immunosuppressive efficacy attributed to T-cell depletion through apoptosis, antibody-dependent cytolysis and complement-dependent lysis	Polyclonal effects: cytokine release syndrome, serum sickness, leukopenia, thrombocytopenia. *De novo* tumors and opportunistic infection: CMV and HSV.
Alemtuzumab	Binds to CD52 antigen, (expressed on 95% of peripheral blood lymphocytes, NK cells, macrophages, and thymocytes) Results in profound lymphopenia	Opportunistic infection: disseminated *Candida* and CMV infection
Basiliximab	Binds to IL-2R with similar affinity as IL-2, thereby inhibiting IL-2-driven T-cell proliferation	Occasional hypersensitivity reactions, inadequate immunosuppression in immunologically high-risk recipients

IL-2, interleukin-2; IL-2R, interleukin-2 receptor; NFAT, nuclear factor of activated T cells; DHFR, dihydrofolate reductase; mTOR, mechanistic target of rapamycin; CMV, cytomegalovirus; HSV, herpes simplex virus.

donor-derived APCs are cleared, the immunogenicity and risk of rejection decreases.

Chronic immunosuppression is associated with several undesirable sequelae (Table 81.1), in particular an increased relative risk of infections and malignancy, cardiovascular morbidity (the leading cause of death with a functioning graft in transplant recipients), and target organ damage.

Many different immunosuppressive regimens for SOT are in clinical use and are dependent on local factors and guidelines. An introduction to the immunosuppressive agents currently in widespread use is provided below.

Immunodepletion

The more recent therapeutic strategies are based on induction therapies that concentrate on profound immune cell depletion at the time of transplantation, when immune activation is most intense.

CLINICAL PEARLS

Treatment Options for Rejection

- Acute cellular rejection
  - High-dose steroids
- Rejection refractory to steroid treatment
  - Antithymocyte globulin
  - Alemtuzumab
- Acute humoral rejection
  - Plasmapheresis
  - Intravenous immunoglobulin
  - Rituximab

Antithymocyte Globulin

Rabbit-derived antithymocyte globulin (rATG) is a lymphocyte-depleting polyclonal IgG preparation with specificity toward human thymocytes. It binds primarily to the peripheral blood lymphocytes as well as to those present in the lymphoid organs, including lymph nodes, spleen, and thymus, as demonstrated by *in vivo* studies in monkeys. The agent's polyclonal nature enables it to display specificity toward a wide variety of molecules expressed on the surface of T cells, B cells, DCs, NK cells, and endothelial cells, including those involved in T-cell activation, proliferation, apoptosis, signal transduction, cell adhesion, and trafficking.

The precise mechanism of action underlying the immunosuppressive efficacy of rATG in SOT recipients is unknown at present, although has been primarily attributed to T-cell depletion. Data from *in vitro* studies have suggested that rATG modulates the expression of various lymphocyte surface antigens resulting in apoptosis, antibody-dependent cytolysis, or complement-dependent lysis. Lymphocyte depletion with rATG has been further demonstrated in adult recipients of renal transplants in several randomized, comparative clinical studies, with repopulation reported to take at least 3 months.[23] More recently, data from preclinical and clinical studies have suggested that rATG therapy may induce the expansion and enrichment of certain Treg subsets, such as $CD4^+CD25^+$ Forkhead box $P3^+$ ($FOXP3^+$), CTLA-4^+, and glucocorticoid-induced TNF receptor $(GITR+)^+$ Tregs from human peripheral blood lymphocytes or peripheral blood mononuclear cells *in vitro*[24]; these Treg subsets are key to immune response modulation and are further discussed in the "Tolerance" section.

In terms of clinical use, rATG induction in combination with tacrolimus-based immunosuppressive therapy is more effective in preventing episodes of acute renal graft rejection than with tacrolimus-based therapy without induction, as reported by primary endpoint data from two, randomized, open-label, multicenter trials.[25,26] Moreover, the median time to biopsy-proven acute rejection (BPAR) was >1 week longer in rATG induction than in noninduction; however, it should be noted that there was no significant difference between induction and noninduction regimens in terms of patient or graft survival.

Several randomized, multicenter studies have reported that the efficacy of rATG induction therapy is generally no different from that of basiliximab or low-dose daclizumab (IL-2 receptor [IL-2R] mAbs, which are an alternative induction agent; discussed later in this section) with regard to the incidence of BPAR, graft loss, or death at 6 and 12 months after transplantation, in the context of renal transplant recipients receiving triple immunosuppressive maintenance therapy. These trials, however, were not powered to show overall superiority of one agent over the other and were powered to address safety rather than efficacy parameters or used a limited daclizumab dosage regimen.[24] More robust studies that are designed to evaluate the efficacy of rATG relative to IL-2R mAbs specifically, are needed to definitively establish the use of rATG with respect to these monoclonal agents.
